Taken together, the literature provides limited experimental means to test how DTs, when combined with robotics as autonomous hardware, affect construction management outcomes. Existing work tends to study DTs without meaningful physical actuation, or robots as isolated machines without management-related use cases. We address this gap by proposing a low-cost, scalable laboratory environment that integrates DT features from both the physical and virtual worlds to support controlled experiments in DT-enabled construction management.

Design Requirements

The development of the DT testbed is based on translating insights and challenges from prior DT studies into concrete system features. A primary requirement concerns representational breadth: the environment must support multiple construction use cases that can benefit from DTs, including project monitoring and control, dynamic replanning under uncertainty and workflow

analysis for performance evaluation. A second requirement addresses the virtual-to-physical twinning, requiring the inclusion of actuation for at least one mechanized site process, such as material lifting, to allow digital decisions to be evaluated against physical outcomes. A third requirement concerns decision authority, mandating support for both human-in-the-loop supervision and autonomous action execution in routine situations with explicit logging of decision rationales. In addition to these use-case-driven requirements, the testbed must realize system-level DT features including real-time communication, reliable data logging and querying, and adaptability across construction scenarios and scripting languages. We address these requirements through a combination of LEGO®-based haptic simulation with Raspberry Pi computers.

LEGO®-based mock-ups demonstrate effectiveness in modeling construction management tasks and in evaluating the impact of digital tools such as Building Information Modeling (BIM) or virtual reality (VR) (Sacks, Esquenazi and Goldin, 2007). Extending LEGO® bricks with programmable LEGO® motors enables actuation and creates closed-loop cyber-physical systems without extensive hardware development (Gawthrop and McGookin, 2004). The LEGO® Spike platform offers modular, preconfigured components that support rapid prototyping and system expansion.

Raspberry Pi SBCs provide a cost-effective yet performative computational backbone and are widely adopted as prototyping tools in scientific research across varying degrees of complexity (Mathe *et al.*, 2024). Their Linux-based ecosystem and compatibility with additional electronics hardware via GPIO interfaces and the Build HAT support integrated implementation of sensing, actuation, and computational functions.

Digital Twin Testbed

The DT testbed consists of (i) a LEGO®-based gantry robot and (ii) interactive workstations for human-DT interaction. Figure 1 presents the integrated setup.

Gantry Robot

The gantry robot serves as a programmable transport system for LEGO® elements, autonomously managing material flows, logging operational data and exchanging information with external services.

The mechanical structure consists of a crane track supported by four pillars on each side, carrying a crane bridge that moves longitudinally on four wheels. Mounted centrally on the bridge is a Raspberry Pi 5 SBC, fixed in position to ensure stable computation during operation. A LEGO® Build HAT is attached to the Raspberry Pi, enabling direct control of four motors that together define the robot's four degrees of freedom (DoF). Horizontal motion is realized through a trolley unit that travels across the crane bridge and carries the gripping mechanism. This gripper is guided by vertical rods and operates through a circular opening-and-closing motion. Except for two components, all mechanical elements are made from original LEGO® parts. A custom-designed container houses the Raspberry Pi computer. In addition, the gripper claws are 3D printed and shape-optimized to improve gripping reliability.

Actuation is achieved using LEGO® SPIKE motors, with each motor controlling a single DoF independently (see Figure 2). Calibration happens by moving each motor toward a fixed mechanical endpoint and detecting stalling. This sensor-free approach simplifies system design but implicitly assumes consistent mechanical behavior, which becomes a critical assumption as operational complexity increases.

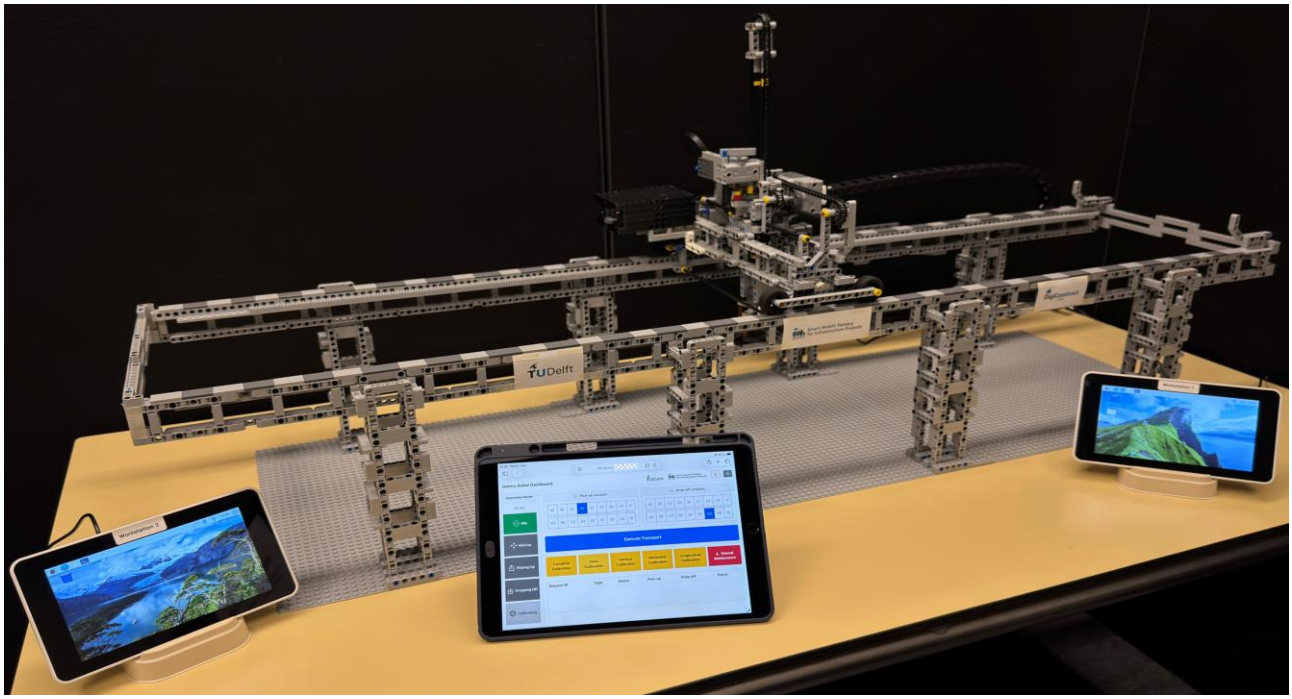

Figure 1: Overview of the modular digital twin testbed, consisting of the gantry robot and two interactive workstations. The tablet (optional) displays the gantry robot's web-based UI served via a FastAPI endpoint that is accessible from devices on the WLAN.

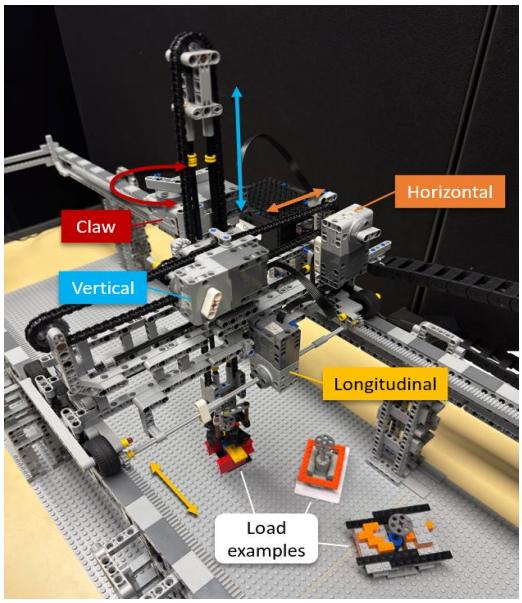

Figure 2: Gantry Bridge with 4 motors and 3 different examples of loads that can be transported.

The digital layer runs on a Linux distribution on the Raspberry Pi and is structured using Docker containers to enable adaptability. This digital system separates responsibilities into service, motor control, and storage containers. The service container functions as the system integrator, linking physical actuation, data storage, and order processing. It runs a FastAPI instance that exposes REST endpoints for querying system state and submitting transport commands, while a dedicated service script manages the order queue and database communication. Motor execution is delegated to a dedicated container that interfaces directly with the hardware through the BuildHAT Python library. Data storage is handled by a third container that supports interchangeable database systems for long-term storage of movements, transport requests and operation modes. Both GraphDB and MongoDB containers were tested in this setup.

User interaction is provided through a web-based interface served directly by the FastAPI framework using Jinja templates. The interface retrieves the gantry robot's operation mode via REST calls at configurable polling intervals and allows users to trigger calibration and transport commands by sending JSON payloads. This approach enables wireless control through common devices such as smartphones and tablets (Figure 1). While polling is sufficient for the demonstrated use cases, FastAPI also supports WebSockets.

Interactive Workstations

The interactive workstations represent the user-facing side of the DT testbed and operationalize direct human interaction within the distributed DT architecture. A workstation operates as an independent edge node, allowing for local data processing and storage. This configuration enables shifting interaction logic away from the actuated system core and toward decentralized components that remain tightly coupled via network communication.

Each workstation consists of a Raspberry Pi computer paired with a 7″ touchscreen. The touchscreen serves as the sole interaction modality, unifying user input and system feedback without reliance on external devices. By omitting actuators, the workstation maintains a clear functional boundary between interaction and physical execution within the DT architecture. At the same time, hardware extensibility remains available through Raspberry Pi's GPIO interface. For example, an RFID reader was connected in the testbed to explore contactless identification as a means of reducing repetitive user input and lowering the likelihood of interaction errors.

The digital architecture follows the same principles as the gantry robot by running Docker container services on a Linux platform (see Table 1). A minimal container setup is sufficient, consisting of a FastAPI-based service container that manages the touchscreen interface and communication logic, and a database container for persistent storage. The interface is generated using HTML Jinja templates and displayed directly on the touchscreen, reinforcing consistency across the gantry robot and the interactive workstations. Data exchange between the robot and workstations is implemented via REST-based communication, with WebSocket support available but not required for the demonstrated scenarios.

Digital Twin Experiments Performed with the Testbed

The following subsections describe how the testbed was used in other studies, illustrating its versatility and applicability for evaluating DT-focused research. Specific details on the experiment variables and evaluation criteria will be provided in separate publications. At the time of writing, they have yet to be published.

Agents in Construction (AiC) Ontology Verification

Study 1 used the testbed to functionally verify the *Agents in Construction (AiC)* ontology as an operational, machine-readable representation for real-time site coordination (Čustović, Cao and Soman, 2025). In this study, the AiC ontology served as the shared model for coordination-relevant facts. Accordingly, the evaluation examined whether information expressed using AiC concepts and relations could coordinate a construction process digitally across repeated runs.

Verification was conducted in the testbed because DT experiments on active construction sites often depend on enabling conditions that are difficult to ensure simultaneously, including integrated sensing and actuation, continuous capture of worker interactions, and uninterrupted wireless connectivity. The modular testbed provided these conditions in a controllable environment.

The coordination scenario was instantiated as a LEGO®-based simplified infrastructure assembly (see Figure 3). The elements of the infrastructure were decomposed into batches of LEGO® bricks within the gantry's carrying capacity and the workspace was segmented into multiple work zones plus a storage zone. Within this setup, the gantry robot operated as a transport agent moving

Table 1: Overview of Digital Twin Features of the Gantry Robot and the Interactive Workstations.

DT Feature	Gantry Robot	Interactive Workstation
User Interface / Visualization	Web-based UI (HTML / CSS / JavaScript)	Web-based UI (HTML / CSS / JavaScript); 7-inch mounted touchscreen UI
Computing Unit	Raspberry Pi 5, 8 GB RAM, BuildHAT	Raspberry Pi 5, 8 GB RAM
Application / Service Layer	Linux distribution; containerized with Docker	
Network Interface	REST API (FastAPI endpoints)	
Data Management	Time-series DB (e.g., MongoDB); graph DB (e.g., GraphDB); relational DB (e.g., PostgreSQL)	
Sensing	Internal motor state and telemetry from LEGO® SPIKE Prime / Powered Up Motors	RFID reader via GPIO interface
Actuation	LEGO® Spike motor actuation; 4 degrees of freedom (4-DoF)	-

materials between storage and site locations. The interactive workstations served as DTs for the human agents, displaying and enabling updates to information during execution. Four participants played different roles: two construction workers were building the LEGO® structure and used interactive workstations to request material delivery from the crane; a manager responsible for task assignment; and a packer assisting the gantry robot by positioning the pieces in the pickup area. In the unlikely event that the gantry robot fails to grip or release a load, this fourth operator serves as a human backup (DT has routine autonomy).

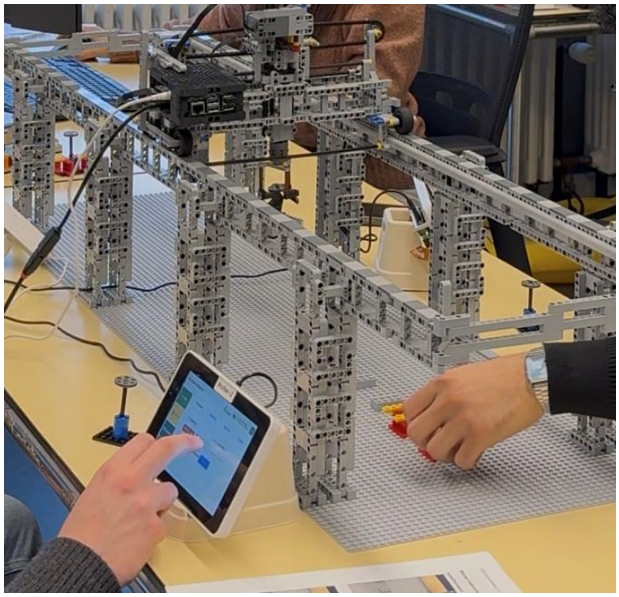

Figure 3: Scene from the AiC ontology verification experiment conducted using the DT testbed.

To perform the evaluation and monitor agents and agent-to-agent communication, the AiC ontology was implemented as the data model, and GraphDB was deployed on all Raspberry Pi computers. Participants viewed and updated operation modes, process lists, material and equipment usage, and locations as tasks advanced, while the manager exchanged process assignments with the workstations via REST calls; these interactions exercised coordination loops repeatedly and were captured for subsequent analysis.

The modular testbed enabled real-time investigation of DT-based site coordination that relied on the AiC ontology. It was possible to repeat the same coordination scenario and vary relevant variables (worker availability or the task execution sequence) while logging time-stamped coordination messages.

Serious Game with an Autonomous Site Crane

Study 2 examined how humans work when selected construction decisions and actions are taken autonomously by a DT. The goal was to simulate a site scenario in which workers collaborate and must coordinate around a shared, autonomous robotic resource.

Running comparable studies on live construction sites is difficult. Conditions on site vary in ways that are hard to control; the number of robots that can operate autonomously in changing environments is limited, and cost and safety constraints are high. Nevertheless, the development of such autonomous systems needs systematic evidence on how they shape coordination and work practices. We therefore used the DT testbed as a controllable, observable environment that supports repeatable autonomous execution together with structured human-DT interaction, allowing us to capture effects that would be hard to isolate on site.

These needs were operationalized in the DT testbed by using the gantry robot as an autonomous site resource. The robot followed scripts corresponding to predefined autonomy levels; in addition to the routine autonomous transport examined in Study 1, Study 2 incorporated shared-resource allocation decisions, which are common in construction (see Figure 4): the gantry robot DT decided which participant would be served next, requiring participants to plan and coordinate around a single robotic bottleneck. The testbed also enabled systematic variation in decision autonomy by altering the information available to the robot's decision scripts. In the routine autonomy condition, the robot relied on limited state data; in the non-routine autonomy condition, the gantry robot

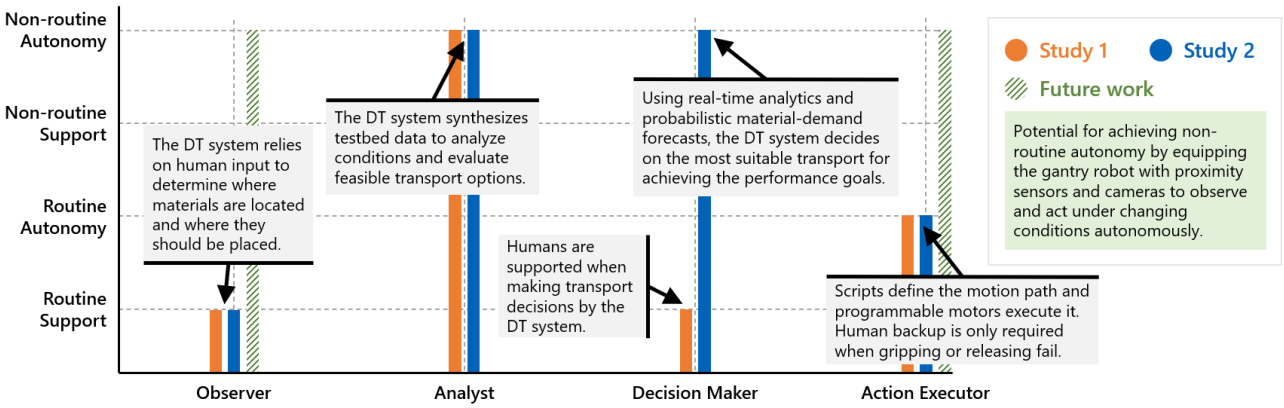

Figure 4: Different DT autonomy levels that were examined in the testbed mapped to the framework by Agrawal et al. (2023).

DT used real-time progress-data updates and probabilistic material-demand estimates. This design isolated the effects of autonomy and information availability while holding the physical system, task structure, and interaction channels constant.

Discussion

The laboratory testbed advances construction automation research by addressing a persistent gap at the decision-making and actuation layer of DTs. While many DT studies articulate data acquisition, integration and visualization in detail, their realization lacks fast feedback loops and high degrees of DT autonomy (olde Scholtenhuis and Soman, 2026). The programmable gantry robot introduces a tangible site actor that autonomously transports materials in routine situations while exposing operation conditions and commands through defined interfaces. The gantry robot supports systematic experimentation across different levels of autonomous analysis, decision-making, and action execution (see Figure 4). Combined with the interactive workstations, the modular DT testbed allows for controlled investigation of how human actors interact with and respond to automated execution. This aligns with the categorization of DTs that highlights human-system interaction and autonomy as defining dimensions in construction contexts (Agrawal *et al.*, 2023). Rather than assuming idealized coordination between human and digital actors, the testbed enables examination of frictions, delays, and behavioral adaptations that emerge under real-time conditions with immediate feedback.

At a broader level, the testbed supports scenario-based experimentation in which construction management conditions are deliberately constructed and compared (Li *et al.*, 2025). Real-time representation of site-like activities, combined with controllable execution, enables repeatable experiments that are rarely feasible in real construction projects. This capacity supports theory-driven inquiry into DT features, rather than one-off demonstrations of technological feasibility.

The contribution is further strengthened through the full-stack implementation of DT building blocks (AlBalkhy *et al.*, 2024; Saif, Doukari, and Kassem, 2026), spanning sensing, communication, storage, analytics, visualization, and action implementation, using embedded computing and containerized services. The reliance on low-cost hardware and open-source or free software addresses financial barriers that constrain DT experimentation and replication across institutions (Zhu *et al.*, 2024). The distributed interactive workstations extend this contribution by enabling a structured investigation of how information is distributed, interpreted, and acted upon by human participants, highlighting organizational and cognitive aspects that are often underrepresented in DT research (Čustović *et al.*, 2025). The modular hardware and software architecture positions the testbed as an evolving research platform that can be reconfigured or expanded with additional sensors and actuators. Docker containers can be replaced or redeployed across alternative hardware with minimal architectural change.

The testbed is intentionally simplified and therefore differs in scale and context from real construction sites, so the transferability of results must be explicitly assessed in follow-up studies. While the testbed provides the technological backbone for serious games to be conducted within it, the transferability of the resulting findings to real-world contexts depends on how well reality is modeled through game elements and mechanics (Freese and Bekebrede, 2025). Besides, the gantry robot is a material-movement actor rather than a building or assembly robot. It also inherits fundamental workspace constraints, limited DoFs, inability to reach around obstacles, and strong collision-avoidance requirements, which restrict the representation of complex access conditions or overhangs. Data quality further depends on human input at interactive workstations, which creates the risk of missing or inconsistent updates; audio hardware for voice control or automated sensing (e.g., computer vision) could reduce this dependency. The gantry robot cannot sense whether it has properly gripped a load, so it only supports routine autonomy for actions that require human backup. Precision and timing fidelity are limited by LEGO® motor accuracy, sensor-free calibration drift, and latency from containerization and REST-based communication, making the setup better suited for coordination and decision-logic studies than for high-precision or hard real-time control validation.

Conclusions

This paper introduced a scalable testbed for experimenting with DT capabilities in construction management scenarios. The testbed combines a LEGO®-based haptic simulation with programmable motors, Raspberry Pi 5 SBCs and touchscreen workstations, enabling a digital-physical feedback loops and human-DT interaction. The testbed can be reconfigured to represent different DT scenarios by changing the physical layout, the digital functions and the number of stations involved.

The testbed offers value for academia and industry. For researchers, it provides a replicable, configurable environment for testing a wide range of DT hypotheses under controlled conditions. Its design deliberately relies on consumer-ready hardware and software, reducing costs and setup effort and supporting adoption by other research groups. For the industry, it provides a concrete demonstration environment to communicate DT concepts to practitioners and to trial DT features against company-specific use cases before large financial commitments.

As an initial working prototype, the testbed provides a solid basis for extensions that improve realism and broaden the experimental scope. Key priorities are enhanced sensing for reliable state capture (e.g., precise position tracking with proximity sensors and RFID-based element detection), camera vision (fixed or gantry-mounted), more robust messaging, such as MQTT, to support scalable device communication, and wearable hardware that goes beyond an interactive workstation. Further avenues include integrating additional programmable controllers or components from the LEGO® SMART Play™ system (The LEGO Group, 2026) to represent other task types. Finally, future work can extend the setup with local AI models running on the gantry robot or the interactive workstations and develop educational programs around the testbed.

Supplementary Data

The source code for the gantry robot alongside the digital models of the LEGO® structure and the custom 3D-printed elements can be found in this repository:

ENRICHING VERSION INCREMENTS WITH ENGINEERING INTENT FOR ENHANCED BIM MODEL CHECKING

Abstract

BIM-based model checking helps improve the quality of design data throughout the planning phase of a built asset. However, rule-based checking can be time-consuming for large, frequently updated BIM models. Increment descriptors for BIM models are enriched with engineering intent, thereby unveiling additional information about the changes made. The proposed method enhances model-checking efficiency by executing only the rules affected by changes, rather than reprocessing the entire model. A case study demonstrates that selective rule triggering reduces redundant checks by re-executing only the rules affected by a given change, automatically identifying which open issues a model update resolves, thereby improving traceability between design edits and compliance outcomes.

Introduction

In recent years, substantial progress has been achieved in coordinating interdisciplinary models in the Architecture, Engineering, and Construction (AEC) industry, largely through the adoption of Building Information Modeling (BIM) approaches into collaborative design workflows. Design data is primarily stored in discipline-specific BIM models, which users typically access as distinct monolithic files. An especially important application of model-based workflows is the validation of models against a predefined rule set, a process often referred to as BIM-based model checking (Eastman et al., 2009) These rules are derived from client requirements or codes and standards that the multidisciplinary design must comply with. Any identified problems are recorded as issues and returned to the designer, who is responsible for adjusting the design models so that they ultimately conform to the stated rules.

Model checking is typically performed at predefined milestones and on a complete model without reusing results from previous runs. The intermediate steps designers take to resolve issues are neither documented nor communicated. Consequently, current checking systems do not support incremental validation on updates, increasing checking time and resulting in unnecessary rework. So far, no mechanisms are in place to automatically track whether the changes have resolved the previously identified issues. As a result, engineers or reviewers must manually review the model-checking results to determine whether new issues need to be documented and assigned, and which existing issues were resolved in the latest design iteration.

Contribution

This paper introduces a new method that applies version control concepts to transmit only the changes made to a BIM model, rather than sending entire model files. These version increments are subsequently used to provide the rule system with more precise information about which modified model elements need to be checked. To this end, the graph transformations that constitute the version increments are supplemented with higher-level annotations that express the engineering operations performed and identify the affected parts of the BIM model. Consequently, only those rules influenced by recent model changes need to be re-executed when a model increment is shared. Furthermore, associating each version increment with its enriched descriptors and the rule outcomes generates a valuable information resource for the subsequent issue management, as it reveals which issues may need a status update and directs the engineer to areas that warrant particular attention.

Related Works

BIM-based Model Checking and Issue Processing

The fundamental concepts of BIM-based model checking were introduced by Eastman et al. (2009) and subsequently adopted and further developed by other scholars. In summary, a model-checking routine typically involves four main stages: translating the rules into a machine-readable language, preparing the building model data, carrying out the checking process, and finally presenting the results.
Lee et al. (2026) provides an overview of recent advances in code-compliance checking, highlighting three key research areas: interpreting regulatory text into computable formats, model checking workflows with BIM and IFC data, and integrated workflows linking interpretation, checking, and reporting. To overcome manual translations, Fuchs et al. (2024) employed Large Language Models (LLMs) to convert regulatory documents into actionable, machine-executable representations. The execution logic of the checking routines must also be presented clearly and transparently. Preidel and Borrmann (2016) proposed a visual programming framework that accelerates the creation of rules and provides more flexibility than conventional model-checking tools. As an extension to these previous works, Iversen and Huang (2026) have investigated whether LLMs can directly be used for rule

interpretation, information extraction from BIM models, rule execution, and reporting bypassing manual preparation of distinct elements in a model-checking workflow. Even though these advancements are promising, most software products on the market provide predefined rule templates that can be adapted to specific scenarios to be checked.

Despite these advances in rule interpretation and representation, existing automated compliance checking workflows still determine the scope of checking through model-level filtering. This mechanism presupposes that the entire BIM model is available and consistently structured, but more importantly, it prevents the system from identifying which elements are affected by design changes. As a result, the current approaches cannot support incremental compliance checking and instead require full re-evaluation after every update.

Design Intent and Rationale

Every decision made during the design and planning phase of a built asset entails reflections on *how* and *why* it is constructed. Although these modes of thinking are at the heart of the design and planning disciplines in the AEC sector, they are rarely explicitly documented in design models. Wyke and Munch Lindhard (2025) report that it would be highly advantageous if the models also contained the underlying engineering intent that caused a change, as well as the reasoning behind the modifications performed. Developing effective methods to capture the rationale of a design has been a longstanding goal in engineering design (Siddharth and Sarkar, 2018). Without an explicit representation of design intent, design changes can easily introduce inconsistencies in building planning. For example, changes in architectural design can cause sprinkler layouts to become misaligned, making MEP revisions necessary to reestablish the intended coordination with the updated architecture (Sacks et al., 2022).

Currently, issue-related communication for BIM models is primarily facilitated via the BIM Collaboration Format (BCF). Because the BCF provides only very limited metadata about identified issues, the actions taken to resolve them can currently be recorded only as written comments attached to the issue. Such textual notes can convey intent and rationale only to a very limited extent, which is insufficient to support further automation of downstream processes. Consequently, the engineering intent behind a model change is generally implicit and is expected to correspond to the issues and defects revealed in the preceding model check. To support the design decision-making process, Wu et al. (2025) introduce a Design Healing framework that searches for code-compliant alternatives to resolve identified building code violations while remaining close to the originally intended solution. This framework focuses on localized changes, such as wall movements, and avoids modifications that would alter the existing building design topology. However, design changes in practice often alter the original building topology, for example, by creating or deleting building elements, and there is still limited support for systematically analyzing the underlying engineering intent behind such changes. Hu et al. (2021) capture the dependency between clashes and generate an optimal component change list to minimize the impact on the project. This method addresses the challenge posed by highly interdependent building systems, where clashes can propagate across related components.

Change propagation and version control of BIM models and issue representations

To establish a connection between implemented changes and unresolved issues, a robust method is needed to record and reveal the modifications made to the design models. Precisely monitoring changes across multiple model versions is labor-intensive and has to be performed again for every new version. This situation was primarily driven by the lack of version control techniques for BIM models that track changes based on the underlying object structures in the past.

As a result, changes between different model states often require substantial manual investigation before potential impacts on other disciplines can be evaluated. Whereas some methods have focused solely on algorithms for performing diff operations directly on the underlying data structures of BIM models (Shi et al., 2018; Liu et al., 2026), Esser et al. (2022) proposed dedicated version control mechanisms grounded in graph-based representations of BIM models, enabling more fine-grained, efficient management of model changes. In essence, BIM models are transformed into Labeled Property Graphs. Changes are then classified as either topological modifications covering inserted or removed nodes and edges, or semantic modifications, capturing attribute-level edits to structurally unchanged nodes. Any change information is ultimately assembled into a graph transformation rule p_{ij}, which is exchanged as an incremental change description. Figure 1 illustrates the approach schematically.

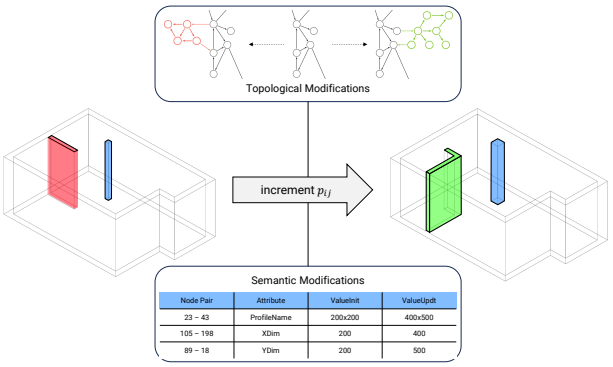

Figure 1: Incremental Version Control of BIM models.

Further efforts have focused on embedding version-control concepts directly into the issue representations. Oraskari et al. (2022) explored different ways to capture the history and evolution of issues within bcfOWL, which encodes issue data as a triple-based semantic graph in accordance

with the Resource Description Framework (RDF) principles.

There has also been research conducted to analyze the as-happened BIM authoring process using BIM logs. As data sources for understanding incremental authoring events, BIM logs provide information about how models are revised over time. Although BIM logs have initially been developed for monitoring and maintenance of authoring systems, several studies have enhanced their metadata to better capture modeling activities (Jang et al., 2023). Yarmohammadi and Castro-Lacouture (2018) introduced a bounding-box-based building element logs to quantify modeling performance. Gao et al. (2021) proposed a graph-structured event log that links modeling commands to the geometry they affect, enabling the analysis of trial-and-error patterns during authoring. Although these efforts commonly focus on improving the representation of element-level modeling events and revision trajectories, such logs do not capture the inter-element relationships that are essential for understanding model compliance. Moreover, they primarily record the state of BIM elements affected by modeling actions, whereas compliance checking requires tracking change propagation, which is significant in model checking.

Identified research gap

As discussed, model checking not only requires a carefully prepared set of rules but also well-prepared BIM models to be subjected to the checking process. However, current rule-checking workflows typically re-execute the entire rule set for each new design model file, regardless of what has changed in the interim, reflecting a lack of mechanisms to identify incremental checking targets. Moreover, existing approaches do not provide explicit representations to capture how changes in one model element propagate to related elements and their associated rules, making it difficult to reason about the true impact of a modification. Finally, there is no structured way to record compliance issues, the changes made in response, and how those issues are resolved over time. Incorporating version control principles into BIM-based workflows could address these gaps by systematically tracking edits, modeling their propagation across related elements and rules, and maintaining structured records that support more transparent, targeted, and repeatable compliance checking. Therefore, this paper aims to bridge these gaps by linking model updates to the subset of rules required to evaluate the performed changes, connecting checking results with subsequent issue information for coherent tracking across model updates, compliance assessments, and project communication items.

Proposed Methodology

Our approach aims to improve the preparation of the building model and the rule execution process by determining which rules to apply based on the exact changes made to the design model. When new components are first introduced to the design model, they are evaluated against the complete set of rules relevant to that modification scope. Any subsequent changes are then evaluated only against the subset of rules affected by those updates. In particular, by applying version control to the design models as they evolve, we gain direct access to detailed information about the changes made. The version increment that records these modifications describes the alterations at a strictly data-representation level following concepts of set and graph theory. Consequently, we propose additional enrichment and processing of this information to enable its effective use in the subsequent workflow.

Processing Pipeline

The envisioned processing pipeline is illustrated in Figure 2 and considers a designer who incrementally enhances their BIM model containing information about a specific discipline or trade, and a model checking workflow is used to validate whether the model complies with a given set of rules, indicated in the right part of Figure 2. The modification details captured in the version increment are enriched to determine which rules must be executed, enabling a more efficient assessment of the model's compliance. To accomplish this, four processing steps need to be incorporated into the standard model checking workflow:

Rule setup: Each rule performs checks on specific elements contained in the BIM model. In this way, we can understand which elements are checked by which rules and what additional context they require.

Increment Interpreter: In this stage of processing, we apply pattern matching to the version increments to derive engineering-level insights from the underlying graph transformation.

Assignment Module: This module uses the version increment and the identified modification scope to determine and trigger which rules must be re-validated in light of the design changes made.

Reasoning Module: In this step, the outcome of the performed check, along with the version increment, is used to decide whether a new issue must be created or whether satisfying the rule should instead trigger an update to an issue's status or its closure.

Rule setup

Figure 3 schematically shows the configuration of the rules. Each rule is defined by its application target, the necessary model context, a modification scope to which the rule is sensitive, and the specific checking procedure. Together, these elements form the digital representation of a particular aspect derived from a code or standard that the design is required to comply to.

The *application target* defines the primary focus of a rule, specifying which elements are explicitly examined. Targets can be selected based on element types and/or spatial or functional containment, or their combinations (e.g., all windows from the second floor upward). In addition to the application target, a rule can specify *supplementary model context*. This context provides additional informa-

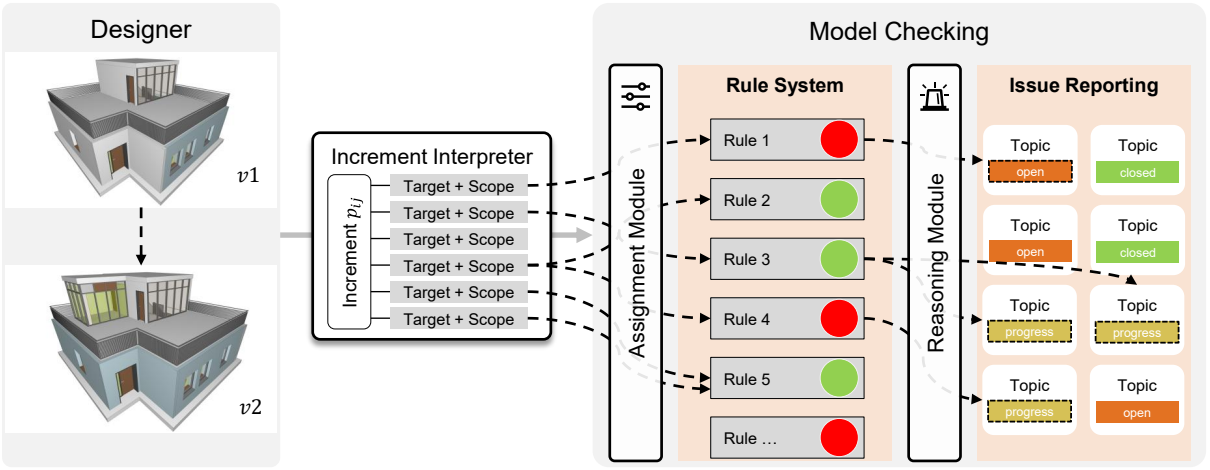

Figure 2: Overall processing pipeline: a model author creates two versions of a BIM model, from which version control principles produce an increment representing the performed changes. The increment is enriched before being fed into the model checking system.

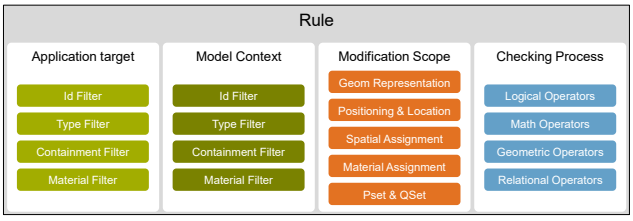

Figure 3: Rule Setup with the Application Target, Model Context, Modification Scope, and Checking Process.

tion that the checking process may require for execution. It can be retrieved from the model at any time, independently of whether the corresponding elements were modified in the latest design iteration.

For example, consider a rule that checks whether doors intersect with furnishings when opened. The application target of this rule would be the insertion of doors or modifications to their geometry and position. However, the furnishing elements are part of the model context and are fetched from the BIM model when the checking process needs them for geometric overlap calculation. Because rules can depend both on their application target and on their model context, rule execution must be defined in a commutative way: the rule must be re-executed not only when the application target changes, but also when elements forming the model context are modified — even if the application target itself would not otherwise be triggered.

The *modification scope* serves as a trigger interface that determines which types of model modifications the rule must be assessed for, both in terms of the application target and the model context. It consists of various categories of changes that can occur within a BIM model and is used to determine, for both the specific elements addressed by the rule (application target) and the surrounding conditions in the BIM environment (model context), under which circumstances the rule should be executed. The operators shown in the checking process section in Figure 3 correspond to those introduced by Preidel and Borrmann (2016), but can be expanded further to address specific issues.

Increment Interpreter

The version increment that captures the applied model modifications is formalized as a graph transformation rule and adheres to well-established notations from fundamental graph and set theory. In the method presented by Esser et al. (2022), a Double-Push-Out formalism is used to define how the underlying object network forming the BIM model must be altered by deleting and inserting subgraphs to transform the model from its initial state to its updated state. These subgraphs are described in the Left-Hand-Side (LHS), the Interface graph I, and the Right-Hand-Side (RHS), reflecting the required transformation steps.

The modification operations captured in a version increment describe changes at the raw data level, interacting only with nodes and edges in the graph. While model updates at any level of granularity can be reliably expressed in this way, additional interpretation is required to derive higher-level information from these version increments that can guide our decisions about which rules need to be re-evaluated. Consequently, the increment interpreter is introduced as a preprocessing step before the data enters the model checking system (as illustrated in Figure 2). Figure 4 illustrates the interpretation process.

In this processing step, we examine the contents of the version increment and perform pattern matching on the graphs that constitute the underlying transformation rule, describing the necessary actions to update the BIM model (i.e., its graph representation) from version 1 to version 2. More formally, this means that we look for an occurrence of an operation pattern O_i within the graph patterns that form the Left-Hand Side (LHS) and the Right-Hand Side (RHS) of the transformation rule. The operation patterns O are assumed to be predefined and are supplied as a library. For each pattern, the library provides additional logic that extracts information about the target of the modification (e.g., the globally unique identifier of the object

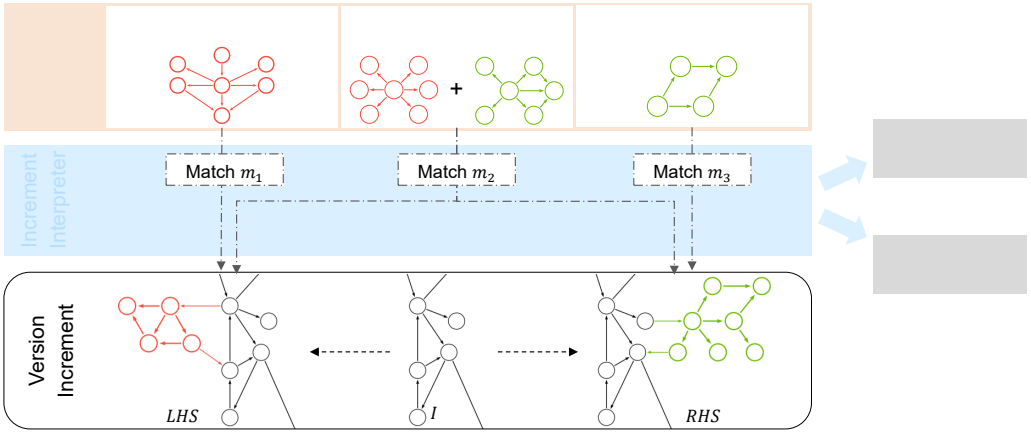

Figure 4: Increment interpreter: The version increment obtained from comparing two versions of a BIM model is shown at the bottom. The Interpreter's goal is to identify occurrences of the graph patterns defined in the operation library to reveal the scope and its target.

being modified) and the modification scope. Both aspects form the output of the increment interpreter, which will then be utilized in the assignment module.

Naturally, semantic changes also provide an informational foundation, meaning that the graph paths uniquely identifying nodes affected by semantic changes can likewise be used to infer higher-level statements about the target and the extent of the modification. Common examples of semantic changes include modifications to the Cartesian coordinates that define an element's location, as well as alterations to its name or description attributes, which are attached to nodes representing instances of subclasses derived from IfcRoot.

Assignment Module

The assignment module is responsible for linking the modification scopes and application targets, as determined by the Increment Interpreter, to the rules that must be executed in response to the detected model changes. In essence, it decides which rules are affected by which changes and orchestrates their re-execution. When existing components in the model are modified, the corresponding rules are selectively re-triggered, restricted to the identified modification scope, so that only the impacted portions of the model are reconsidered. In contrast, when elements are removed, any rules that reference them within the model context must be re-evaluated. If deleted elements were the original targets of specific rules and had already caused problems, those rules may be closed once the elements are removed. Similarly, when new elements are introduced, the assignment module identifies all rules that are applicable to these elements and ensures that they are executed accordingly. This targeted rule assignment enables incremental, efficient, and consistent evaluation of model changes without recomputing the entire rule set.

Reasoning Module

After the rules have been evaluated, their outcome is essentially a basic pass-or-fail result, typically accompanied by information about the elements that were checked and failure information about missing properties or violated parts of rules. These results are then further processed to support the system operator in managing issues.

In this step, the Reasoning Module preserves an explicit link between the performed model changes, the rules that were (re)evaluated as a consequence, and the issues that arise from those rule activations. It maintains the connection from the originating rule, through its evaluation outcome, to the corresponding problem descriptions and the resulting change requests addressed to the model authors. The issues themselves are recorded using the BIM Collaboration Format (BCF), which stores key metadata for each identified problem, such as its name, description, and the GUIDs of the affected elements. On top of this, the issues are enriched with identifiers that allow us to trace back precisely which rule triggered the documented problem or topic, and which model revision it relates to.

Because we can track how modifications to the model affect each rule's output, we can also determine which open issues are likely to be resolved by the considered model update. Although much of this analysis can be automated using the maintained links between model changes, rule activations, and issues, the final decision on each issue's status is ultimately left to the model reviewer.

Rationale of the Processing Pipeline

The proposed approach integrates into existing model-based workflows as a preprocessing layer, without requiring fundamental changes to the underlying rule system or issue management infrastructure, while the rule setup module enables practitioners to define checking targets at a finer granularity than conventional model-level filtering. The increment interpreter replaces the implicit assumption that reviewers can manually identify the scope of a modification, and the assignment module translates this information directly into rule-execution decisions, ensuring that only the affected subset of rules is re-triggered, thereby reducing the computational overhead associated with frequent model updates. Beyond efficiency gains, the reasoning module closes the feedback loop by connect-

ing rule outcomes to issues, introducing a level of process transparency that current workflows lack and enabling reviewers to trace why a particular check was triggered and which design decision prompted it. Over time, the accumulated change-issue pairs constitute a structured record of a project's compliance history, which could inform both design decisions and quality assurance processes in future projects.

Case Study

The following case study demonstrates the key ideas of the proposed method using a small-scale building model. The designer arranged a main hall as the central meeting space, with several auxiliary service rooms located at the rear of the building. To verify the design compliance, two specific rules out of a larger rule set are considered:

- Exit-Positioning rule: When two exits are required from an exit access area, they must be separated by at least one-half of the longest diagonal of the area, measured in a straight line [1].
- FireRatingPSet rule: Each door and window must be assigned a property set that includes its fire rating information.

Each rule provides the system with the parameters that it requires to run. For the Exit-Positioning rule, doors constitute the primary application target, and the rule requires the adjacent space geometry as model context in order to derive the minimum clearance distance to be maintained between individual doors. The rule is therefore sensitive to any modification in the geometric representation of the doors or their placement within the spatial configuration. In comparison, the FireRatingPSet rule applies specifically to doors and windows and focuses on fire-resistance data. Consequently, this rule reacts to modifications in the corresponding pSet attributes.

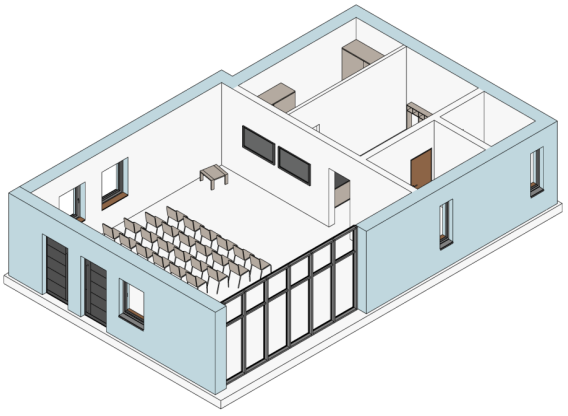

Figure 5: Case Study Model.

[1] Summarized from IBC Rule 1007.1.1, available `https://codes.iccsafe.org/content/IBC2018P6/chapter-10-means-of-egress#IBC2018P6_Ch10_Sec1007.1.1` (last access 2026-01-26)

Figure 5 illustrates the model in its initial version state, which is checked against any rule, as any information contained in the design model was newly inserted. In the initial design, two primary exit doors are positioned next to each other to provide access to the main hall. Given that the diagonal of this room is approximately 11.30 m, the spacing between these doors is clearly insufficient. Consequently, an issue is generated directly from the detected violation, and the association between the rule and the resulting issue is recorded. All doors and windows in the initial design contained adequate property set data; therefore, the FireRatingPSet rule confirmed their compliance. After returning the detected issues to the designer, they revised the model. Figure 6 illustrates the design modifications performed. One door has been repositioned on another wall, and a new window has been inserted.

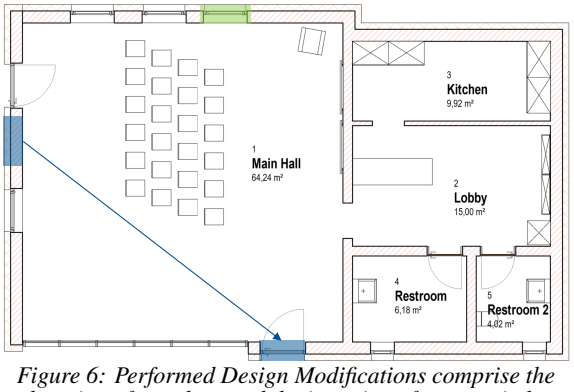

Figure 6: Performed Design Modifications comprise the relocation of one door and the insertion of a new window.

The changes are recorded as a version increment, comprising 287 nodes and 282 relationships in the removed pushout pattern, and 613 nodes and 637 relationships to be inserted via the inserting pushout pattern. Furthermore, 1817 node attributes have been edited. These nodes have not been altered in their topological position within the model graph but underwent semantic changes.

Figure 7 shows the operation patterns O that are available in the operation library. The increment interpreter applies these patterns to recognize that an entrance door has been modified and then reports the changes to the object's position and its nesting assignment, since the door is now placed on a different wall. As the version increment does not alter the fire resistance parameters of the relocated door, it is concluded that the door continues to comply with the fire resistance rule. Consequently, only the Exit-Positioning rule is re-assessed. As this rule reports no violations, the issue raised based on the original design model can be marked as resolved by the model modification and may be closed by the model reviewer, given the positive evaluation result. However, the newly inserted window is checked against the FireRatingPSet rule to ensure it meets the required element criteria. If compliance is confirmed, no issue needs to be created; if not, a new issue is generated that retains information about the originating rule and the non-compliant element.

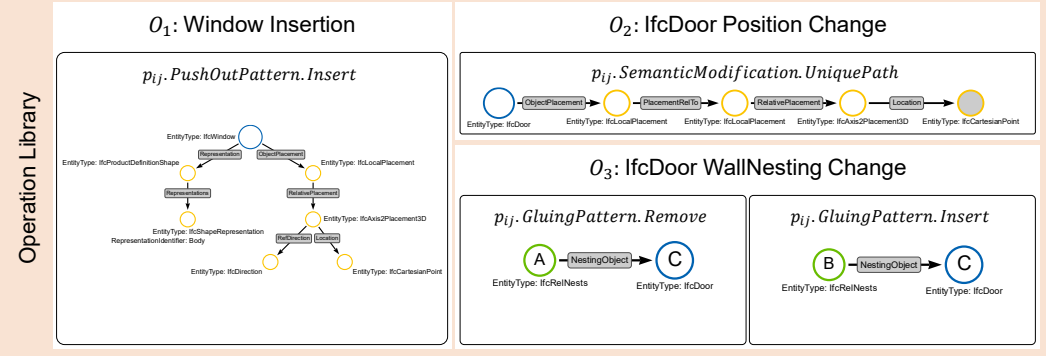

Figure 7: Case Study: Operation library used to identify the performed design modifications.

Limitations

Despite the potential benefits of the proposed approach, several limitations must be acknowledged.

First, the proposed concept relies heavily on an operation library that maps concrete design modifications to corresponding rule triggers. A core limitation is the assumption that this operation library is complete and accurate. In reality, constructing such a comprehensive operation library is challenging as certain modeling operations may not be fully captured or formalized. Furthermore, new modeling patterns and tools can introduce operations that are not yet known to the increment interpreter. If the operation library is incomplete or inaccurately specified, relevant triggers may not be fired, resulting in missing relevant checks. Consequently, the overall reliability of the approach is directly dependent on the continuous maintenance, validation, and extension of this library.

The current approach focuses on design changes that explicitly trigger rule checks. However, there can be intricate rules, which can be violated implicitly, even when no formal change trigger has been activated. Modifications in one part of the model may indirectly affect constraints or assumptions embedded elsewhere in the rule system, leading to undetected non-compliance. For example, design compliance with evacuation time depends on many interrelated factors such as space connectivity, door and corridor widths, and fire compartmentation. A local change, such as moving a door or partition, may not trigger an explicit evacuation check, yet it can still invalidate the relevant computed egress path or partially undermine its underlying design intent. While running the complete rule system on a periodic basis (e.g., weekly) partially mitigates this risk, it does not eliminate the possibility of temporary non-compliant states between full runs. In practice, this means that some violations may only be discovered with delay, and selective checks cannot yet guaranty full coverage of all rule interactions.

Another limitation of this study can be found in the limitation to single-discipline problems. Many industrial model-checking scenarios, however, involve multidisciplinary design models, where several domains are simultaneously represented. Interdisciplinary dependencies among building elements are common, and a change in one discipline may require corresponding updates in others to maintain conformance with relevant constraints and compliance requirements, for example, moving a wall may require relocating pipes and connected equipment in the MEP model. The current reasoning approach primarily targets change analysis within a single domain and must be extended to serve for interdisciplinary aspects, accordingly. In summary, while the method improves responsiveness and focuses rule-checking effort around actual changes, its effectiveness is constrained by the completeness of the operation library, the handling of implicit rule interactions, and the ability to reason over multidisciplinary models.

Summary and Outlook

In this paper, we introduced a novel approach to improving model-checking workflows by leveraging incremental version control as a fine-grained source of information for intelligent rule selection and subsequent reasoning about issue documentation. The approach decomposes the overall problem into smaller processing steps. First, version control principles are applied to track the evolving BIM model on the author's system. Performed changes are encoded as version increments, which are essentially graph transformations leveraging the underlying object network in the BIM model from its initial to an updated state. Then, we use these version increments to guide informed rule selection and focused model checking. Instead of running the full rule set after every modification, our method constructs a dependency mapping between model-edit operations and the rules that may be affected by those edits. Guided by this mapping, the model checking is invoked selectively, concentrating only on rules whose input parameters have been modified. By linking the outcomes of checks to the resulting issues, the approach enables both retrospective and predictive reasoning. Detected issues are associated with the specific changes that introduced or resolved them, thereby building a corpus of annotated change–issue pairs.

By exposing the relationship between detected issues and the underlying model changes, our method offers deeper insights into model evolution and the root causes of problems. Future work should extend the current illustra-

tive case study through experiments on real-world projects to examine more explicitly the reduction in rule executions enabled by enhanced traceability in model checking workflows. Moreover, collecting and learning from this data may enable future systems to propose solutions to issues with similar characteristics, paving the way for more proactive, intelligent support in model-based design environments.

Use of AI tools

While preparing this work, the authors utilized Large Language Models inside Overleaf Writefull AI to refine the language and identify spelling errors. After using these tools, the authors reviewed and edited the content as needed and take full responsibility for the publication's content.

A COMPUTATIONAL DEA-BASED DECISION SUPPORT FRAMEWORK FOR GREEN SUPPLY CHAIN MANAGEMENT IN CONSTRUCTION

Erawati Ravindra Kadam, and Ann Francis
Department of Civil and Environmental Engineering, Indian Institute of Technology Delhi, India

Abstract

In construction, greening supply chains requires balancing economic performance with environmental impact, making systematic evaluation and comparison difficult. Current approaches rely on single indicators or subjective assessments, limiting their ability to identify relatively efficient configurations. This paper proposes a Data Envelopment Analysis (DEA)-based framework to computationally evaluate green supply chain management (GSCM) scenarios. Economic and environmental parameters are treated as inputs and outputs in the DEA model. An application to 81 scenarios identifies supply chain configurations that achieve environmental improvements without disproportionate economic penalties, addressing a key challenge in implementing GSCM in the construction sector.

Introduction

The construction industry plays an important role in the world's economic growth and infrastructure development. Apart from construction activities, a substantial amount of construction-related environmental and economic impact is embedded in upstream material production, transportation, and logistics decisions (Wibowo, Handayani and Farida, 2022). As a result, attention has increasingly shifted toward construction supply chains as a key leverage point for improving overall project performance. In response, green supply chain management (GSCM) has emerged as an approach that integrates conventional supply chain decisions with environmental considerations, while maintaining economic and operational performance (Farida, Handayani and Wibowo, 2019). In construction, GSCM practices include reducing material wastage, improving energy efficiency, lowering carbon emissions, and optimising transportation and logistics operations (Castellano *et al.*, 2023). However, these strategies rarely improve all performance dimensions simultaneously.

A primary challenge in implementing GSCM in construction lies in managing trade-offs among multiple, often conflicting parameters, including cost, emissions, waste generation, time, and profitability (Wibowo, Handayani and Farida, 2022). Therefore, evaluating alternative options in GSCM configurations is a complex multi-criteria decision-making problem. Existing practices focus on a single dimension or a descriptive comparison, such as cutting emissions or reducing costs and time. Because of focusing on one dimension, these approaches often fail to capture the multidimensional nature of supply chain performance and typically require subjective weighting of criteria.

These constraints are particularly evident in project-based construction contexts where total material demand is fixed, and variations among alternative supply chain configurations arise primarily from differences in resource utilisation efficiency rather than scale. Under such conditions, conventional evaluation methods struggle to provide objective benchmarking across green supply chain scenarios. There remains a lack of structured, scenario-based analytical frameworks tailored to project-level construction supply chains, capable of simultaneously capturing economic, environmental, and operational performance while enabling objective efficiency benchmarking under constant material demand conditions. Addressing this gap requires an efficiency-based evaluation approach that can handle multiple inputs and outputs concurrently, avoid subjective weighting of performance criteria, and benchmark alternatives relative to best-performing configurations.

Data Envelopment Analysis (DEA) offers a comprehensive solution to this issue. DEA is a non-parametric method for evaluating efficiency that measures the relative performance of similar entities by examining their capacity to convert various inputs into preferred outputs, without the necessity for predetermined weights (Charnes, Cooper and Rhodes, 1978; Banker, Charnes and Cooper, 1984). DEA has shown potential applications in supply chain studies as well as environmental and sustainability research to evaluate performance independently (Zhou, Ang and Poh, 2008). These attributes make DEA particularly suitable for assessing GSCM in construction projects that involve competing economic and environmental objectives.

Therefore, this study proposes a structured, scenario-based DEA framework for assessing GSCM efficiency in project-level construction supply chains under constant demand conditions. Alternative supply chain configurations are systematically developed using literature-based economic and environmental parameters and evaluated as decision-making units within a variable returns to scale (VRS) DEA model. By focusing on project-oriented supply chain contexts where material

quantities are design-driven, the study provides a targeted analytical approach for comparing green supply chain configurations and identifying improvement pathways. The findings contribute methodological support for efficiency-based decision-making in construction supply chains and offer practical insights for managers and policymakers evaluating sustainable supply chain interventions.

Research background

Conventionally, construction supply chains have been designed primarily to minimise costs, improve efficiency, ensure on-time deliveries, and maintain sufficient inventory to prevent construction delays. However, these priorities often conflict with sustainability goals, leading to overproduction, excessive transport, and material wastage (Cataldo *et al.*, 2022) .

The rising urgency of climate change and resource scarcity has placed sustainability at the forefront of supply chain management. Governments, investors, and clients now demand construction projects that reduce carbon emissions, minimise waste, and adopt circular practices(Chen, Feng and Garcia de Soto, 2022). For cement, reducing emissions is a global priority, as its production contributes significantly to overall greenhouse gas levels (GCCA India-TERI, 2025) . But project stakeholders cannot ignore cost pressures, productivity requirements, and delivery deadlines. This dual pressure creates a fundamental tension over whether to focus on environmental outcomes or efficiency-focused measures (Golpîra, 2021).

This tension is especially evident in decisions around production and inventory (Castellano *et al.*, 2023). For example, producing and storing more material than immediately needed helps prevent material shortages on site, but increases emissions, costs, and risks of wastage (Chen, Feng and Garcia de Soto, 2022). In construction, the problem is more constrained to the project level. Total material demand is often fixed by design, and performance differences among alternatives arise from differences in per-unit costs, emissions intensity, and operational losses, such as material wastage. Transportation choices further complicate the trade-off, as frequent deliveries may improve responsiveness but generate higher emissions (Suhaib, Amir Babak Rasmi and Türkay, 2023).

In response, GSCM enhances conventional supply chain management by including environmental impacts into procurement, production, transportation, and waste management decisions. In the construction industry, GSCM methods typically encompass the adoption of low-carbon resources, energy-efficient technology, optimal logistics planning, and minimisation of material waste (Farida, Handayani and Wibowo, 2019; Wibowo, Handayani and Farida, 2022).

A variety of techniques have been utilised to assess green supply chain effectiveness. Life Cycle Assessment (LCA) is extensively employed to measure environmental consequences throughout the supply chain and identifies emission hotspots in construction materials and processes (Backes and Traverso, 2022). However, LCA predominantly emphasises environmental factors but does not explicitly include economic efficiency or the trade-offs among various performance metrics.

Multi-Criteria Decision-Making (MCDM) methodologies, like the Analytic Hierarchy Process (AHP), TOPSIS, have been widely utilised to assess green supply chain options by consolidating various criteria into a singular score(Paul *et al.*, 2021). Although these systems provide flexibility, they depend on predetermined or gathered weights to reflect decision-making preferences. Numerous assessments indicate that MCDM outcomes are significantly influenced by weighting methods, potentially introducing subjectivity and constraining transparency, especially when objective benchmarking is necessary (Paul *et al.*, 2021)

In project-based construction environments, where possibilities are evaluated under set demands and standardised functional units, dependence on subjective weighting is a considerable constraint. Thus, there is a necessity for performance evaluation methodologies that may objectively assess many options based on empirical performance data without necessitating prior determination of preference weights.

DEA gives a non-parametric framework for assessing the relative efficiency of analogous decision-making units utilising various inputs and outputs without predetermined weights (Charnes, Cooper and Rhodes, 1978; Banker, Charnes and Cooper, 1984). The DEA formulates an efficiency frontier based on observable data, designating efficient units as benchmarks for their inefficient counterparts, while also measuring prospective improvement objectives.

DEA has been extensively utilised in energy, environmental, and sustainability research to evaluate eco-efficiency by including costs, energy consumption, emissions, and resource losses as inputs, while financial performance indicators serve as outputs (Zhou, Ang and Poh, 2008). In supply chain research, DEA has been employed to assess companies, logistics networks, and supply chain designs, providing insights about efficiency rankings and opportunities for enhancement (Zhou, Ang and Poh, 2008).

In contrast to LCA and MCDM methodologies, DEA is especially appropriate for objective benchmarking scenarios that need the simultaneous assessment of numerous quantitative metrics. Its capacity to eliminate subjective weighting and to offer reference sets and proportional improvement metrics renders it very appropriate for assessing the green supply chain for the construction industry, contexts defined by fixed demand and various efficiency determinants. Despite existing contributions, a distinct vacuum persists in the systematic benchmarking of various GSCM scenarios within construction project-based frameworks. Current research predominantly applies descriptive comparisons, utilises MCDM methods with subjective weighting, or focuses on firm-level efficiency

assessments instead of scenario-based evaluations under constant project demand.

This paper proposes a DEA-based framework for assessing the efficiency of green supply chains to solve this gap. The approach utilises an input-oriented VRS-DEA model to benchmark literature-informed scenarios, facilitating objective comparisons of economic and environmental performance, identification of efficient configurations, and quantification of prospective improvements. This enhances both the theoretical and practical aspects of decision-making in GSCM for the construction industry.

Methodology

This study proposes a structured, DEA-based multi-stage framework to address the need for systematic, objective benchmarking methods for assessing GSCM scenarios in the context of project demand. The methodology aims to facilitate transparent scenario construction, minimise dependence on subjective performance weighting, and promote quantitative efficiency benchmarking across various supply chain configurations.

The proposed methodological framework shown in Figure 1 combines literature-informed parameter identification, scenario development, DEA model formulation, computational implementation, improvement potential analysis, and decision support interpretation to facilitate a comprehensive and replicable assessment of GSCM efficiency.

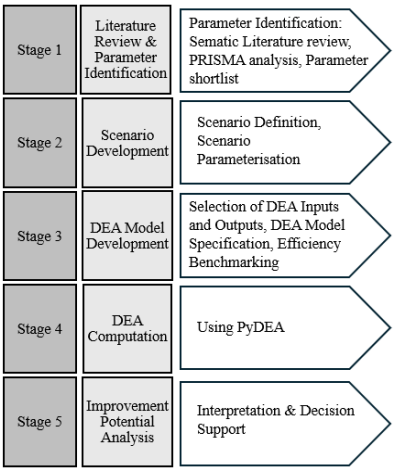

Figure 1: DEA-Based Methodological Framework

Stage 1: Literature Review & Parameter Identification

A systematic literature review using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) was performed to identify performance parameters associated with the efficiency of GSCM(Page *et al.*, 2021). Relevant studies were sourced from prominent academic databases such as Google Scholar, Web of Science, and Scopus. Based on their applicability to construction supply chains and their utilisation of quantitative performance indicators. From the collected literature, economic, environmental, and operational parameters frequently used to assess green supply chain performance were extracted and categorised. Table 1 represents the shortlisted Economic, Environmental, and Operational parameters with their sources. The selection of parameters was guided by their relevance to GSCM objectives, the availability of quantitative benchmarks, and their appropriateness for efficiency-based evaluation. This approach ensures that scenario development and subsequent DEA analysis are anchored in established literature rather than arbitrary assumptions.

Table 1: Shortlisted Parameters

Category	Parameter	Description	Source
Economic	Production cost (₹/t)	Costs associated with material manufacturing and processing	1,2,3
	Transport cost (₹/t)	Cost of conveying materials from the origin to the site	1,2,3,4
	Carbon cost/Tax (₹/t)	Costs related to carbon pricing or emissions Taxes	7,8
	Net profit (₹/t)	The financial worth produced per unit of material provided	1,2,3
Environmental	CO_2 emissions (production) (tCO_2/t)	Emissions produced during the manufacturing of materials	4,5,6
	CO_2 emissions (transport) (tCO_2/t)	Emissions produced during the transportation of materials	4,5,6
Operational	Material wastage (%)	Percentage of material wasted due to handling and inefficiencies	9,10

1.(Khaiyum, Sarker and Kabir, 2023), 2.(Castellano *et al.*, 2023), 3.(Bhagwat and Sharma, 2007), 4.(Francis and Thomas, 2020a), 5.(GCCA India-TERI, 2025), 6.(Okay, Sencer and Taskin, 2024),7. (Pan *et al.*, 2024),8.(Santos, 2022),9.(Gulghane and Khandve, 2015), 10.(Golzarpoor and González, 2013)

Stage 2: Scenario Development

This study characterises a scenario as a unique construction supply chain configuration distinguished by varying operational and environmental management approaches, with each scenario considered as a Decision Making Unit (DMU) within the DEA framework. Scenarios are designed deterministically to represent realistic and comparative supply chain options. A case study construction project is utilised to ensure practical relevance, with the corresponding cement demand serving as the analytical foundation. All scenarios are constructed with regard to this case study.

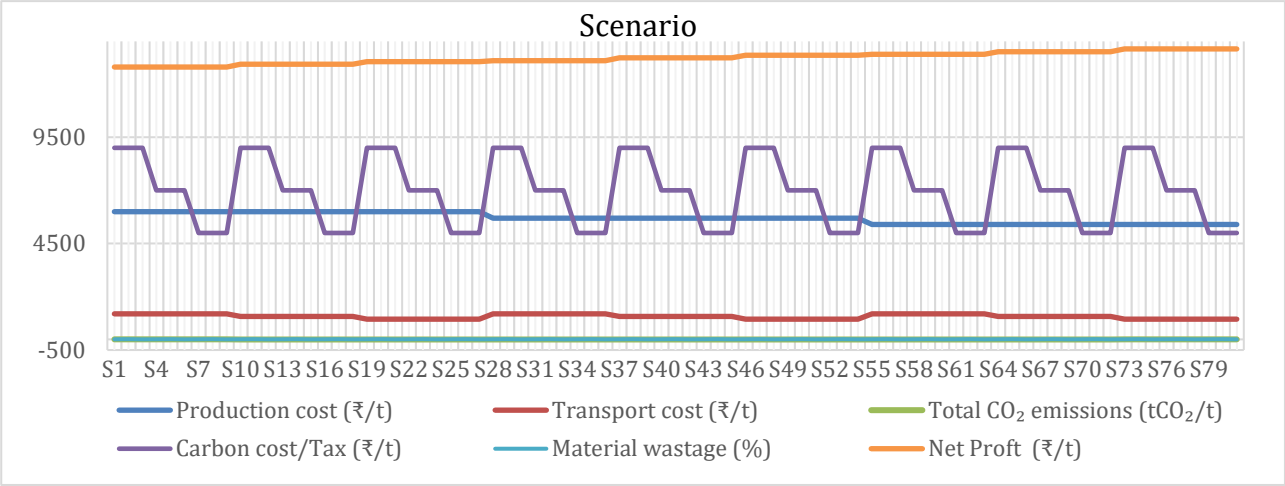

Figure 2: GSCM Scenario Design for DEA-Based Evaluation

A constant project demand assumption is used across all scenarios, representing standard construction conditions in which material quantities are dictated by design and scheduling limitations. This guarantees that the observed discrepancies in efficiency stem from differences in resource utilisation rather than scale effects. A total of 81 scenario archetypes are developed to assess performance across various management strategies, reflecting systematic differences in cost structure, emission intensity, material waste, logistics efficiency, and carbon cost internalisation. Figure 2 shows a graphical representation of all developed scenarios.

Table 2: Parameter Range Summary Table

Parameter	Max	Mid	Min
Production cost (₹/t)	6000	5700	5400
Transport cost (₹/t)	1200	1075	950
Carbon cost/Tax (₹/t)	9000	7000	5000
CO_2 emissions production (tCO_2/t)	0.9	0.65	0.54
CO_2 emissions transportation (tCO_2/t)	2.02	1.9	0.65
Material wastage (%)	5	3.5	2

Table 2 provides a parameter-range summary used in scenario development. The parameter values were selected from industry evidence and published studies. Wastage percentages were defined using industry evidence. Gulghane and Khandve (2015) report that cement wastage in Indian construction typically ranges from 2–3% in well-managed sites, while poorly managed projects experience higher levels. Other studies note wastage levels of 2.6–4% on active projects, which justifies a maximum assumption of 5% and a reduction to 2% for scenarios (Golzarpoor and González, 2013). Cost assumptions were anchored in UltraTech Cement's financials for 2025, which report an average realisation of ₹5,052 per tonne and logistics costs of ₹1,167 per tonne (UltraTech Cement Limited, 2025). Scenarios apply 5–10% premiums in line with early adoption of low-carbon cement, which global benchmarks suggest may be 50–45% more expensive. Finally, CO_2 emission parameters were aligned with sectoral roadmaps.

Francis and Thomas (2020b)shows that Indian housing can achieve up to 40% reductions through material substitution and policy measures, while the Decarbonization Roadmap for the Indian Cement Sector: Net-Zero CO_2 by 2070 (GCCA India-TERI, 2025), outlines feasible reductions of 35–50% by mid-century. Accordingly, the parameter value applies a 50% reduction for both production and site consumption emissions, with incremental reductions at Low and Medium levels.

Carbon cost numbers were articulated in Indian Rupees per tonne of CO_2 to ensure compatibility with project cost data. International carbon tax rates and emissions trading prices indicate that carbon pricing levels often vary from below USD 1/tCO_2 to over USD 100/tCO_2(Santos, 2022; Pan *et al.*, 2024; United Nations Environment Programme and Global Alliance for Buildings and Construction, 2025). Utilising a realistic currency rate, this equates to around ₹100–₹10,000 per tCO_2. Consequently, low, medium, and high carbon cost levels were established within this spectrum to represent voluntary carbon markets, average compliance pricing, and stringent policy scenarios, respectively. While India does not presently enforce a comprehensive carbon tax, this study incorporates carbon costs to account for evolving international carbon pricing frameworks and prospective regulatory conditions, facilitating a forward-looking assessment of the efficiency of GSCM.

Stage 3: DEA Model Development

The selection of DEA inputs and outputs is based on GSCM concepts and the attributes of project-based construction systems. Inputs signify unfavourable economic, environmental, and operational constraints that need to be reduced, and outputs denote favourable economic results.

Each construction supply chain scenario is regarded as a DMU defined by a vector of inputs and outputs. The DEA input set comprises production cost (₹/t), transport cost (₹/t), carbon cost/tax (₹/t), total CO_2 emissions (tCO_2/t),

and material wastage (%). Net profit (₹/t) is designated as the primary output variable as it represents an aggregate performance indicator reflecting the combined effects of production cost, transport cost, carbon cost, and material wastage, which are explicitly modelled as inputs. The quantity of material is omitted as an output variable because project demand remains constant across all scenarios and therefore does not influence efficiency differentiation. All variables are articulated on a per-tonne basis to guarantee comparability and eliminate scale-induced error. Table 3 represents inputs and outputs used in DEA.

Table 3: DEA Inputs and Outputs

Variable type	Parameter	Unit	DEA role
Input	Production cost	₹/t	Minimized
Input	Transport cost	₹/t	Minimized
Input	Carbon cost	₹/t	Minimized
Input	Total CO_2 emissions	tCO_2/t	Minimized
Input	Material wastage	%	Minimized
Output	Net profit	₹/t	Maximized

An input-oriented DEA model is used to assess the relative efficiency of green supply chain scenarios. The aim is to reduce economic and environmental burdens while sustaining the same level of revenue generation. This viewpoint aligns with construction project conditions, where output quantities are limited by fixed demand and efficiency enhancements are primarily realised through reductions in costs, emissions, and waste.

VRS are assumed using the Banker–Charnes–Cooper (BCC) DEA model, which allows efficiency to vary with scale and isolates pure technical efficiency from scale effects (Charnes, Cooper and Rhodes, 1978; Banker, Charnes and Cooper, 1984).

DEA Multiplier Formulation,

For a given scenario, the DEA efficiency score is obtained by solving the following linear programming problem:

$$Max\ E_o = \sum_{r=1}^{s} u_r y_{ro}$$

Subject to,

$$\sum_{r=1}^{s} v_i x_{io} = 1$$

$$\sum_{r=1}^{s} u_r y_{rj} \leq \sum_{i=1}^{m} v_i x_{ij}, \quad \forall_j = 1,2, \dots \dots \dots, n$$

$$u_r \geq 0, \quad v_{i \geq 0}$$

The objective function maximises the weighted sum of outputs for scenario o, normalised by the weighted sum of its inputs. The second constraint ensures that the identical combination of weights does not yield an efficiency score exceeding 1 in any other scenario, thereby establishing the efficiency frontier.

For computational implementation, the equivalent input-oriented VRS envelopment model is used:

$$Min\ \theta_o$$

Subject to,

$$\sum_{j=1}^{n} \lambda_j x_{ij} \leq \theta_o x_{io}, \forall_i = 1,2, \dots \dots, m$$

$$\sum_{j=1}^{n} \lambda_j x y_{ij} \leq y_{ro}, \forall_r = 1,2, \dots \dots, s$$

$$\sum_{j=1}^{n} \lambda_j = 1$$

$$\lambda_j \geq 0$$

This study employs DEA formulations based on the basic input-oriented multiplier and envelopment models initially introduced by Charnes et al., (1978) and then modified to VRS by Banker et al., (1984). Table 4 shows a description of the notation.

Table 4: Notation and Variable Description

Symbol	Description	Unit	Corresponding parameter
n	Number of scenarios (DMUs)	–	81 scenarios
m	Number of inputs	–	5 inputs
s	Number of outputs	–	1 output
x_{1j}	Production cost of scenario (j)	₹/t	Production cost
x_{2j}	Transport cost of scenario (j)	₹/t	Transport cost
x_{3j}	Carbon cost of scenario (j)	₹/t	Carbon cost
x_{4j}	Total CO_2 emissions of scenario (j)	tCO_2/t	Total CO_2 emissions
x_{5j}	Material wastage of scenario (j)	%	Material wastage
y_{1j}	Net profit of scenario (j)	₹/t	Net profit
u_r	Weight assigned to output (r)	–	DEA output weight
v_i	Weight assigned to input (i)	–	DEA input weight
λ_j	Intensity variable	–	Peer contribution
θ_o	Efficiency score of scenario (o)	–	DEA efficiency

Stage 4: DEA Computation Using PyDEA

The DEA model outlined in the preceding part is executed using PyDEA, a Python-based application for data envelopment analysis (PyDEA Developers, 2023). PyDEA calculates efficiency scores by resolving a linear programming problem for each scenario and determines efficient benchmarks and reference sets. These outputs serve as the foundation for later efficiency benchmarking

and analysis of improvement possibilities, which will be addressed in the upcoming section.

Validation and Robustness Checks

This study emphasises the credibility and robustness of the proposed DEA-based framework over prediction accuracy. Conceptual validity is achieved by basing scenario development and parameter selection on recognised literature in GSCM and construction supply chains. All scenarios represent realistic and comparable configurations under constant project demand.

A sensitivity study was performed to evaluate the robustness of the DEA results by adjusting key input parameters within ±10% of their baseline values. The efficiency rankings and benchmark scenario identifications were predominantly consistent, suggesting that the DEA results are not affected by slight data fluctuations. These evaluations increase confidence in the reliability of the proposed framework and its relevance for decision assistance in GSCM planning for construction projects.

Stage 5: Improvement Potential Analysis

The next phase of the methodology focuses on synthesising DEA outputs to facilitate decision-making in GSCM planning for the construction industry. Efficient scenarios are recognized as benchmark configurations exemplifying best practices under constant project demand, whereas inefficient scenarios are assessed in comparison to their reference counterparts and their potential for improvement. The next part discusses detailed efficiency scores, benchmarking correlations, and opportunities for improvement.

Results and Discussion

The proposed DEA-based framework assessed 81 scenario-based DMUs representing different green supply chain configurations in the construction industry. Figure 3 represents the efficiency score across all scenarios with the considered parameters. All scenario configurations were developed within constrained and literature-informed parameter ranges to ensure realistic techno-economic and environmental relationships across production and transport stages. Production costs, transportation costs, transportation and production carbon emissions, carbon cost levels, and material wastage levels for the economic and environmental inputs are integrated into each scenario. Performance is evaluated using an economic outcome indicator under uniform functional assumptions. With scenarios S1–S27 obtaining an efficiency score of roughly 0.727, scenarios S28–S54 achieving an intermediate efficiency of roughly 0.88, and scenarios S55–S81 forming the efficient frontier with an efficiency score equal to 1, the resulting DEA efficiency scores indicate a structured pattern.

Scenarios S1–S27 exhibit high-intensity production configurations, featuring a production cost of ₹8,800 per tonne and production-related emissions of 0.90 tCO_2 per tonne, reflecting typical high-emission production regimes where higher emissions are associated with less efficient and more resource-intensive processes. Despite the reduction of wastage from 5% to 2% and decreasing the carbon tax from ₹9,000 to ₹5,000 per tCO_2e, these scenarios continue to exhibit relative inefficiency in terms of DEA. An efficiency score of 0.727 indicates that, on average, these scenarios necessitate a 27% decrease in their aggregate economic and environmental inputs to align with the performance of frontier scenarios. From a GSCM perspective, this outcome suggests that downstream green practices, such as waste minimisation and logistics optimisation, enhance absolute performance by reducing material losses and carbon emissions; however, their efficacy is limited when upstream production technologies are significantly carbon- and resource-intensive.

Scenarios S28–S54 indicate medium-intensity, characterised by a production cost of ₹7,200 per tonne and decreased production emissions of 0.65 tCO_2 per tonne. These scenarios attain an efficiency score of roughly 0.88, indicating the synergistic impact of moderate emission intensity and enhanced cost structure. This also reflects a realistic transition regime where improvements in emission intensity are accompanied by more efficient cost structures rather than conflicting trade-offs. Within this cohort, fluctuations in wastage and transportation emissions result in quantifiable enhancements in net profit and carbon cost liability. For instance, a 3 % point reduction in waste effectively reduces material losses and associated carbon costs, thereby improving economic performance even at elevated carbon tax rates. The results closely align with GSCM principles, indicating that operational greening and emission-control strategies significantly enhance supply chain performance when industrial systems are not overly carbon-intensive. Nevertheless, despite these advancements, none of the scenarios under this category attain the efficiency frontier, showing that even incremental greening cannot entirely offset the lack of low emissions during production.

Scenarios S55–S81 constitute the DEA efficient frontier, characterized by low-intensity production configurations, with a production cost of ₹6,400 per tonne and production emissions of 0.54 tCO_2 per tonne, alongside relatively reduced transport emissions. These configurations represent technologically feasible low-emission production pathways rather than idealised or unconstrained combinations of low cost and low emissions. Across all examined policy and operational situations, these configurations currently encompass various aspects of optimal green supply chain practices. Under this system, slight alterations in wastage or carbon tax do not lead to shifts in dominance, as the scenarios function near the least viable combination of economic and environmental costs within the specified scenario space. In the context of GSCM, these scenarios exemplify advanced, cohesive green supply chains where technological decisions, operational rigour, and regulatory readiness together enhance eco-efficiency.

The analysis shows that waste reduction and carbon taxes affect supply chain performance through production and logistics frameworks rather than as standalone efficiency

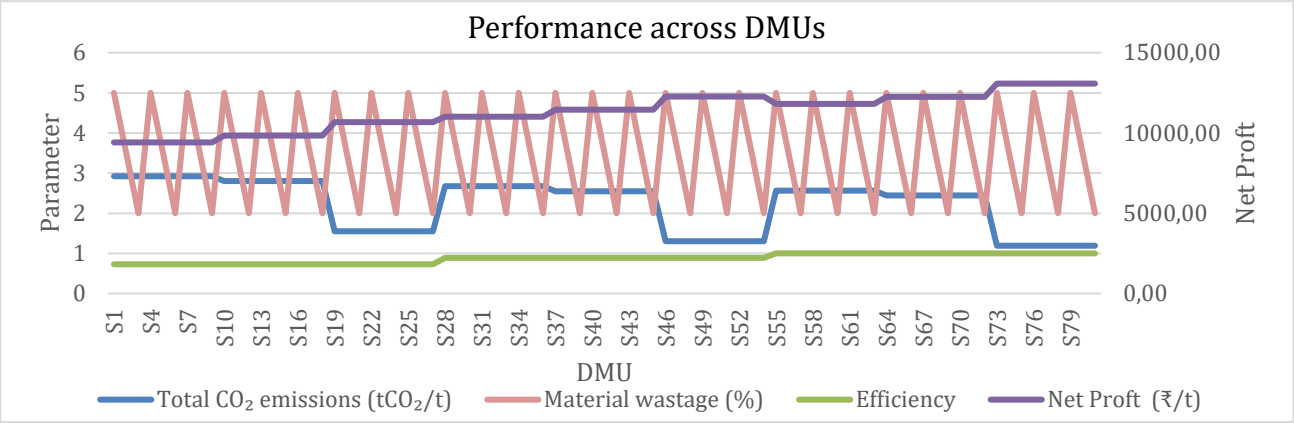

Figure 3: Integrated Environmental, Operational, and Economic Performance across DMUs

drivers. Under the fixed-revenue assumption, wastage and emission reductions improve absolute profitability and regulatory resilience but may not always improve relative efficiency scores compared to fundamentally cleaner setups. This supports GSCM theory, which distinguishes between incremental efficiency improvements within a technological regime and frontier-shifting transformations through low-carbon production and sourcing.

The results support the GSCM principle that technological, operational, and regulatory choices must align to sustain environmental advances. Performance and resilience improve with incremental greening, while structural investments in low-emission manufacturing and logistics redefine the efficiency frontier. This multi-scenario, multi-input–output framework ranks scenarios and reveals structural efficiency drivers, allowing decision-makers to compare supply chain configurations, identify non-dominated pathways, and understand how technology, operations, and policy changes may affect performance in a complex, sustainability-oriented decision environment.

Conclusions

This study proposes a structured, scenario-based DEA framework designed for project-level green construction supply chain decision-making under constant demand conditions. The primary contribution lies not merely in the application of DEA, but in the systematic development and benchmarking of alternative supply chain configurations using multi-dimensional economic, environmental, operational, and regulatory parameters. By organising scenario-based supply chain strategies as decision-making units within a consistent functional boundary, the framework enables objective efficiency comparison without requiring subjective weighting of sustainability indicators. This project-oriented perspective provides a targeted analytical approach for evaluating green supply chain strategies in construction contexts where material demand is design-driven and efficiency improvements must be assessed across feasible operational and technological alternatives.

The framework is useful for decision-makers in complex green supply chains where cost efficiency, carbon emissions, material waste, and regulatory demands are interdependent. Managers and policymakers can examine how production technology, transport emissions, wastage, and carbon taxation affect efficiency and net profit using multi-scenario analysis. Instead of offering a single solution, the framework shows dominance relationships and improvement potentials, helping stakeholders distinguish between operational and fundamental technology inefficiencies. This helps decide whether greening should focus on incremental operational improvements or deeper transitions to low-emission industrial technology.

The results are relative efficiency outcomes under fixed modelling assumptions and scenario-based inputs; therefore, they enable decision-making rather than prescriptive optimization for real-world implementation. While the use of a single output simplifies the analysis, it enables clearer interpretation of relative efficiency, with scope for extending the framework to multi-output DEA formulations in future work. In practice, demand variability due to design changes or schedule pressure can alter resource utilisation, cost structures, and emission intensity, potentially affecting relative efficiency rankings. Future research can address this limitation by extending the model using stochastic or dynamic DEA approaches that incorporate probabilistic demand variation, time-dependent resource allocation, and uncertainty in economic and environmental parameters.

[3]University of Applied Sciences and Arts Northwestern Switzerland, Muttenz, Switzerland

Abstract

Digital Fabrication (DFAB) proposes to increase productivity and digitalisation in Architecture, Engineering and Construction (AEC). Demonstrator projects are used to showcase novel DFAB innovations to disseminate knowledge, learning, and attract future investment to support their transfer from research to commercialisation. Currently, no unified definition of what constitutes a DFAB demonstrator in AEC exists, thus, this paper aims to address that. This offers distinction to the phenomenon reflecting its real-world context, subsequently effecting how humans think and act on it. A definition is proposed based on analysis from literature and interviews to inform future studies on DFAB demonstrator projects in AEC.

Introduction

Architecture, Engineering and Construction (AEC) is the world's largest industry by share of gross domestic product. However, it is also ranked as one of the lowest in terms of productivity and digitalisation (Ribeirinho *et al.*, 2020). The complexity of AEC sets it apart from other industries (e.g., manufacturing, automotive) due to the individuality of each built asset's design and construction needs based on unique (site) conditions and stakeholder requirements (Garcia De Soto *et al.*, 2018). One systemic innovation proposed as a solution to increase productivity and digitalisation in AEC is Digital Fabrication (DFAB). DFAB is pushing the boundaries of creativity, design and construction of the built environment and is seen as a building block of realising the digital transformation of AEC into Construction 4.0 (Graser, 2023). Examples of DFAB in practice include the MX3D Printed Bridge, a robot printed steel structure once located in Amsterdam's Red Light District in the Netherlands (Figure 1); and DFAB House, the world's most comprehensive demonstration of DFAB in the AEC domain (Figure 2).

DFAB is "*a fabrication or building process driven by the seamless conversion of design and engineering data into fabrication code for digitally controlled tools*" (Gershenfeld, 2012, cited in Kaseman and Graser, 2020, p. 189). A relatively new field of innovation, DFAB was initiated to AEC in Japan in the 1980s with the deployment of robotics systems to automate and standardise the construction of buildings (Kaseman and Graser, 2020). It is described as a system-level innovation

Figure 1: MX3D Printed Bridge, Amsterdam, The Netherlands (Arup, 2025)

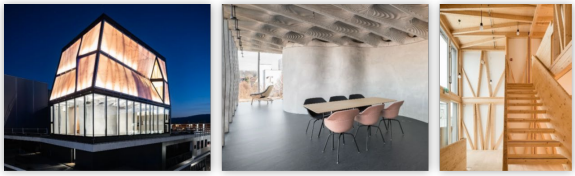

Figure 2: DFAB House, Dübendorf, Switzerland (Graser, 2023)

that combines digital design with advanced manufacturing technologies to automate construction activities and enhance the quality of built assets (Ng, Graser and Hall, 2023). Today, it is seen as a potential solution to solve some of the AEC industry's most pressing issues, such as the need to build more sustainably (Khadim *et al.*, 2023), increase productivity in light of a stagnant workforce (Mischke *et al.*, 2024), and increase digitalisation (Alsharef *et al.*, 2024) to increase efficiency. Digital technology adoption has been found to have positive effects on economic, social and environmental performance (Li *et al.*, 2022).

Despite the positive outlook for DFAB, is has yet to achieve mainstream adoption across the AEC industry due to a "*large gap between research feasibility and industry adoption*" (Graser, Kahlert and Hall, 2021, p. 853). This gap is often related to socio-technical factors such as business models and processes, integration into existing practices, product architecture and organisational structures (Graser, Kahlert and Hall, 2021). Ng et al. (2022) offer several reasons for this including the need for a new level of systemic thinking to seamlessly integrate the design and construction processes that requires "*more detailed knowledge, participation, and computation than*

traditional craft production", and the lack of understanding of DFAB as a "*standardized process or an integrated digital system*" (Ng *et al.*, 2022, p. 1).

Demonstrator projects

Demonstrator projects are one way the prevailing challenges of integrating DFAB into AEC praxis are being addressed. They constitute a phase in technology development that provides a vehicle to showcase technologies, methods and processes beyond the research boundary to attract interest and further investment with the goal of transferring innovations to industry and commercialisation. Moultrie (2015) describes demonstrator projects as *boundary objects* acting as a mediator between different social actors. They typically embody some level of risk (e.g., technical, production, commercial, operational), and require substantial investment (Aaron and McGill, 2012). They are receiving increasing attention as evident in literature where many demonstrator projects are published (e.g., in the FABRICATE series whose focus is on the integration of digital design and manufacturing processes (FABRICATE, 2025); and international exhibitions such as the International Architecture Exhibition, established in 1980 as part of La Biennale di Venezia, that showcases some of the world's cutting edge architectural solutions to address the most pressing challenges seen in society and the built environment (La Biennale di Venezia, 2024)). Despite their growing application to demonstrate the potential of new technologies, methods and processes, demonstrator projects are often discussed as failures as vehicles to facilitate transfer of innovations from research to industry (Sjöö and Frishammar, 2019), and there is limited literature on the objective, types and designs of demonstrator projects (Bobbe *et al.*, 2023). In addition, their focus is often on technical feasibility but omits the social aspects that are required for the success of a new innovation (Graser, 2023; Preston, Sujan and Habli, 2025).

Despite these challenges, application of demonstrator projects in the development of new technologies including DFAB is increasing. They are an effective method of exploration, their implementation increases acceptance (if not yet adoption) of DFAB in AEC, and they are instrumental in the establishment of a new praxis for DFAB (Graser, 2023). Given this growing attention, this paper aims to provide a comprehensive definition for demonstrator projects in the domain of DFAB in AEC. It does so by evaluating current understanding of demonstrator projects generally through literature, and engages with researchers and practitioners of DFAB in AEC specifically. Providing a useful definition is an important step in enhancing understanding of demonstrator projects' philosophical role for DFAB in the AEC community. Definitions provide "*distinctions that mirror common language use and real-world phenomena while paying special attention to context and implications*" (Mitcham and Schatzberg, 2009, p. 27). The act of "*sorting out, classifying, and defining […] remain fundamental to human acting and thinking*" (Mitcham and Schatzberg, 2009, p. 56). The research question for this paper is therefore: *How do we define demonstrator projects for DFAB in AEC to enhance understanding of their purpose in the transfer of DFAB innovations from research to commercialisation?*

The remainder of this paper is structured as follows: the next section presents the methodology adopted for this paper, then definitions for demonstrator projects are presented. Following analysis, a comprehensive definition for DFAB demonstrator projects in AEC is proposed and its implications discussed. Finally, the paper is concluded.

Methodology

As there is little literature available on the topic of demonstrators and even less on demonstrators in DFAB for the AEC industry, this research adopts an interpretivist epistemology to uncover new theory around the practice of demonstrators. The study adopts a qualitative research enquiry that engages with researchers and practitioners with experience of demonstrators in DFAB. The steps taken to conduct this study are shown in Figure 3.

Figure 3: Methodology

First, a traditional literature review was conducted to identify any existing definitions of demonstrator projects in DFAB and beyond. The criteria for selecting papers included: demonstrator projects as the main subject of the paper, inclusion of a definition of demonstrator projects, and related to the production of something physical (i.e., this study is not concerned with software demonstrations). Then, semi-structured interviews were conducted with participants of the DFAB House demonstrator to understand what they believed their notion of the purpose and effects of a demonstrator to be. The interviews were conducted as part of a wider longitudinal study of DFAB House and to establish a methodology for DFAB demonstrator projects in AEC. However, the scope of this paper is concerned only with defining demonstrators and, therefore, only one question related to this subject is included here: *How do you define a demonstrator project in the context of DFAB in AEC?* DFAB House was chosen as the case study as the most comprehensive representation of the use of DFAB in AEC to date (Graser *et al.*, 2020). DFAB House combines six different DFAB objects as a demonstration of some of the leading advances in DFAB showcasing its feasibility and potential to the global community.

The sample included eight academics and one client (specific roles can be seen in Table 1), selected for their work on DFAB House during its design, development and/or construction, and because some were previously interviewed for a study on DFAB House shortly after its completion as they form part of the longitudinal study. The interviews were recorded and transcribed in Microsoft Teams and the interviewees were asked to approve the transcript post processing. Relevant

Table 1: Definitions of demonstrator projects in literature

#	Reference, domain	Definitions
R1	Aaron and McGill (2012), defence/public services	"short term projects (or project activities) that help demonstrate the level of maturity of technologies in support of capability management decisions" (UK Ministry of Defence cited in Aaron and McGill, 2012, p. 2).
R2	Bobbe et al. (2023), Internet of Things (IoT) and robotics	"(a) an embodiment or representation, (b) of a hypothesis about the future and (c) that is communicated to a specific audience" (p. 4); "an artefact which is created during the scientific process to support science itself, but also the dissemination and communication of it" (Moultrie, 2015, cited in Bobbe *et al.*, 2023, p. 2).
R3	Graser (2023), AEC	"tools of digital fabrication research and development: Demonstrator projects implemented on the construction scale span the boundaries of research and implementation practice, usually focusing in-depth on a single building system or fabrication technology" (p. 7).
R4	Husain, Wehrmeyer and Reeby (2023), demonstrator projects	"the process by which new thinking is tried and tested at scale and proactively communicated to target audiences, in order to improve processes, products, and services" (p. 32).
R5	Karlström and Sandén (2004), fuel cells and hydrogen supply systems for public transport vehicles	"a finite initiative to test hypotheses about a technology" (p. 287); "a finite initiative to test a technology according to the project objectives. […] The project starts with a conceptual design and by deciding project objectives. It ends when the technology is implemented and the results are evaluated and communicated" (p. 287).
R6	Moultrie (2015), design	"technological prototypes which are close to market" (p. 2).
R7	NASA (2023), space exploration	TRL 6: "System/sub-system model or prototype demonstration in an operational environment"; TRL 7: "System prototype demonstration in an operational environment".
R8	Sjöö and Frishammar (2019), sustainability transitions	"'technological infrastructures' often intended for multiple uses by a number of actors (rather than being geared towards one firm)" (p. 331); "they 'bridge' basic and small-scale knowledge generation in laboratories with large-scale industrial application and commercialization" (p. 331).
R9	Stelvaga and Fortin (2022), aerospace	"a project devoted to the development of a functional piece of technology with the goal of showing its capabilities" (p. 275).
R10	Sviridova and Verlinden (2023), product development and industrial design	"at least a partially physical one-off design object that facilitates the interests of designer, client, user, and technology, and communicate them to the audience in an interactive way" (p. 950).

responses to the question asked above were extracted and put into a table to allow for coding and content analysis to be performed along with analysis of the definitions found in literature. This consisted of finding recurring terms and phrases across both sets of definitions as well as identifying any terms and phrases that are applicable. The terms and phrases were then examined to establish whether they were indeed relevant for the domain of DFAB in AEC and the results were formulated into a comprehensive definition.

Defining demonstrator projects for DFAB in AEC

Finding a unified definition for DFAB demonstrator projects is challenging, in part because many projects have the intention of 'demonstrating', e.g., a new method or process (Husain, Wehrmeyer and Reeby, 2023), but they are not necessarily a demonstrator project per se. For example, a prototype project can be used to demonstrate something but the scale of development cannot yet be considered a demonstrator project. In current literature, terms are often interchangeable, such as in Wang, Hunhevicz and Hall (2025) who refer to both demonstrator and prototype, without clearly defining either; the Rijksdienst voor Ondernemend Nederland (the Netherlands Enterprise Agency) (RVO, 2025) indicates use of the Technology Readiness Levels (TRLs) system and refers to demonstration of a prototype (TRL 7), which mixes terms; and often demonstrators are not defined by papers that write about them, which could mean a) authors assume the concept is understood by the reader, or b) the authors are unsure themselves of how to define them.

The literature review conducted for this study found only one paper with a definition in the context of AEC. To supplement this, definitions were found in papers from other domains bringing the total to 10. The definitions along with the domain to which they belong can be seen in Table 1.

To ensure the study's ability to position demonstrators specifically in DFAB in AEC, interviews were conducted with people who had been involved in the DFAB House project. The participants responses are shown in Table 2.

Analysis and discussion

Across these two sets of definitions, there are several recurring themes that appear to be relevant to formulating a comprehensive definition for DFAB demonstrator projects in the AEC domain. Relevance was determined

Table 2: Direct quotes from interview participants on the definition of demonstrator projects for DFAB in AEC

Interviewee	Definitions
P1: project manager	"the use of a digital or digital fabrication technology, or method, on the full scale, meaning the scale of buildings, and I think it needs to be in an environment that resembles the process of construction"; "in the technical sense, a demonstrator is usually something you do once the technology is already at a certain [TRL] level and the demonstrator is basically your final proof".
P2: researcher	"the demonstrator is one way to prove the feasibility of a certain approach, maybe a technological methodology or a complicated workflow"; "first and foremost, geometric scalability".
P3: researcher	"an attempt to show that this is not just an academic exercise, and that there is the possibility to do something with a meaningful scaling"; "it has to leave the lab, but it can be produced in the lab".
P4: client	"takes technology, systems, materials, concepts from a laboratory level to a near market level".
P5: PI	"a real world installation involving the outcomes so that the finished research is demonstrated"; "something that goes beyond the function of a demonstrator; it is actually something that demonstrates by using the research outcomes"; "it would ideally be something that is then also in use"; "the confrontation of research with the real world scenario"; "a demonstrator should be out of the lab".
P6: PI	"an attempt to benefit from the challenges of transferring research to application very early on in research by actually making the full scale application of digital fabrication".
P7: PI	"it needs to be enough to leave the lab"; "there is an expectation to the outcome that is beyond only demonstrating literally a new technology, so that you add the challenge of giving it a function, either a more infrastructural and architectural and engineering kind of function perhaps"; "the threshold of a demonstrator project: did you have to face the real conditions? So even though the client is set up, even the budget might be not typical, but at least all the other aspects like building codes and stuff like that"; "demonstration is challenging your concept to a real scale".
P8: member of NCCR DFAB (role hidden to maintain anonymity)	"It's a demonstration of the innovation that you've created, but it's also a demonstration that you or the surrounding team around you know how to make that thing and make it ready for the real world"; "a demonstrator is a proof-of-concept, whereas a prototype is a development of an idea. A prototype is a working document, and a demonstrator is the document itself, it's the finalised version of the document"; "in DFAB, a demonstrator has industry partners working on it. That's a major difference between a prototype and a demonstrator, that you engage people who are going to learn from this demonstration already in the making of the demonstrator".
P9: member of NCCR DFAB (role hidden to maintain anonymity)	"a demonstrator project is whether it's with or without industry, but usually it's with industry, is that you upscale from the lab scale to the real scale, to the one-to-one construction site scale. And demonstrator project means actually to demonstrate that all the processes work out at the larger scale"; "to demonstrate that all the processes can work in reality given the building codes and other constraints".

by frequency of occurrence (set as a minimum of two) as well as recognition of importance from the authors based on their knowledge and experience of the topic. The results of the coding process are shown in Table 3 ordered in terms of frequency.

While many of the definitions from literature are specific to the subject of the individual publication, the material aspects of them can be applicable to other fields, i.e., AEC. The interviewees' definitions are more specific to the AEC context, but could equally be applicable outside of that if reference to, for example, buildings and the construction site are removed. The themes are described below in order of frequency as they appear in Table 3, not necessarily in order of importance.

Scale: many of the definitions explicitly refer to the scale of the demonstrator project mentioning full- or one-to-one scale. This scaling is what provides the technology, method or process the experiential learning of transitioning outside of the laboratory context, such as the requirements to move from research to production at scale for mainstream adoption and commercialisation.

Environmental context: demonstrators take place in an environment that exposes the potential innovation to real-world risks and challenges that cannot be experienced in a laboratory including but not limited to permitting, regulations, and site conditions.

Maturity and readiness: demonstrators provide an opportunity to demonstrate readiness of a technology, method or process, as well as an opportunity for learning during the project. The project forces the concept to be implemented in a real-world context that it has not yet seen in the laboratory. Thus, a concept may increase its maturity and readiness through the demonstrator process.

Inter- or trans-disciplinarity: as a boundary object, demonstrators bring different disciplinary actors together to co-create. At some point in the project, all parties contribute to the production of an artefact and through doing so contribute to the knowledge created and learning

Table 4: Coding of literature and interview definitions of demonstrators

Code	Occurrence	Frequency
Scale	R3 R4 R8 P1 P2 P3 P5 P6 P7 P9	10
Environmental context	R3 R7 R8 P1 P3 P5 P6 P7 P9	9
Maturity and readiness	R1 R6 P1 P2 P4 P8	6
Inter- or transdisciplinary	R3 R8 R10 P8 P9	5
Communication and dissemination	R2 R4 R5 R9 R10	5
Functionality	R8 R9 P5 P7	4
Novelty	R4 R10 P7	3
Social feasibility	R4 P7 P9	3
Temporality	R1 R5	2
(Hypothesis) testing	R2 R5	2

experienced. The level of disciplinarity often occurs at the higher end of the disciplinarity scale i.e., interdisciplinary or even transdisciplinary projects. This inevitable collision of social groups often occurs at the boundary between research and industry.

Communication and dissemination: demonstrators have the purpose of communicating and disseminating knowledge, learning and level of maturity of the technology, method or process beyond the project team to interested industry practitioners and potential future investors.

Functionality: demonstrators should produce something that has some level of functionality or use beyond the end of the demonstrator project (i.e., the construction phase of the demonstrator) that proves its utility in the real world over a (defined) period of time.

Novelty: a common theme across the definitions is novelty, that what is being demonstrated is offering something new to complement or replace existing praxis, or establish new praxis.

Social feasibility: the focus of demonstrators tends to be on the technical feasibility and often omits the social feasibility. However, as a boundary object, demonstrators force project participants to communicate outside of their day-to-day environment by considering the organisational context, business model(s) and process(es) of implementing a new technology, method or process along with any changes required to current operations.

Temporality: demonstrator projects are short term and finite endeavours.

(Hypothesis) testing: testing is central to demonstrator projects to test hypotheses about research and its ability to meet the project's objectives across many of the themes discussed above, such as scale, readiness, context and feasibility.

Based on the analysis here and the recurring themes identified across the definitions from literature and the interviews, the following definition for demonstrator projects in DFAB in the AEC domain is proposed:

> *Digital fabrication (DFAB) demonstrator projects in Architecture, Engineering and Construction (AEC) are finite endeavours of co-creation to materialise the maturity and readiness of a novel technology, method or process. This is done through production and testing of a functional artefact at full scale in a realistic, non-laboratory-based, construction-specific environment.*
>
> *A demonstrator project spans the boundaries of research and industry to generate knowledge of technical and social feasibility for active communication and dissemination to parties beyond the project team. The goals are to inform industry of the potentials of DFAB, and attract investment for future development to achieve transfer to commercialisation.*

To answer the research question: *How do we define demonstrator projects for DFAB in AEC to enhance understanding of their purpose in the transfer of DFAB innovations from research to commercialisation?*, this paper has collected definitions from literature across different sectors (due to a lack of definitions from within the AEC domain) and from AEC-specific researchers and practitioners to establish what the key aspects of DFAB demonstrator projects in the AEC industry are. This has ensured the definition proposed here encompasses the most important aspects of demonstrator projects to provide a comprehensive and useful definition to enhance understanding within research and outward to industry practitioners. In line with Mitcham and Schatzberg (2009), such a definition is important in the discourse on demonstrator projects for DFAB in AEC because definitions offer a distinction to a phenomenon that reflects its real-world context, that can then effect how humans think and act on it. While acceptance of a unified definition remains the longer-term goal for DFAB demonstrator projects in AEC, we propose here a definition designed to be immediately useful across disciplinary contexts and argue that such practical utility is a necessary condition for any definition to eventually achieve wider adoption.

The definition can solidify the purpose of conducting demonstrators for researchers and practitioners by understanding how they fit into the wider process of technology development. What comes before and after a demonstrator project is as important as the demonstration itself to ensure its success. This definition both enhances understanding of DFAB demonstrator projects and encourages a more holistic approach to the development of DFAB in AEC. This is particularly important if we approach it from a *needs* perspective. In a "push" scenario where academia is developing a new DFAB technology, it can support them in their efforts to seek industry buy-in. In an industry-led "pull" scenario where industry is proposing a technology to solve an industry issue, the definition can support them in seeking validation in collaboration with research.

Finally, highlighting that a demonstrator project is a process of co-creation encourages researchers and industry to focus collaboratively on this transitionary phase of technology transfer and the mechanisms required for it to be successful.

Conclusions

DFAB is a growing systemic innovation that could contribute to solving some of the AECs most pressing issues such as needing to build more sustainably and increase productivity and digitalisation. However, DFAB requires new systemic thinking to address some of its barriers to adoption, compounded by lack of a unified understanding of DFAB. One phase in the trajectory of technology development is demonstration to support the transfer of DFAB innovations from research to commercialisation. Demonstrator projects are still relatively new in the diffusion of innovations and as a result there is little academic discourse on the subject. This paper is part of a wider study to look at how demonstrators take place, how they create learning, how they play an important part of the research process in DFAB, and how they can be used to increase the transfer of innovations from research into industry and commercialisation. The aim of this paper was to define the role of demonstrators for DFAB in the AEC industry that will form the basis for the wider study, that is to develop a methodology for DFAB demonstrator projects in AEC.

The paper identified several definitions of demonstrator projects in literature, only one of which came from the AEC domain. These were supplemented by interviews with researchers and a client for the DFAB House project. These definitions were analysed and a comprehensive definition for DFAB demonstrator projects in AEC was proposed. This definition can provide a distinction to the phenomenon of DFAB demonstrators that can effect how humans think about and act on it. It is hoped that this definition will provide some consistency for DFAB in the AEC industry to support its understanding as a viable stage in technology development across research and industry and form the basis for a unified definition in the future.

Limitation and future research

While the wider study is a work-in-progress, this paper is limited by the small sample size and skew of interview participants toward the side of research, as opposed to providing a balanced view with the inclusion of more industry practitioners. This will be addressed in the next steps of the study by conducting further interviews with academics and industry practitioners with demonstrator experience, to evaluate the success of demonstrator projects using DFAB House as a case study, and to formulate a methodology for conducting DFAB demonstrator projects in AEC that can a) support students and researchers in their endeavours to innovate in DFAB, and b) support practitioners with the transfer of those innovations to industry and commercialisation.

Acknowledgments

This project was funded by the Swiss National Centre for Competence in Research (NCCR) Digital Fabrication.

[1] The Hong Kong University of Science and Technology, Hong Kong SAR, China
[2] Southeast University, Nanjing, China

Abstract

While modularization techniques can reduce installation complexity and improve the efficiency of MEP projects, existing approaches predominantly focus on static constraints and overlook the dynamic environmental interactions in assembly process. Addressing these challenges, this paper developed an MEP installation optimization framework integrating DSM-based module division and a simulation-based feedback mechanism. The framework extracts IFC data for dynamic modeling, clusters elements into modules, and employs a feedback loop to optimize installation sequences. Validated on a real-world project, the system successfully generates collision-free kinematic paths and significantly reduces installation costs, demonstrating enhanced efficiency and constructability for MEP systems.

Introduction

Mechanical, Electrical, and Plumbing (MEP) systems are essential in building systems, providing essential services to maintain a comfortable environment (Wang et al., 2025). However, the installation of these systems is challenging due to their inherent complexity, characterized by high component density and intricate spatial layouts (Lee, 2014). Consequently, the installation constructability of MEP systems, defined as the ease and efficiency of installation, has become a critical determinant of overall project constructability (Wang et al., 2016). The successful installation of MEP systems within pre-existing building structures relies heavily on a robust installation plan (Wu et al., 2022), specifically the precise sequencing and path planning of components. Suboptimal installation sequences often lead to on-site congestion and spatial conflicts (Yan et al., 2024), severely compromising construction efficiency. Therefore, developing an automated system to optimize the installation plan is imperative for enhancing MEP constructability.

To mitigate the inefficiencies and installation difficulty in traditional on-site MEP installation, off-site modular construction and multi-trade integrated MEP (MiMEP) has been widely adopted in MEP project. This approach divides the MEP system into different modules, then pre-fabricates and pre-installs the module to reduce the on-site installation (Zhao et al., 2026), thereby enhancing the installation constructability. For MiMEP, the installation plan includes determining the module division and determining the installation sequence and path for each module. However, the granularity of module division (i.e., module dimension and quantity) critically dictates the feasibility of the delivery path (Zhao et al., 2024). Determining the optimal module division remains a significant challenge, as it must balance the benefits of prefabrication against the rigorous spatiotemporal constraints imposed by the constructed environment.

Existing matrix-based methodologies have demonstrated significant efficacy in MEP modularization. For example, Samarasinghe et al. (2019) utilized the Dependency Structure Matrix (DSM) to quantify the interaction strength between MEP components, which effectively clusters MEP elements into cohesive modules. However, current module division methods predominantly prioritize static physical constraints, such as stiffness, structural integrity, and weight. Consequently, these methods often fail to adequately account for the dynamic environmental interactions inherent to the installation process, specifically overlooking critical factors like transportation trajectories and evolving spatial availability.

Furthermore, current research usually formulates the MEP installation sequences schedule as a mathematical optimization problem to determine optimal sequence. For instance, Yin et al. (2024) modeled the sequencing task using mixed integer linear programming (MILP), aiming to minimize potential spatial conflicts. However, such approaches often overlook the reciprocal influence between the installation sequence and the dynamic site environment, which fails to consider how an installed module alters the feasible path planning for subsequent components. Moreover, these methods typically lack a quantitative framework for evaluating installation costs and efficiency. Therefore, integrating 4D simulation into the optimization framework is necessary, as it provides a dynamic testbed that can rigorously capture the evolving spatiotemporal environment, ensuring that the continuous changes in site constraints are fully accounted for during sequence planning.

For the implementation of 4D simulation, the Robot Operating System (ROS) has emerged as a predominant platform. It offers a robust ecosystem featuring advanced physics engines and modular libraries that enable high-fidelity modeling of kinematic interactions and collision dynamics (Kim et al., 2021). While recent studies have

successfully demonstrated the conversion of building information modeling (BIM) data into ROS environments for general construction simulations (Liang et al., 2025), research specifically targeting the complex domain of MEP systems remains limited. Furthermore, given that MEP optimization inherently involves evolving spatiotemporal constraints, there is a distinct lack of a unified framework that effectively integrates 4D simulation with the dynamic constraint management required for the MEP installation process.

Addressing this contextual backdrop, this paper proposes a two-stage MEP installation optimization framework that integrates DSM-based module division and 4D simulation. The system aims to generate optimal installation sequences and collision-free kinematic paths, thereby maximizing constructability within the dynamic on-site environment.

Methodology

To enhance installation constructability through precise sequence planning, this study proposes a comprehensive MEP installation optimization framework driven by 4D simulation, presented in Figure 1. The methodology comprises three integral steps: 1) Dynamic environmental modeling, this step extracts constructability-related data from IFC files to instantiate a physics-based 4D simulation environment within the ROS; 2) MEP module division, a DSM-based approach is employed to decompose complex MEP systems into discrete, manageable modules, thereby facilitating off-site prefabrication and on-site assembly. 3) Installation sequence optimization, the optimal installation sequence and kinematic paths are determined via a two-stage optimization algorithm with feedback mechanisms.

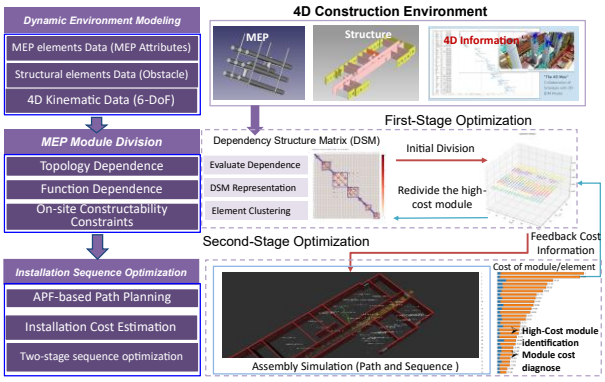

Figure 1: MEP Installation Optimization Framework

Dynamic environment modeling for MEP installation

To address the complexities of the dynamic construction environment, this study establishes a high-fidelity kinematic model (Robot Operating System, ROS) of the dynamic environment, which can precisely simulate the installation trajectories of MEP components to calculate installation cost and analyze sequence conflicts, thereby supporting subsequent optimization of installation paths and sequences. The establishment of dynamic environment involves two steps: (1) Extraction of Constructability-related Information from IFC data, and (2) Establishment of kinematic simulation environment within ROS.

Extraction of Constructability-related information from IFC data

To facilitate the precise extraction of constructability-related data for MEP installation, the IfcOpenShell library is employed to parse the BIM data in Industry Foundation Classes (IFC) files. Table 1 summarizes the specific instances of the MEP and structural elements extracted to support the optimization process. The study focuses on four fundamental categories of MEP elements: segments, fittings, controllers, and terminals. These categories encompass the primary components of MEP systems and provide a sufficient basis for analyzing and enhancing installation constructability. Additionally, structural elements, specifically entities under IfcBuildingElement, are extracted and treated as static obstacles (i.e., spatial constraints) during the installation process.

Table 1: Constructability-related IFC Information

Element	Entity	MEP Instance
MEP Element	IfcFlowSegment	IfcPipeSegment IfcDuctSegment IfcCableSegment
	IfcFlowFitting	IfcPipeFitting IfcDuctFitting IfcCableFitting
	IfcFlowController	IfcValve IfcFlowMeter IfcSwitchingDevice
	IfcFlowTerminal	IfcAirTerminal
Structural Elements	IfcBuildingElement	IfcWall IfcColum IfcBeam IfcSlab

To support dynamic modeling, the constructability-related information for each MEP element (the target of the optimization) is categorized into three distinct domains:

1) Geometric Information: The geometric configuration and spatial positioning of MEP elements are prerequisites for developing the assembly kinematics model used in installation simulations. The shape representation of each element is derived from IfcShapeRepresentation and stored as a triangulated boundary representation (B-Rep). Furthermore, the position of each element is retrieved from IfcObjectPlacement and transformed into a unified global coordinate system by traversing the relevant chain of local coordinate systems.

2) Production Information: This domain encompasses critical fabrication and installation attributes, including material type (e.g., galvanized steel, PVC), assembly method (e.g., flange, weld), and element weight. These attributes significantly influence the complexity of MEP

installation. For instance, modules requiring heterogeneous assembly methods necessitate frequent switching between different tooling or processes on-site, thereby increasing installation difficulty. Regarding data extraction, material types are queried from the IfcMaterial of the associated entities, while assembly methods are derived from specific property sets (e.g., Pset_DistributionPortTypeDuct) attached to IfcDistributionPort. Additionally, element weights are retrieved directly from IfcQuantityWeight.

3) Functional Information: This category defines the functional classification of an MEP element and its functional-related elements. The functional classification of the element identifies the specific purpose of an element (e.g., pipe system or duct system) and is used for clustering elements based on their utility. This information is extracted from the PredefinedType attribute (e.g., IfcDuctSegmentTypeEnum) of the respective IFC entities. Furthermore, the functional-related elements refer to the connected elements to ensure the systemic functionality, which can be derived from IfcRelConnectsElements or IfcRelFlowControlElements of the associated entities.

Establishment of Simulation Environment for Path and Sequence Planning

To develop the simulation test platform, the extracted IFC information is instantiated within the ROS environment (Figure 2), which defines the boundary specifications (obstacles) and environmental constraints necessary for MEP elements installation. The ROS environment provides a physics-based computational framework that enables spatiotemporal optimization of construction sequences and installation path planning under dynamic on-site environmental constraints.

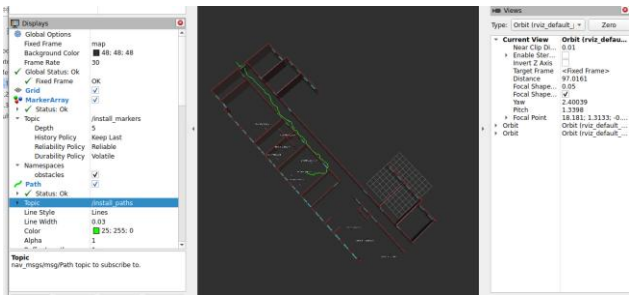

Figure 2: Interface of ROS

The configuration of ROS for 4D installation optimization includes 3 parts as follows:

1) Static Environmental Constraints: Structural elements (e.g., columns, beams, and slabs) completed prior to the MEP phase are instantiated as static rigid bodies. These elements serve as hard constraints, explicitly delineating the occupied volumetric space that must be avoided during the operation.

2) Traversable Space Definition: The system identifies architectural openings, such as corridors, doors, and windows, to define the navigable volume. This volume maps the available free space designated for the logistical transport of MEP components.

3) Configuration Space Configuration: By integrating the static structural data with the traversable volume, the environment establishes a collision-free configuration space. This representation serves as the foundational input for subsequent path planning algorithms, ensuring that any generated trajectory strictly adheres to the physical realities of the partially built structure.

MEP Model Division considering constructability constraints

To mitigate the inefficiencies inherent in traditional on-site MEP installation, off-site modular construction has been widely adopted. This approach decomposes complex, large-scale MEP networks into discrete, manageable modules. These modules are pre-assembled in a controlled off-site environment, thereby reducing on-site operations to relatively simple inter-modular connections. However, determining the optimal division (i.e., quantity and dimensions) of these modules presents a significant challenge, particularly given the spatial constraints imposed by the on-site constraints. The module division strategy critically impacts both assembly cost and installation complexity; therefore, the system must be divided to minimize complex on-site assembly operations.

To obtain the optimum module division, this study develops a dependence structure matrix (DSM)-based framework for module division and facility the module installation. The DSM-based method uses a matrix represent the dependence (i.e., interaction strength) of each MEP elements and cluster the high-dependent elements into a cohesive module. The framework comprises two primary stages: (1) Evaluation of MEP element dependence in DSM; (2) Module division considering on-site constraints.

Evaluation of MEP element dependence in DSM

The interdependence of the MEP elements is depicted in matrix form using DSM, which identifies the clusters of the elements have stronger inner interactions by mapping the interaction between elements in the system. DSM typically has a square symmetric matrix, where the diagonal axis of the matrix represents the elements and off-diagonal points represent the dependent value of one element with another.

The dependence values are estimated based on Eq. (1), which includes two components i.e., the topology dependence and function dependence. The detailed indexes for dependence estimation is shown in Table 2.

$$d = d_{Topology} + d_{Function} \quad (1)$$

Module division considering on-site constraints

The module division phase employs a Constrained Agglomerative Clustering algorithm to group MEP elements into different modules. This process is governed by a greedy optimization strategy as the following stages:

1) Prioritization via Greedy Strategy: To maximize intra-module cohesion, the algorithm prioritizes element pairs with the strongest coupling. All elements (D_{ij}) in the DSM are sorted in descending order based on their dependent value. This ensures that elements with the highest

Table 2: MEP elements dependence evaluation

Dependence type	Index	Description
Topology Dependence	Connectivity Constraint	If two elements are physically connected (i.e., sharing a common flow port or joint), the dependency $d_{Topology}$ score is incremented by 1.
	Adjacent Elements	To account for potential spatial clustering, the $d_{Topology}$ score is incremented by 1 if the Euclidean distance between two elements is less than a predefined threshold of 0.5 meters.
	Loop Integrity	If elements constitute a closed-loop sub-system or a local hydraulic cycle (e.g., bypass piping loops, valve manifolds), their $d_{Topology}$ score is incremented by 1 to preserve the integrity of these functional groups during modularization.
Function Dependence	Homogeneity	The $d_{Function}$ score is increased by 1 if the pair of elements belongs to the same IFC entity class or functional category, ensuring consistency in component handling.
	Process Compatibility	The $d_{Function}$ score is incremented by 1 if the elements share identical connection mechanisms or assembly interfaces (e.g., flange-to-flange connections)
	Operational Coupling	The $d_{Function}$ score is incremented by 1 for element pairs exhibiting operational interdependency

topological and functional dependencies are evaluated for merging with higher priority.

2) Cluster Aggregation Process: Initially, each MEP element is treated as a discrete singleton cluster. The algorithm iterates through the sorted dependence value. For any two distinct clusters with high dependence value, a tentative merge operation is initiated to form a potential candidate module.

3) Dynamic Constraint Verification: Before finalizing the union of two clusters, the candidate module must pass a rigorous feasibility check to ensure compliance with on-site limitations (e.g., logistics and installation), which is shown in Table 3. The Union operation is executed if and only if the candidate module satisfies all constraints. If a constraint violation is detected, the merge is rejected, and the clusters remain independent to prevent the formation of infeasible super-modules.

Installation Sequence Optimization with feedback mechanism

While off-site modularization significantly mitigates on-site complexity, overall construction efficiency and cost remains critically sensitive to the assembly sequence. A suboptimal sequence often leads to spatial conflicts, where previously installed components obstruct the feasible installation trajectories of subsequent modules. To address this, this study implements a two-stage optimization strategy, it utilizes the Artificial Potential Field (APF) method for path planning, integrated with a feedback mechanism that triggers module redivision when viable paths cannot be found.

Table3: The on-site constraints for module division

Constraint	Description
Dimensional Constraints	The geometric dimensions of each module are validated against the maximum transportable envelope (e.g., $3m \times 6m \times 4m$) determined by project logistics.
Payload Constraints	The cumulative mass of the module must strictly adhere to the rated lifting capacity of the on-site hoisting equipment.
Gravity Stability	The module's center of gravity is constrained to fall strictly within its support footprint to guarantee static stability during hoisting and placement.
Clustering Coefficien	A module should not contain two dense clusters connected solely by a slender or fragile element, which is extremely prone to breakage during transportation.

Formulation of installation optimization

The objective of the optimization is to obtain installation sequence $S = [m_1, m_2, \dots, m_N]$ with lowest total installation cost, where m_i is the module installed in the i-th step. The objective function can be formulated as Eq. (2). The E_{i-1} is the installation environment for i-th step which includes the static structural elements (e.g., walls, columns) and the installed MEP elements in previous i-1 steps. The installation path should satisfy the collision free constraint as Eq. (3) represented, specifically, for each module m_i, a continuous path must exist that remains strictly collision-free with respect to both static environmental obstacles and the cumulative volume of all previously installed modules $(m_1, \dots, m_{i-1})$.

$$Obj: \text{Min } Cost = \sum_{i=1}^{N} Cost(m_i|E_{i-1}) \quad (2)$$

$$Constraint: \text{Path}_{m_1} \cap E_{i-1} = \emptyset \quad (3)$$

To calculate the comprehensive installation cost and improve the installation efficiency, the installation cost for m_i consist of the weighted cost of translation and rotation manipulation ($Cost_M$), the cost penalty for operational difficulty caused by proximity ($Cost_P$), the cost for trajectory smoothness ($Cost_S$), which are shown in Eq. (4).

$$Cost_{m_i} = Cost_M + Cost_P + Cost_S \quad (4)$$

$Cost_M$ is calculated based on the length of the installation path, since rotational manipulation typically incurs significantly higher costs and control efforts compared to translational displacement, a higher weight coefficient is assigned to the rotational cost, which is shown in Eq. (5).

$$\text{Cost}_M = \text{w}_1 T + \text{w}_2 RL \quad (5)$$

Where w_1 and w_2 are the weight for translational cost and rotational cost, respectively, $\text{w}_1 < \text{w}_2$, T is the total amount of translational manipulation, R is the total amount of rotational manipulation (rad), L is the length of the module.

The $Cost_P$ quantifies the operational difficulty imposed by spatially constrained environments (e.g., narrow pipe shafts). Limited space increased the control precision of manipulation and reduced the maneuvering speeds.

$$Cost_P = \int_{p_0}^{p_1} \max\big(0, D_S - \text{D}(p,\text{O})\big)\, dp \quad (6)$$

Where p_0 and p_1 are the start point and end point of the path, respectively, D_S is the safe distance between MEP and obstacles, $\text{D}(p,\text{O})$ is the actual distance between MEP and obstacles.

The $Cost_S$ evaluates the geometric continuity of the trajectory. Even in obstacle-free zones, trajectories exhibiting high tortuosity (e.g., frequent sharp turns or erratic zigzag maneuvers) are operationally inefficient due to the requirement for frequent acceleration and deceleration.

$$Cost_S = \sum_{q=1}^{P} \left|\Delta\theta_q\right| L \quad (7)$$

where $\Delta\theta_q$ represents the turning angle (i.e., the change in heading) between adjacent path segments at waypoint q.

The simulation-based heuristic search algorithm employed to determine the optimal installation sequence in ROS platform. Specifically, the proposed approach adopts a Greedy Strategy with Look-ahead to iteratively select the next module for installation. The procedure for each installation step is detailed below:

1) Candidate Generation: To reduce the search space, a subset of potential candidates is identified from the remaining uninstalled module set, denoted as R. A heuristic filter selects the top- K modules ($CandidateSet \subset R$) based on geometric volume, prioritizing larger modules to resolve major spatial constraints early in the sequence.

2) Feasibility Simulation: For each candidate module $c \in CandidateSet$, a physics-based simulation is executed to verify installation feasibility. The system invokes the path planner (using the Artificial Potential Field method in this study) to generate a collision-free trajectory from the supply point to the installation target, considering the current environmental state (static structures plus previously installed modules). Candidates for which a valid path cannot be generated are deemed infeasible in the current iteration.

3) Cost Evaluation and Selection: The installation cost, $Cost(c)$, is computed for each feasible candidate using the multi-objective metric defined previously (incorporating manipulation effort, safety clearance, and path smoothness). The module yielding the minimum cost is selected as the optimal choicem_i for the current step.

4) Dynamic State Update: Upon selection, the geometry of module m_i is instantiated into the simulation environment and registered as a dynamic obstacle. Consequently, the path planning for all subsequent steps $(i+1)$ must strictly avoid the volume occupied by m_i, ensuring the physical validity of the evolving assembly sequence.

Artificial potential field-based module installation path planning

In this study, the APF algorithm is employed as the core trajectory generator, which provides computationally efficient, real-time motion planning with simple mathematical formulation (Liu et al., 2020). The fundamental objective is to compute a collision-free path for each module from its supply point to the installation target. The supply point refers to the storage location of prefabricated MEP components on the construction site. The installation target is the geometric location of the installing MEP element exported from design model.

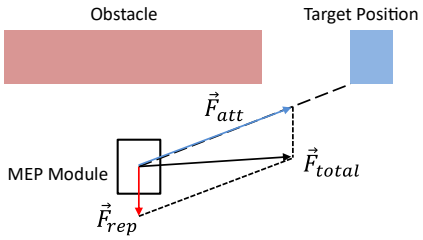

Figure 3: Artificial Potential Field Method

The algorithm conceptually abstracts the MEP module as a point mass moving within a composite virtual force field, driven by the interaction of two distinct potential functions:

1) Attractive Force ($\vec{F}_{att}$) Generated by the target installation position, this force exerts a gravitational-like pull on the module, guiding it towards the destination. The magnitude of the attractive force is typically proportional to the Euclidean distance between the module and the target, ensuring global convergence.

$$\vec{F}_{att} = k_{att} \cdot \left(\vec{P}_{goal} - \vec{P}_{current}\right) \quad (7)$$

Where k_{att} is the coefficient for attractive force.

2) Repulsive Force ($\vec{F}_{rep}$) Generated by obstacles to enforce collision avoidance. The obstacle set comprises static constraints (e.g., structural walls, columns) and dynamic constraints (i.e., the set of previously installed modules). Analogous to magnetic repulsion, these obstacles exert a pushing force that increases exponentially as the module approaches the obstacle boundary (ρ_0), thereby preventing physical intersection.

$$\vec{F}_{rep} = \eta\left(\frac{1}{\rho} - \frac{1}{\rho_0}\right)\frac{1}{\rho^2} \quad (7)$$

Where η is the repulsive gain coefficient.

The motion of the module is governed by the superposition of the attractive and repulsive forces. At each iterative step, the system calculates the resultant force vector acting on the module. The module's position is updated incrementally along the direction of this resultant force (following the negative gradient of the potential field) until it successfully converges at the target coordinates.

$$\vec{F}_{total} = \vec{F}_{att} + \vec{F}_{rep} \quad (7)$$

Feedback high-cost information for module redivision

Suboptimal module partitioning often leads to computational instability during path optimization, manifesting as deadlocks (local minima) or oscillatory trajectories. This typically necessitates excessive manual tuning of stochastic perturbation parameters to achieve convergence. To address this, a closed-loop feedback mechanism is introduced. When a module exhibits an anomalous trajectory, the aggregate navigation cost is decomposed to evaluate the contribution of individual constituent elements within the DSM. An element is identified as a high-cost contributor if it violates specific kinematic or spatial criteria:

Spatial Constriction: The element maintains persistent proximity to obstacles, indicating a clearance bottleneck.

Kinematic Amplification: The element is located at the distal end of the rotation radius, resulting in high linear velocity and an excessive swept volume.

Based on this diagnosis, these high-cost elements are imposed as separation constraints within the DSM to trigger module re-partitioning, followed by a re-optimization of the installation sequence.

Results

Case Description

To rigorously validate the feasibility and robustness of the proposed MEP installation optimization framework, a real-world construction project in Figure 4 was selected as the empirical testbed. This case study represents a large-scale, high-density engineering scenario, comprising 17283 distinct MEP elements and 762 structural entities (e.g., beams, columns, and shear walls). Characterized by its intricate spatial layout and complex topological entanglements, this project presents a significant computational challenge, making it an ideal benchmark to verify the effectiveness of the proposed method in handling high-dimensional combinatorial optimization problems, which need to consider both the module division and installation path.

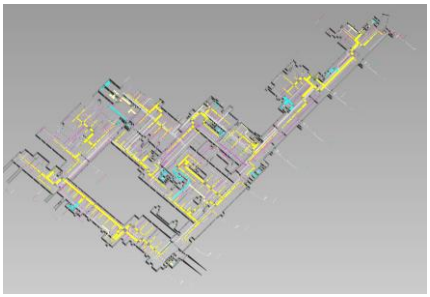

Figure 4: MGY underground parking garage MEP model

Module Division Results

By applying the proposed DSM-based framework which integrates topological dependencies with physical constraints, the 17283 MEP elements in the MEP design were successfully divided into 2564 distinct modules.

To provide a granular visualization of the partitioning efficacy, a representative sub-region comprising 100 contiguous elements was selected for detailed analysis. As illustrated in Figure 5, these elements were algorithmically grouped into 17 modules, where distinct colors denote separate modular assignments. The visualization confirms that physically connected and spatially adjacent components are coherently grouped, ensuring geometric continuity.

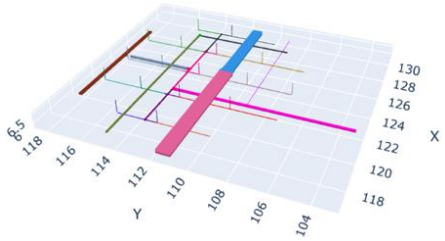

Figure 5: Module division example (100 elements)

The corresponding clustered Dependency Structure Matrix (DSM) is presented in Figure 6. The blue bounding boxes along the main diagonal delineate the boundaries of the identified modules. The heatmap reveals a distinct block-diagonal structure: high-dependency interactions (indicated by darker red hues) are concentrated within the modules, signifying strong intra-module cohesion. Conversely, the sparse distributions outside the diagonal blocks indicate minimal inter-module coupling, validating the algorithm's effectiveness in minimizing complex on-site connections.

Optimization Results

Following the initial module partitioning, the proposed two-stage optimization algorithm was employed to determine the globally optimal installation sequence. Figure 7 illustrates the generated optimal trajectory for a representative module. Crucially, the simulation environment is dynamic; modules scheduled earlier in the sequence are instantiated as static obstacles, thereby

enforcing strict spatiotemporal constraints on the current path planning task.

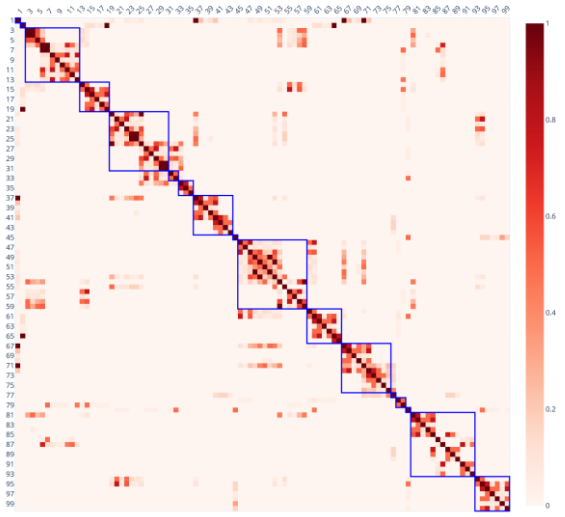

Figure 6: DSM heatmap and element dependence (100 elements)

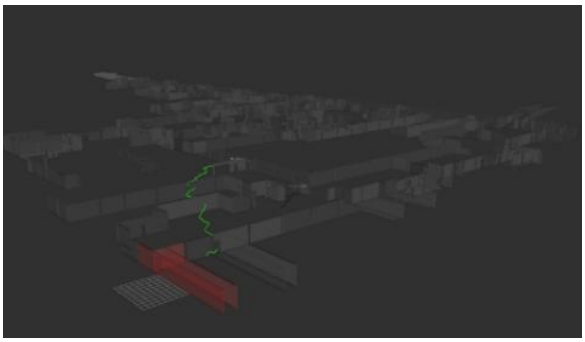

Figure 7: Module installation path diagram

Figure 8 presents the optimized installation sequence and corresponding installation costs for the initial 20 MEP modules. To ensure the installation robustness, the kinematic anomalies of the paths are identified through oscillatory motions detection (i.e., repetitive back-and-forth movements), which is highlighted in red in Figure 8.

These identified anomalies necessitate further optimization via the feedback loop. As illustrated in Figure 9, such kinematic instabilities (e.g., zig-zag trajectories) are often attributed to suboptimal module division, specifically inappropriate module dimensions. The feedback mechanism is utilized to identify high-risk elements that contribute disproportionately to the installation cost.

As detailed in Table 5, these high-risk elements are characterized by high-risk scores (e.g., 0.97), resulting from either persistent proximity to obstacles (high Prox value) or excessive swept volumes due to large rotation radius (Radius close to 1.0). These metrics serve as the basis for imposing separation constraints in the DSM for re-partitioning.

Install Order	Module ID	Module Name	Total Cost

Finally, the overall efficacy of the framework is validated through comparative cost analysis.

Table 6: Total installation cost of different method

Method	Optimal Installation cost
Two-stage Optimize	602006
No redivision feedback	1014465
No module division	2752630

As summarized in the comparison Table 6, the proposed two-stage optimization achieves a significant installation cost reduction compared with the baseline methods, which delivers a 78 % lower installation cost than the traditional direct component installation strategy (i.e., without module division) indicating the advantage of modular installation. The two-stage method also shows a 41% cost reduce over no redivision feedback method,

confirming that the integration of modularization with feedback-driven optimization yields the most efficient construction process.

Conclusions

To address the critical challenge of modeling dynamic on-site environments and optimizing installation sequences under complex on-site installation constraints, this paper proposes a two-stage MEP installation optimization framework that integrates DSM-based module division and 4D simulation. The system aims to generate optimal installation sequences and collision-free kinematic paths, thereby maximizing constructability within the dynamic on-site environment. Our proposed MEP installation optimization system has three major contributions: 1) IFC-based 4D Simulation Environment, this study establishes 4D simulation environment within ROS, rigorously transforming IFC building information into dynamic spatiotemporal constraints to support virtual construction planning. 2) DSM-based MEP Module Division, the DSM-based framework is developed to streamline off-site fabrication, which employs constrained agglomerative clustering to decompose complex MEP systems into transportable modules based on functional and topological dependence considering on-site constraints. 3) MEP Installation Sequence Optimization with Feedback Mechanism, installation efficiency is maximized via a two-stage sequence optimization algorithm incorporating a closed-loop feedback mechanism, which refines inappropriate module division to resolve kinematic conflicts and path planning deadlocks.

The proposed methodology was validated on a real-world MEP project characterized by high component density and complex layouts. The results indicate that our proposed framework can successfully divide the MEP elements in different modules based on DSM and optimize the installation path and sequence of the MEP module based on 4D simulation. As Table 6 shows, this two-stage MEP installation optimization can significantly reduce the total installation cost, thereby enhancing the installation constructability and efficiency.

With our proposed MEP installation optimization system, users can obtain the robust and collision-free installation plan for MEP project in an efficient and automated way. Additionally, our system leverages the 4D simulation to simulate the changing on-site environment, which can integrate the dynamic installation constraints into the optimization framework. Future research will focus on extending the framework's applicability to more domain-specific and highly complex scenarios, such as intricate HVAC plant room assemblies.

EMERGING OPPORTUNITIES FOR INTEGRATING DIGITAL PRODUCT PASSPORT INTO LEAN CONSTRUCTION WORKFLOWS: A CONCEPTUAL PERSPECTIVE

Yanh Ribeiro[1], Pedro Mêda1[1,2], and Jorge Teixeira[1]
[1]ICS, CONSTRUCT, Faculty of Engineering, University of Porto, Portugal
[2] CONSTRUCT, Faculty of Engineering, University of Porto, Portugal

Abstract

Digital Product Passports (DPPs) are emerging as mandatory, standardised sources of product information under EU policy. Yet their implications for construction-phase Lean workflows remain underexplored. Current practices still suffer from late discovery of product-related constraints, missing documentation, and weak traceability, undermining task readiness and plan reliability. This study combines a scoping search with conceptual mapping of DPP data categories to digital Last Planner System (LPS) decision points. Results include a DPP-to-LPS integration framework and construction-oriented guidelines for make-ready, commitments, and receiving/QA. The contribution is a practical research agenda for operationalising DPPs in Lean execution and enabling data continuity (e.g., DBLs-related).

Introduction

Lean Construction aims to improve production reliability and workflow stability on construction sites by reducing variability and preventing tasks from starting without the necessary prerequisites. In practice, however, construction-phase planning and control often experience challenges related to product information availability, such as missing or outdated specifications, unclear compliance evidence, limited traceability across changes, and inconsistent access to installation and handling instructions. These shortcomings often surface late, during make-ready or even during execution, contributing to disruptions, rework, and "making-do" situations where crews proceed despite incomplete inputs (Amaral et al., 2023).

In parallel, European policy has moved towards mandating Digital Product Passports (DPPs) as structured, product-level information containers intended to support transparency, traceability, and circularity across value chains. Within the construction domain, recent work has discussed DPP information needs and adoption barriers, emphasising issues of stakeholder roles, data governance, and interoperability with existing information practices (Mêda et al., 2024; Mêda et al., 2023). Research on material and product passports has also highlighted that data availability is uneven and that explicit data templates are needed to operationalise passport concepts in real settings (Çetin et al., 2023). This aligns with findings from construction information systems, where the classification and standardization of item parameters within work breakdown structures are fundamental to enable integration and interoperability (Ribeiro et al., 2023b). Yet, despite the growing DPP discourse, relatively little has been published on how DPP data could be operationalised to support construction-phase production planning and control mechanisms, particularly Lean workflows on site.

While product-related information is typically generated during design and planning phases, it may become fragmented, outdated, or misaligned with site and product reality during construction execution. This disconnect undermines the effective use of information at the moment when it is most needed for decision-making. DPPs are an instrument to bridge this gap by making product information more available and accessible, while maintaining it structured, standardised, and traceable across project phases and stakeholders (Preamble 32, European Parliament, 2024).

In this context, the relevance of DPPs lies in their potential to improve process reliability and stability in construction workflows by enhancing the consistency and traceability of product information during execution. By supporting more reliable and usable information flows, DPPs can help reduce errors associated with information gaps and strengthen feedback loops within production control.

From this perspective, the DPP can be positioned as a practical enabler of Lean execution, not by "making construction lean" on its own, but by improving the timeliness, structure, and verifiability of product information at decision points where Lean depends on reliable inputs. Key DPP attributes, such as unique identifiers, technical specifications, and traceability events, can support earlier constraint detection, more robust make-ready screening, and more reliable decisions. These capabilities align with the requirements of Last Planner System (LPS) implementations, which increasingly act as centralised production control environments for coordinating commitments, constraints, and feedback loops (McHugh et al., 2025), and with emerging evidence that structured product data integration can improve site logistics and flow reliability (Berroir et al., 2023).

This paper makes three main contributions to the body of knowledge of computing in construction. First, it

proposes a structured mapping between Digital Product Passport (DPP) data categories, construction-phase decision points in planning and control, and expected Lean mechanisms such as improved task readiness and reduced making-do, grounded in digital LPS workflows. Second, it introduces a conceptual integration framework that positions DPPs as an operational information layer supporting make-ready, commitment, and receiving decisions during execution. Third, it derives a set of actionable, system-oriented guidelines that translate DPP requirements into traceable and usable data needs for site-level decision-making. To support these contributions, the study adopts a targeted scoping search to confirm the scarcity and fragmentation of DPP–Lean Construction research and concludes by discussing implementation considerations (e.g., identifiers, access control, interoperability) and outlining a research agenda for empirical validation in project settings.

Method

Research design

This study adopts a conceptual and scoping-based research design (Arksey and O'Malley, 2005; Jaakkola, 2020). The research combines a targeted scoping search to assess the maturity and thematic focus of literature connecting Digital Product Passports (DPPs) with construction workflows and Lean production control, with a conceptual synthesis that develops an integration framework and operational guidelines for DPP-enabled digital Last Planner System (LPS) workflows.

The scoping component aims to identify the extent to which existing research addresses the operational use of product-level digital information within construction-phase planning and control. The conceptual component builds on this evidence to propose a structured mapping between DPP data categories, construction-phase decision points, and Lean execution mechanisms.

Targeted scoping search

A targeted and iterative scoping search was conducted to explore research at the intersection of Digital Product Passports (DPPs), construction workflows, and Lean production control. The purpose of this search was not to provide an exhaustive systematic review, but to identify the existence, maturity, and thematic characteristics of research connecting these domains.

Searches were conducted in the Scopus and Web of Science databases due to their extensive coverage of engineering, construction management, and digitalisation research. The search strategy followed an iterative logic, beginning with the focal research intersection and progressively expanding the terminology when limited or no results were retrieved.

The initial search string combined the central concepts of this study: "digital product passport" AND "lean construction". This search returned no results in either database, suggesting a potential research gap at the explicit intersection between DPPs and Lean Construction.

To verify whether conceptually related research existed under broader terminology, the search scope was expanded by relaxing the Lean Construction concept. The following query was applied: "digital product passport" AND "lean". This search returned two records in each database. Screening revealed that these studies addressed lean manufacturing or used the term "lean" in alternative contexts rather than Lean Construction workflows and were therefore treated as domain-drift results.

A third search aimed to map DPP research within the construction domain more broadly: "digital product passport" AND "construction". This search produced a broader set of records, enabling thematic screening and categorisation of existing research related to DPP implementation in construction.

Considering that Digital Product Passports are frequently operationalised through related constructs such as material passports and structured product data templates, additional searches were conducted using these proxy concepts. This decision was supported by prior research indicating that material passports and data template structures represent foundational building blocks for DPP implementation (Honic et al., 2024). Therefore, the following search strings were applied: "material passport" AND "lean"; "data template" AND "lean".

Across all searches, records were screened to assess their relevance to: (a) construction-phase planning and control workflows; and (b) Lean Construction mechanisms such as constraint management, make-ready processes, and Last Planner System routines. Studies addressing Lean concepts outside the construction domain were considered false positives and excluded from thematic synthesis.

Scoping results and evidence of scarcity

The targeted search "digital product passport" AND "lean construction" returned no results in either database. The expanded search "digital product passport" AND "lean" returned two results in Scopus and two in Web of Science; however, screening confirmed that these studies addressed lean manufacturing or used the term "lean" outside the Lean Construction domain.

The search "digital product passport" AND "construction" produced 32 results in Scopus and nine in Web of Science. After duplicate removal across databases, 32 unique publications were retained for thematic screening.

The retrieved publications were categorised inductively based on their dominant research contribution. Categories were defined to reflect the functional role of the research in enabling, structuring, governing, or operationalising DPP implementation within the construction sector, and are presented in Table 1.

The screening indicates that current research on DPP implementation in construction is predominantly focused on circularity, lifecycle management, interoperability, and enabling digital infrastructures. No studies were identified that explicitly address the operational use of DPP data within construction-phase Lean production

control workflows. This observed gap motivates the conceptual framework and operational guidelines proposed in this study.

Complementary searches

To ensure that relevant contributions were not overlooked, broader sensitivity searches were conducted using combinations of synonyms and adjacent concepts related to product passports, data templates, circular economy, production planning, and construction workflows.

The searches combined DPP-related concepts, Lean production synonyms, product data approaches, circular economy–related concepts, and construction-related terms (e.g., digital product passport, material passport, product passport, data template, product data, circular economy, circularity, EPD, lean construction, last planner, production control, workflow, construction, site, building). Results retrieved from Scopus and Web of Science consistently showed that the identified studies either focused on adjacent domains or reflected domain drift, such as workflow digitalisation, lifecycle sustainability, data modelling, or Lean Manufacturing. Most records either overlapped with previously identified studies or addressed related research areas without explicitly linking Digital Product Passports to construction-phase Lean production control workflows.

Overall, the complementary searches did not reveal additional directly relevant studies beyond those identified in the primary search. Consequently, these results did not alter the thematic synthesis and were not included in further analysis. This approach is consistent with scoping-based research aimed at assessing the extent and boundaries of emerging research domains rather than exhaustively synthesising all available literature.

Conceptual synthesis and outputs

Given the limited availability of empirical evidence directly linking Digital Product Passports (DPPs) to Lean Construction execution, the study proceeds with a structured conceptual synthesis to operationalise the potential interaction between product-level digital information and construction-phase production control. The synthesis followed an iterative, multi-step process designed to ensure traceability between theoretical constructs and operational outcomes.

First, DPP data categories relevant to construction activities were derived through documentary analysis of emerging standardisation efforts and construction-focused DPP literature. Key sources included ISO 22057 data template frameworks (ISO, 2022) and research addressing data availability and structuring requirements for material and product passports in construction (Çetin et al., 2023; Vangelova et al., 2025). This step aimed to consolidate recurring product information attributes that are technically feasible and relevant to construction execution.

Second, operational decision points within Lean Construction production control were identified through review of canonical Last Planner System literature and recent developments in digital LPS implementations (Ballard and Howell, 2003; McHugh et al., 2025). This step focused on identifying planning and control moments where reliable product information is required to support workflow stability, including lookahead/make-ready planning, weekly work planning commitments, receiving and quality verification, and exception management.

Third, DPP data categories and LPS decision points were systematically mapped to identify potential interaction mechanisms between product information and Lean execution processes. The mapping aimed to establish how specific DPP attributes could support Lean objectives such as improved constraint removal, increased task readiness, and reduction of making-do and rework.

Fourth, operational system guidelines were derived from the conceptual mappings with emphasis on practical applicability within construction workflows and digital LPS environments. The guidelines were formulated to translate conceptual relationships into actionable information management practices for site-level planning and control.

The synthesis process resulted in two main research outputs: (1) a conceptual DPP-to-LPS integration framework linking product information categories to production control decision points, and (2) a set of construction-oriented system guidelines to support operational implementation.

DPP-to-LPS integration framework

This section presents the conceptual DPP-to-LPS integration framework, linking structured product-level information to construction-phase decision points within digital Last Planner System workflows. It focuses on how DPP data can support key Lean execution processes, including lookahead planning, weekly commitments,

receiving/QA, and exception management, by improving the reliability and availability of product information at decision-making moments.

Lean Construction conceptualises production not as a sequence of isolated tasks, but as an integrated process oriented towards flow reliability and waste reduction, enabling more predictable planning and control (Garcés et al., 2025). Lean theoretical foundations further emphasise the coordination of value flows over mere task conversion, reflecting the conceptual arguments originally introduced by Koskela and consolidated in subsequent literature (Porras Díaz et al., 2014). These foundations provide the theoretical grounding for the proposed framework and guidelines.

Although Lean Construction may not necessarily suffer from a lack of information, its effectiveness is closely linked to the availability of reliable and timely information at key decision points. The Last Planner System, as a production control mechanism, is designed to improve planning reliability and manage workflow variability through collaborative commitment-making and continuous learning, relying on the availability of sound prerequisites for task execution (Ballard and Howell, 2003). In this context, research on lookahead planning shows that unresolved constraints, often related to missing or unclear product information, can affect the ability to anticipate and remove obstacles before execution (Hamzeh et al., 2015). At the operational level, such information gaps may result in making-do situations, contributing to variability and rework (Amaral et al., 2023).

Framework overview

The framework is organised around three elements: (i) DPP data categories relevant to construction execution, (ii) LPS decision points during construction-phase planning and control, and (iii) Lean execution mechanisms expected to benefit from improved product information reliability.

DPP data categories for construction execution

Based on the construction-focused DPP literature, product/passport data templates, and interoperability discussions, we define the following DPP data categories as most relevant to the construction phase:

- Identification and versioning
- Technical specifications and performance
- Compliance and documentation
- Traceability and chain-of-custody events
- Installation, handling, and safety information

These categories reflect recurring needs reported for construction products, including harmonisation challenges across passport terminologies and the requirement for machine-interpretable and interoperable product data (Aragón et al., 2025; Çetin et al., 2023; Vangelova et al., 2025). They are also consistent with stakeholder expectations and barriers such as balancing transparency with intellectual property concerns (Ruismäki et al., 2025).

Construction-phase decision points in digital LPS workflows

Digital LPS systems provide a natural integration point for DPP data because they coordinate commitments, constraint management, and feedback loops across planning horizons. In particular, DPP information can support decision-making at:

- **Lookahead planning and make-ready screening:** verifying prerequisite availability and identifying product-related constraints early
- **Weekly Work Planning commitments:** supporting reliable "can" decisions by providing verified product requirements and documentation
- **Receiving and quality checks:** confirming that delivered products match specified versions/batches and that required documentation is available
- **Exception management:** handling substitutions, non-conformities, and late changes with controlled traceability and version awareness.

Digital LPS implementations emphasise centralised information management and situational awareness for coordination, making them suitable entry points for structured product data (McHugh et al., 2025).

Mapping DPP data to Lean execution mechanisms

Table 2 summarises the mapping between DPP data categories, LPS decision points, and the primary operational purpose supporting Lean execution. For example, reliable identifiers and versioning can reduce planning failures caused by incorrect substitutions; traceability events can strengthen logistics reliability and receiving controls; and compliance documentation can prevent work starting without required approvals, thereby reducing making-do situations. Prior Lean research has linked missing prerequisites and product-related issues to waste and rework, reinforcing the importance of timely and reliable product information in production control (Amaral et al., 2023). Related work on product data integration for lean site logistics further supports the relevance of structured product information to improve flow reliability (Berroir et al., 2023).

Table 2: Mapping DPP data categories to LPS decision points and expected Lean effects

DPP category	Lookahead	WWP	Receiving/QA	Exceptions
ID & versioning	Right item/version	Reliable "can"	Delivery match	Substitution control
Technical specs	Prerequisites/compatibility	Task readiness	Properties confirmed	Equivalence check
Compliance & docs	Approvals available	Commit with evidence	Acceptance gate	Ncr re-approval
Traceability	Logistics status	Availability certainty	Batch/serial verify	Rca & targeted fix
Install/handling/safety	Handling constraints	Safe method prereqs	Prevent damage/ncr	Corrective guidance

System guidelines for DPP-enabled digital LPS workflows

This section translates the proposed framework into practical guidelines for construction teams and for digital LPS implementations that aim to incorporate DPP information during the construction phase. The guidelines are written from a production planning and control perspective, focusing on how DPP information should be used to support make-ready, commitments, logistics reliability, and quality assurance.

These guidelines describe how project teams can use DPP information within LPS routines (lookahead/make-ready, weekly commitments, receiving/QA, and learning) to increase task readiness and reduce avoidable variability. When a digital LPS platform is used, these guidelines translate into practical requirements for what the platform should make visible, record, and enforce during planning and control.

Guideline 1 — Define a "minimum DPP dataset" per product group for construction execution

For each relevant product group (e.g., façade elements, MEP equipment, firestopping products), define a minimum set of DPP data categories that must be available before work can be made ready. This minimum should prioritise identification/version, technical requirements affecting installation, and mandatory compliance documentation, avoiding information overload while ensuring decision usability (Cetin et al., 2023; Ruismäki et al., 2025).

Guideline 2 — Treat DPP-based checks as explicit make-ready constraints

In lookahead planning, create a dedicated constraint type for "product information readiness" and link it to DPP evidence (e.g., verified documentation available, correct version identified). A task should only move to "can" when these DPP-related constraints are removed.

Guideline 3 — Use DPP identifiers to control substitutions and protect plan reliability

When changes happen (due to availability, lead times, or design late decisions), record the product replacement using its DPP identifier/version and require an explicit check of: (i) equivalence/compatibility with the intended design intent, and (ii) compliance implications. This makes change a managed, informed and compliance-checked decision rather than an informal field workaround.

Guideline 4 — Link receiving to plan: confirm "right product, right version, right evidence"

At receiving, confirm that delivered items match the planned product identity (and, when relevant, batch/serial) and that required evidence is available (e.g., declarations/certificates, handling instructions). If not, open a constraint immediately and block release to installation until resolved. This creates a direct bridge between logistics and LPS make-ready.

Guideline 5 — Make installation prerequisites explicit at the moment of commitment

When a task is proposed for the Weekly Work Plan, make the key product-specific prerequisites visible and confirm them explicitly (e.g., substrate readiness, environmental limits, curing times, required tools, safety prerequisites). The aim is not to add bureaucracy, but to reduce tacit assumptions that frequently trigger making-do.

Guideline 6 — Classify failures so learning becomes actionable

When tasks are not completed as planned, classify reasons for variance using categories that isolate "product information" problems (e.g., missing documentation, unclear requirements, wrong version/substitution, traceability uncertainty). Over time, this helps quantify how much unreliability is driven by product information and where DPP use would prevent recurrence.

Guideline 7 — Establish responsibility for DPP information completeness in the supply chain

Assign clear responsibilities for ensuring that required DPP fields are available and validated before delivery and installation (e.g., supplier/manufacturer provides documentation; contractor verifies readiness; trade confirms prerequisites). This is essential to avoid shifting the burden to site crews at the last minute.

Guideline 8 — Use DPP to support work packaging and logistics planning

For work packages and kitting/logistics plans, use DPP identifiers to define package contents (correct items, versions, and quantities) and to confirm completeness at handoff points. This guideline supports more reliable material flow to the workface and reduces making-do triggered by missing components (Amaral et al., 2023; Berroir et al., 2023).

Guideline 9 — Roll out incrementally: start where constraints are most frequent and costly

Do not attempt full DPP integration across all products at once. Start with product groups that are (i) high-cost, (ii) high-risk for rework or non-compliance, or (iii) recurrent sources of constraints in lookahead planning. An incremental strategy is consistent with observed implementation priorities in construction contexts (Mêda et al., 2024).

Guideline 10 — Maintain an auditable decision trail for DPP-based readiness

At key points (task made ready, weekly commitment, receiving acceptance, installation completion), record which product identity/version and which evidence supported the decision. This should be lightweight (not a full dossier), but sufficient to answer later: what was installed, where, when, and under which requirements/evidence? This guideline supports accountability, reduces dispute ambiguity, and enables structured downstream information continuity.

Link to Digital Building Logbooks (DBL)

The evidence trail in Guideline 10 also creates a straightforward pathway to future Digital Building Logbook (DBL) use. A DBL can only function reliably if product-level information is connected to where products were installed and which version/batch and documentation applied. If LPS routines already require teams to confirm readiness and record product identities at natural control points, extending this practice to populate DBL-relevant records becomes a small, non-disruptive additional step rather than a separate documentation effort. In this sense, making DPP use operational in construction-phase control is a prerequisite for credible DBL data continuity across the asset lifecycle.

Discussion and research agenda

The proposed framework and guidelines position the DPP as an operational information layer that can reduce construction-phase variability driven by product uncertainty. The scoping results suggest that most DPP-in-construction research has prioritised circularity and end-of-life use cases, interoperability with BIM/EPDs, and enabling infrastructures, while giving limited attention to how DPP data can support production planning and control on site. By focusing on digital LPS routines (lookahead/make-ready, weekly commitments, receiving/QA, and learning cycles), this paper highlights a practical pathway to translate product information into earlier constraint removal and more reliable commitments.

A key implication is that the value of DPPs in construction depends less on the mere existence of product data and more on whether such data is effectively used at critical decision points within planning and control workflows. Existing approaches to managing product information, including conventional documentation and BIM-based systems, are often limited to the design phase and not consistently maintained during execution, which limits their effectiveness in supporting real-time decision-making (Çetin et al., 2023; Ribeiro et al., 2023b).

If DPP information remains disconnected from planning and control processes, it risks becoming a compliance-oriented repository that is consulted too late to influence workflow reliability. In contrast, integrating minimum product information checks into make-ready processes and linking receiving/QA activities to planning commitments can shift the identification of issues upstream. This contributes to reducing making-do, rework, and informal substitutions, reinforcing flow reliability.

These observations are consistent with prior findings that structured product data integration can support lean site logistics and improve production stability (Berroir et al., 2023), as well as with research highlighting the importance of actionable data templates and stakeholder-aligned information requirements for operationalising passport-based approaches (Çetin et al., 2023; Ruismäki et al., 2025).

The guidelines also clarify governance and adoption challenges. Construction stakeholders highlight intellectual property concerns, unclear ownership of data, and the need to tailor DPP content by product group (Ruismäki et al., 2025). From a site perspective, overly complex or excessive product information can create friction and be ignored under time pressure, particularly when it exceeds what is operationally necessary for task readiness and decision-making. Insights from Lean Information Management (LIM) suggest that the success of such systems hinges on ensuring information flows are reliable, timely, and waste-free. Case studies of construction information systems designed as Lean enablers show that benefits are realized when the system reduces the eight wastes of information (e.g., waiting, overprocessing, defects), thereby increasing the reliability and usability of data for decision-makers (Ribeiro et al., 2023a). The “minimum dataset” approach proposed here is intended to balance usability with compliance and reliability by prioritising a core set of essential attributes that support effective and traceable decisions without overburdening site actors (Elkhidir et al., 2025).

Finally, the evidence trail created at LPS decision points can support lifecycle continuity beyond construction. If product identities and versions are recorded where they are installed and under which evidence they were accepted, the transition to building-level information structures such as Digital Building Logbooks becomes substantially less disruptive. In this view, operational DPP use during construction is not only a Lean enabler but also a prerequisite for credible downstream information management.

Limitations and practical barriers to implementation

It is important to acknowledge the limitations of this conceptual study, and the practical barriers to implementing the proposed framework. First, the framework assumes a level of digital maturity (e.g., use of digital LPS, connectivity on site) and supply chain readiness (e.g., DPP data provision by manufacturers) that is not yet universal. Second, the guidelines introduce new responsibilities and checks; their adoption may face cultural resistance or be perceived as adding bureaucratic overhead, especially if not seamlessly integrated into existing workflows. Third, issues of data ownership, intellectual property, and the cost of implementing the required technological infrastructure are significant real-world hurdles highlighted in stakeholder studies (Ruismäki et al., 2025; Mêda et al., 2024). These barriers underscore the need for the incremental, pilot-based rollout suggested in Guideline 9, and highlight that technological and procedural solutions must be accompanied by aligned contractual and incentive structures.

Research agenda

Future work should focus on empirical validation of the proposed framework through case-based and longitudinal studies in live construction projects. Priority directions include:

- **Pilot implementations in digital LPS environments:** implement a limited set of DPP-based readiness checks for selected product groups and assess effects on planning reliability and constraint removal practices.
- **Measurement using Lean-compatible indicators:** track changes in task readiness, Percent Plan Complete (PPC), and "reasons for variance" categories related to materials/product information, as well as non-conformance and rework events attributable to product documentation or substitutions.
- **Product group tailoring and minimum dataset definition:** test how the "minimum dataset" varies across trades and products, and identify thresholds where information becomes either insufficient for risk control or excessive for site usability.
- **Data governance and responsibility allocation:** study contractual and organisational arrangements that ensure product information is available when needed without shifting the burden to site crews.
- **Continuity to DBL and asset information:** investigate how construction-phase evidence trails can be structured to support handover and operations, including links from installed locations to DPP references.

Conclusions

This paper explored how Digital Product Passports (DPPs) can support Lean Construction execution by strengthening the availability, structure, and verifiability of product information at construction-phase decision points. A targeted scoping search indicates that DPP-in-construction research is currently concentrated on circularity, interoperability, and enabling infrastructures, with limited explicit attention to on-site production planning and control. In response, we proposed a DPP-to-LPS integration framework that maps DPP data categories to digital Last Planner System workflows and expected Lean mechanisms such as improved constraint removal and task readiness.

The paper also provided construction-oriented guidelines for operationalising DPP information in lookahead/make-ready, weekly commitments, receiving/QA, and learning cycles. Beyond near-term Lean benefits, the proposed "evidence trail" approach offers a practical pathway to support future lifecycle continuity, including the population of building-level records such as Digital Building Logbooks. Future research should validate the framework through project pilots and assess impacts using planning reliability, variance reasons, and rework/non-conformance indicators.

As DPP become the norm, a new paradigm emerges in which the challenge shifts from data availability to its effective use. As a philosophy grounded in continuous improvement, Lean Construction cannot disregard this valuable source of structured information, which can support increasingly reliable decision-making in construction execution.

Abstract

This research proposes a real-time tracking method using Light Detection and Ranging (LiDAR) to capture reference points as a positioning technique for non-Global Navigation Satellite System (GNSS) environments, such as mountain tunnel construction sites. Using this to acquire backhoe coordinates during tunnel construction enabled the automation of rough excavation for the invert excavation. Furthermore, by providing an overview visualization of the processes before and after automated construction, the surrounding conditions, and related tasks on a digital twin, it demonstrated safe automated construction management from remote locations. This research contributes to the automation and unmanned operation in mountain tunnels.

Introduction

In open-cut earthwork, high-precision positioning of construction machinery using the Global Navigation Satellite System (GNSS) enables semi-automated machine operation. In contrast, underground spaces such as mountain tunnels are non-GNSS environments where GNSS signals cannot be received, making high-precision position estimation difficult and hindering automation. For mounting tunneling, either the conventional timbering method or the New Austrian Tunneling Method (NATM) is employed. Among mountain tunnel construction methods, invert construction involves excavating the tunnel floor into an inverted arch shape (concave bottom) and reinforcing it with concrete. This aims to withstand pressure from below in weak ground, enhance overall structural strength, and facilitate drainage. Excavation work in invert construction requires both precise excavation shapes and the ability to move autonomously during operations, making position estimation critical and automated construction particularly difficult. The finished form of the invert is managed to ensure its thickness meets or exceeds the design value, typically limiting over-excavation to within a few centimeters. Excessive over-excavation increases both the volume of soil disposal and the amount of concrete required. Therefore, from the perspectives of work efficiency and environmental consideration, it must be avoided.

Furthermore, in mountain tunnel construction, multiple types of works typically alternate while working in confined spaces. This necessitates meticulous coordination by tracking the positions and operational status of construction machinery, materials, and workers. Implementing autonomous operation requires not only high-precision position estimation for the targeted machinery but also real-time, accurate awareness of its spatial relationships and operational status relative to other trades. Traditionally, site staff and workers visually observed conditions and communicated status via radio or similar means. Recently, however, digital twins have been employed as a method to visualize real-time conditions at construction sites during operations. Digital twins offer the advantage of enabling remote personnel to intuitively grasp the entire site, making it easier to understand the relationship between autonomous operation, surrounding tasks, and preceding/subsequent work.

On the other hand, mountain tunnel construction has historically been plagued by fatal rockfall accidents. Additionally, significant safety risks exist, such as water ingress and the generation of combustible gases. There are also substantial health risks, including dust generation from excavation, muck hauling, concrete spraying, and rock bolt installation. Consequently, reducing or eliminating personnel inside the tunnel is highly desirable. Therefore, it is also desirable to enable remote management for personnel overseeing operations within the tunnel. On the ground of the background, this study targets mountain tunnel construction in non-GNSS environments. It aims to propose and demonstrate the usefulness of automated invert excavation operations and a management method for automated operations using digital twins for remote monitoring.

Thus, the research questions of this paper are as follows; 1) How can we automate the invert excavation work of mountain tunnels in non-GNSS environments? 2) How can digital twins be utilized for the automated and unmanned invert excavation operation by safe remote monitoring?

Previous research

Automation in mountain tunnel construction

Mountain tunnel construction typically involves multiple types of work processes in succession within confined spaces. While automation research has advanced for NATM excavation tasks such as drilling and blasting, shotcrete application, steel support installation, and rock bolting, no automation efforts have been observed for

invert excavation. This is likely due to the challenges involved in invert excavation: the backhoe must acquire precise coordinates, move to the excavation position based on those coordinates, and control the excavation depth. Acquiring accurate coordinates while moving within a mountain tunnel is difficult. Furthermore, there are no initiatives for automatically moving to construction sites or automatically switching between work types. This is likely because all work types require auxiliary manual labor on-site either before, after, or during automated construction.

Yuhong et al. (2022) and Zijian et al. (2023) proposed using digital twins to visualize safety risk management in tunnel construction. Mountain tunnels face numerous daily risks, such as face collapses, water inflows, and combustible gas emissions, with conditions constantly changing. By consolidating site data—including ground conditions and worker locations—into a digital twin, it becomes possible to manage overall site operations and predict hazards. As mentioned earlier, digital twins can be utilized as a management method to visualize the flow of work types and worker assignments, enabling appropriate automated construction even in environments where human labor is mixed. Li et al. (2024) clustered many papers on digital twins for intelligent tunnel construction into various areas, including sensor networks, Internet of Things (IoT), computer vision-based twin data acquisition, communications, natural language processing (NLP), automatic control-based connection, and geometric, semantic, and analytical integrated twin modeling. However, no studies have been found that have conducted automated invert excavation of mountain tunnels and employed digital twins for unmanned safe construction and monitoring in non-GNSS environments.

Self-localization in non-GNSS environments

Nakao, Wakayama et al. (2023) conducted position estimation experiments for transport trucks in outdoor yards using LiDAR Simultaneous Localization and Mapping (SLAM). They verified accuracy at varying speeds and reported that while errors increased at higher speeds of 10, 20, and 30 km/h, position estimation was generally achievable with an error of 30–40 cm. They also reported that for driving within non-GNSS environments like tunnels, position estimation was possible with an error of approximately 30–40 cm, 20 and 30 km/h, and the error generally remained within 30–40 cm. They concluded that this method is practical for operation within tunnels, which are non-GNSS environments. Furthermore, Ishida et al. (2022) demonstrated that during automated construction targeting face excavation work (using breakers) in a mountain tunnel, LiDAR SLAM enabled self-position estimation with an error of approximately 30–40 cm and allowed for automated movement while maintaining awareness of its own position. However, these methods struggle to automate excavation tasks requiring quality control with sub-centimeter accuracy, such as invert excavation. The cause of this error is thought to be that the road surface of mountain tunnels under construction is not flat. The laser beams from the LiDAR used in SLAM encounter the tunnel walls or various equipment installed on the walls due to minor vibrations caused by the vehicle's movement, causing distance fluctuations. Depending on whether the beams hit the tunnel wall or this equipment, differences of several tens of centimeters occur in the measured distance. Resolving this issue would require a significant overhaul of the current construction equipment, which is not practical.

Yimin et al. (2022) used AI to detect objects and acquire targets, enabling real-time coordinate alignment for flying UAVs. Similarly, if coordinates for construction machinery inside mountain tunnels could be acquired from known points, more accurate self-position estimation would be possible, facilitating smooth automated construction.

Proposed method

The method proposed in this study consists of two approaches: a technique for high-precision automated invert excavation in mountain tunnels under non-GNSS conditions, and a technique for managing automated operations by remotely monitoring site conditions via a digital twin.

Moving to the worksite and improving localization accuracy

The constructed autonomous machine is shown in Figure 1. To achieve automated invert excavation, precise automatic movement to the excavation site is essential. Therefore, a 2D LiDAR was installed at the front of the vehicle to acquire surrounding point clouds in real time. Regarding the automation of backhoe control, an unmanned construction backhoe (a remote-controlled machine for disaster response) equipped with a hydraulic control system was modified. Four inclinometers for machine guidance (mounted on the body, boom, arm, and bucket link) and a slewing angle sensor measuring the slewing angle between the traveling section (lower part of the backhoe) and the working section (upper part of the backhoe) were installed. This enables the computer to determine the backhoe's posture, and a slewing angle sensor measuring the angle between the undercarriage (lower part of the backhoe) and the upper structure (upper part of the backhoe). This enables computer acquisition of the backhoe's posture. Furthermore, by controlling the hydraulic controller via this computer, a system was created that performs hydraulic control while acquiring travel and posture data. This system can calculate the cutting edge coordinates with the same precision as the guidance system for manned operation. Therefore, this section focuses on the positioning of the backhoe body itself, which is expected to cause particularly large errors in automated construction. It describes methods for acquiring the surrounding environment to enable accurate automated movement and techniques for moving precisely to the excavation position.

Previous studies have shown that SLAM using 2D LiDAR can achieve positional accuracy within 30 to 40 cm when precise positioning is not required, such as for movement

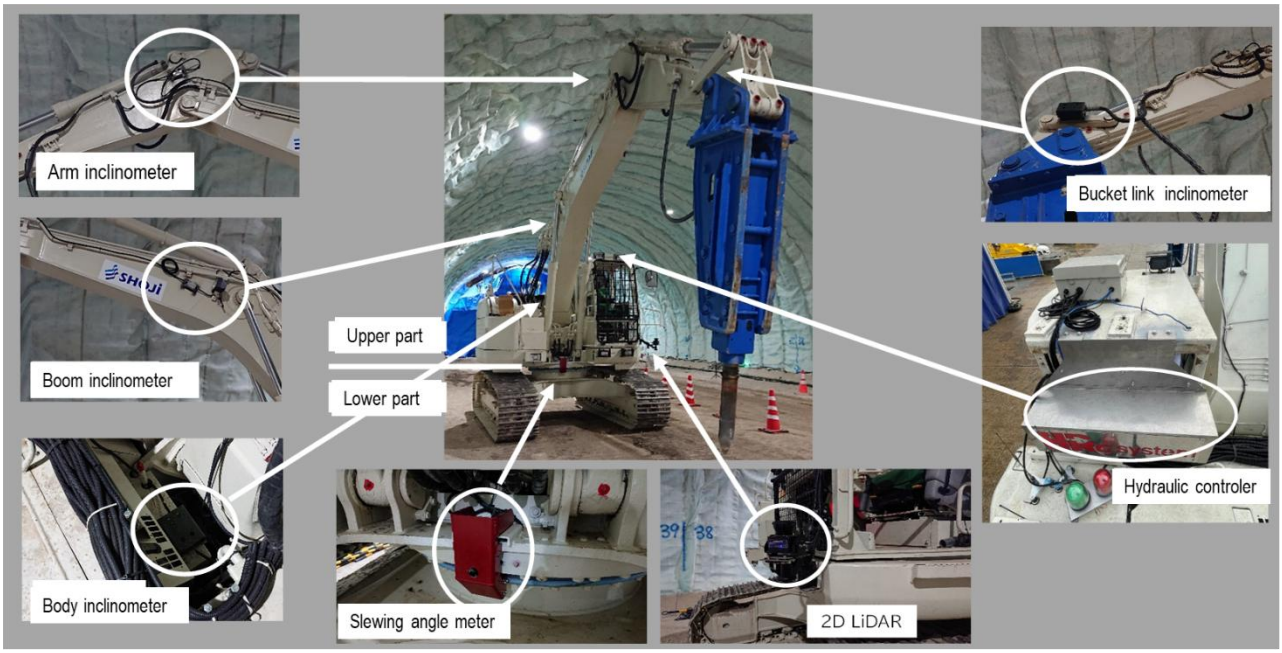

Figure 1: Developed autonomous backhoe for tunnel invert excavation

within a tunnel bore. However, the breaker tip requires accuracy within 5 cm, and the construction precision of the machine guidance system used in this study is also within 5 cm. Therefore, positional accuracy of at least within 5 cm was also deemed necessary. Therefore, as shown in Figure 2, two cylindrical reference points (barrier drums) were installed at the construction site to improve position estimation accuracy. Barrier drums were chosen as reference points because they are numerous on-site, have sufficient diameter and weight for high stability, and their large diameter allows acquisition of a large number of LiDAR measurement points. A typical and used barrier drum's dimensions are D580 mm x H820 mm, and 200 liters.

The procedure is as follows:

1) Pre-install the barrier drums near the construction site, acquire the center coordinates of the circle using a total station (TS), and register them in the system.
2) Drive the backhoe while scanning its front using the 2D LiDAR mounted on the backhoe body. Detect objects. When three or more points are acquired, perform Circle Fitting (Figure 3) using the XY coordinates to determine the shape. If the shape is a cylinder of a specified diameter, it is considered a calibration point.
3) When two calibration points are captured, the center coordinates from Circle Fitting are set to the coordinates acquired by the TS.
4) The coordinates of the two points are used to estimate the autonomous vehicle's own position and the orientation of the working equipment.

Detecting two calibration points enables calculation of the vehicle body's orientation. This method achieves higher accuracy than SLAM. The 2D LiDAR used in this research is VFT-35LX-F0 and detects calibration points in real time. The ranging accuracy of the used LiDAR is ±5 cm within 15 m and ±10 cm beyond 15 m when measuring white paper (a highly reflective target).

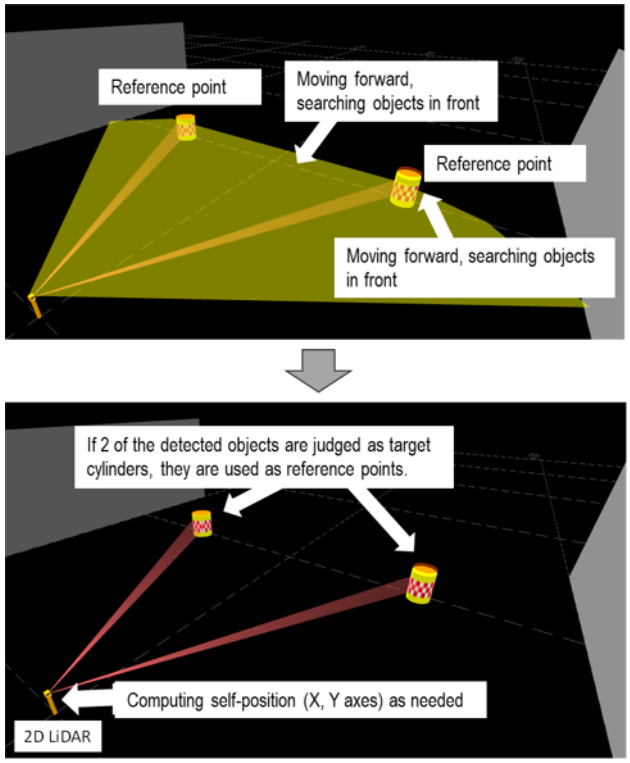

Figure 2: Measuring self-position using reference points

Sufficient accuracy may not be achievable at long distances. In contrast, this study assumes automated construction per block (primarily 10.5 m in length, based on the standard 10.5 m length of a typical tunnel lining form (traveller) as an example of a construction unit for mountain tunnel projects. When the autonomous machine enters within 10 m of a reference point, the system automatically switches from position estimation via SLAM to position estimation using the reference points,

thereby improving accuracy. These functions enable automated invert excavation in non-GNSS environments, demonstrating the proposed method's effectiveness.

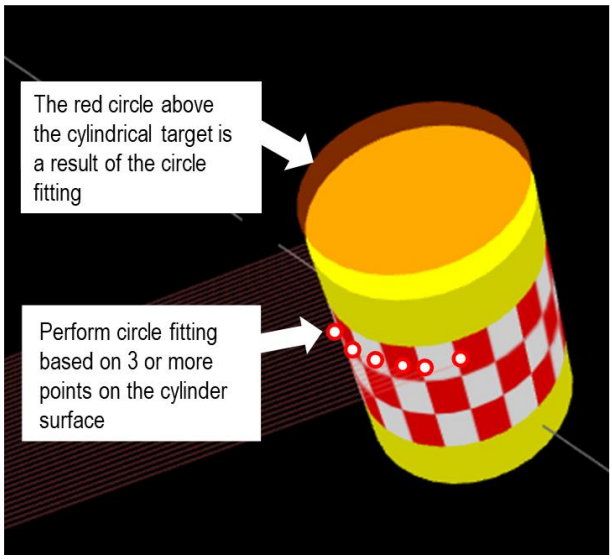

Figure 3: Detection of reference points using point cloud data observed by the 2D LiDAR

Digital twin-based remote site monitoring and automated construction management/control

Figures 4 and 5 show the digital twin used in this research. Figure 4 displays the WebGL view, showing the overall status viewed via a web browser, while Figure 5 shows immersion in the digital twin via VR. Figure 6 shows the system architecture of the digital twin developed in this study. This research proposes using the digital twin for unified management of automated construction and manual operations, anticipating scenarios where automated operation and manual work coexist on-site. This digital twin reflects the site conditions in real time, enabling intuitive grasp of the entire site situation from remote locations. The digital twin displays not only the design geometry but also as-built measurement results and IoT sensor measurement data. For IoT sensors, real-time acquisition of dust concentration, illuminance, and the signal strength of BLE (Bluetooth Low Energy) beacons worn by workers was performed to manage the work environment and worker locations. For the invert excavation section targeted for automation and its surrounding sections, managing the presence of manual labor is critical for safety assurance. Therefore, worker positions acquired via BLE beacons are reflected in the digital twin, and autonomous machines are restricted from entering sections where manual work is in progress.

After invert excavation completes in a section, manual formwork and rebar assembly enter the same section, while the invert excavation moves to an adjacent section. While automated construction and manual work alternate and proceed adjacent to each other, the digital twin manages and controls the automated construction. This allows supervisors to visually confirm the situation while also preventing automated construction from occurring in manual work sections through system control. The digital twin pre-registers the designed shape for invert excavation. The current terrain is captured using a 3D laser scanner immediately before invert excavation begins. This data is imported into the digital twin, which then automatically generates planning data based on both the current terrain and the designed shape (Figure 7). These functions enabled remote monitoring of the site conditions, control of automated operations while separating manned work from automated tasks, and demonstrated the effectiveness of this approach.

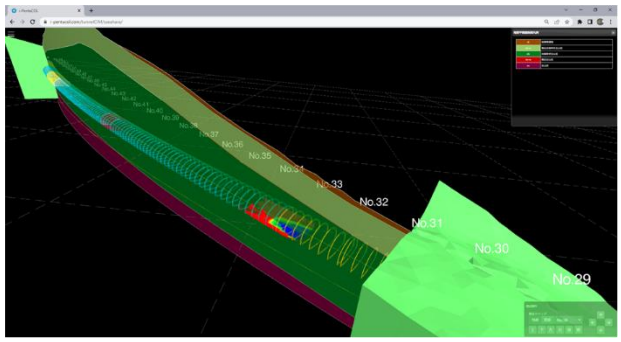

Figure 4: Image of the whole construction site in the developed digital twin (WebGL)

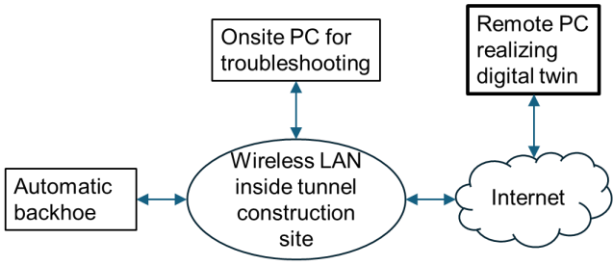

Figure 6: System architecture of the developed digital twin

Demonstration at a tunnel construction site

The proposed method in this study was demonstrated at the National Route 57 Sasahara Tunnel construction project (Location: from Sasahara-cho to Amatsu-cho, Uto City, Kumamoto Prefecture, Japan) commissioned by the Kyushu Regional Development Bureau. This is a mountain tunnel construction project with a width of approximately 14 m, a height of approximately 8 m, and a total length of 679 m.

The autonomous machine moves from the standby location to the construction site using SLAM-based position estimation, automatically avoiding temporary obstacles along the way. After detecting cylindrical reference points, it switches to position estimation based on these points. Subsequently, it automatically moves the cutting edge to the pre-set excavation location and performs excavation using a breaker. The accuracy verification method involved stopping the breaker at its deepest point during excavation and measuring the deviation of the guided cutting edge. The excavation guidance status display is a schematic diagram showing the spatial relationship between captured reference points, the automated machine, and the mesh diagram of the construction target area. The number of mesh points increases as the construction target area expands.

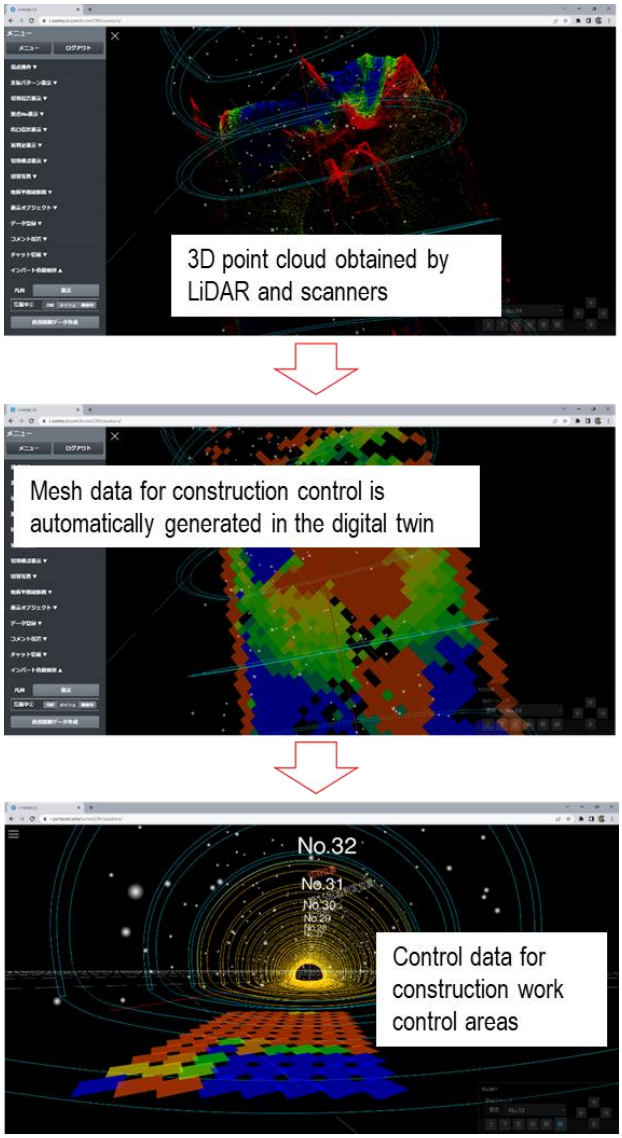

Figure 7: Automated generation of autonomous construction plans in the developed digital twin

The vehicle's front-rear direction was defined as the X-axis, left-right direction as the Y-axis, and depth direction as the Z-axis. For depth measurement, a marker was installed on the upper part of the breaker, and depth was calculated by measuring the height of this marker. The accuracy verification results are shown in Table 1. When an operator is in the cabin performing manual excavation, the positional accuracy of the breaker tip is approximately 5 cm. In this automated operation demonstration, the average error exceeded 5 cm, indicating overall lower accuracy compared to manual operation and unsuitability for finishing excavation. However, for rough excavation targeting 50 cm above the finishing excavation level, an error margin of up to 50 cm is acceptable. Therefore, high precision is not required, and it is sufficiently applicable. Regarding measurement point 1 in Table 1, the depth-direction error is larger compared to other measurement points. For mountain tunnel applications, the breaker unit is heavier than conventional units, and it has been confirmed that this causes greater vibration at points farther from the vehicle body. This is considered to be the cause of the error. Overall, vehicle body vibration is significant when the arm is extended, and the cutting edge often wobbles considerably before reaching the intended position. Therefore, for the end construction, it was judged that contact with the wall surface was possible, and construction was performed using onboard operation.

Table 1: Accuracy verification result of excavation control

Measuring point No.	Average error for each axis		
	x (cm)	y (cm)	z (cm)
1	8.3	9.2	22.3
2	6.0	8.7	12.3
3	5.7	7.0	16.0
4	7.0	5.7	9.3
5	10.3	8.3	12.3
6	7.0	6.0	8.3
7	10.0	8.3	7.7
8	8.3	7.7	5.7

During invert excavation, three workers typically measure the as-built condition on-site as needed to guide the excavation to the specified depth. This not only requires frequent manning of the construction site but also necessitates three workers standing by nearby during excavation. In contrast, this demonstration method implemented automated as-built management using 3D LiDAR (Figure 8). Consequently, invert excavation proceeded unmanned, and measurements could be performed with only one surveyor stationed away from the construction site. This demonstrates that merely automating the construction machinery itself is insufficient to achieve an unmanned construction site. To realize unmanned operation, it is necessary to automate or remote-control associated tasks such as as-built verification.

The preceding process for the invert excavation work in this study was rock bolt installation. However, sufficient time had elapsed since the preceding process, so no particular work coordination was required. Furthermore, since rock bolt installation and invert work are not

performed consecutively, it is considered that no similar work coordination would be required outside this demonstration project. Figure 9 shows an example of the area of a single invert excavation and the surrounding conditions. Since invert excavation reduces ground load, excavation is often performed alternately on each side. After excavation, the schedule is typically adjusted to perform concrete placement and backfilling as early as possible. To use the excavated soil for backfilling during invert excavation, temporary stockpiles are often placed nearby for construction efficiency. Consequently, the actual site is divided into even smaller sections, with manual labor occurring. Manual labor is performing formwork and rebar assembly for the post-invert excavation process. The left side served as a passageway for transporting materials. In the next phase, invert excavation moves to the opposite side. Manual concrete placement for the invert occurs at the tunnel rear, and the completed excavation side becomes the concrete transport route. Managing these chronologically changing conditions around automated construction is also necessary. This study utilized radio signals from BLE beacons worn by workers to manage the location of manual operations, monitor formwork/rebar assembly status and material transport status, and automatically halt automated construction when workers or vehicles approached the automated machinery. However, frequent material transport causes delays in automated construction, necessitating measures to relocate transport routes away from the construction zone.

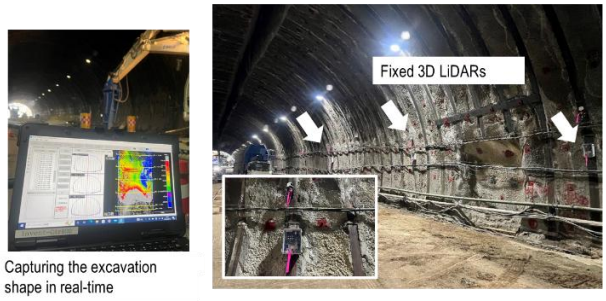

Figure 8: Fixed 3D LiDARS were used for automated as-built management

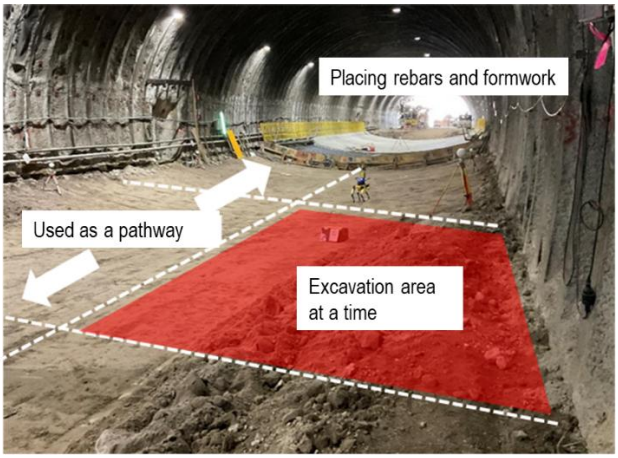

Figure 9: An invert excavation area at a time

Regarding the demonstration content and results, multiple veteran site supervisors with extensive mountain tunnel construction experience evaluated the system. The evaluation was done both in writing and interviewing in terms of precision, safety, productivity, and miscellaneous of automation of invert excavation and the digital twin. Initially, these supervisors considered automated construction in mountain tunnels impractical due to the tunnel's confined space and the complex interplay of numerous work types requiring frequent fine-tuning between tasks. However, through this research demonstration, they gained confidence in the feasibility of automated construction in mountain tunnels. This feasibility stems not only from the automation of construction machinery but also from establishing a system where digital twins enable personnel to oversee the entire site while allowing human management intervention. This allows progress to be made by combining automated construction with conventional methods, even in response to minute changes in conditions.

Conclusions

This research demonstrated two key elements for realizing automated construction in mountain tunnels: 1) automation of invert excavation in non-GNSS environments, and 2) management of automated construction using a digital twin. Regarding 1) automation of invert excavation in non-GNSS environments, while its lower construction accuracy compared to operator-controlled excavation limited its application to rough excavation, it was confirmed that even for rough excavation alone, eliminating the need for heavy equipment operators during simple repetitive tasks offers significant labor-saving potential. According to site personnel, automating even just rough excavation allows operators to spend about half a day on other tasks. 2) Regarding automated construction management and control using digital twins, beacons enabled clear identification of both manual worker locations and automated construction positions. Furthermore, integrating human vision and intuitive judgment through the digital twin made it possible to proceed with a mix of automated construction and conventional manual work.

Furthermore, even with automated construction machinery, frequent on-site tasks such as measuring work progress and guiding during automated construction occur. It was found that advancing automation in these areas also improves the efficiency of automated construction. Moving forward, visualizing movements during handoffs between different work types using the digital twin and defining the operating conditions of automated machines according to each set of conditions will enable smooth coordination with other work types.

Regarding position estimation methods, the approach used in this study requires the installation and removal of calibration points, leading to additional on-site work. At the construction site, only 2 barrier drums were used for referencing. The effects of the number of barrier drums and their locations are our future work. An alternative

approach could involve assigning coordinates to existing feature points, such as formwork, rock bolts, or immovable temporary equipment, and performing position estimation by automatically detecting these points.

While this research managed invert excavation using a digital twin, applying this approach to other trades is feasible. By acquiring detailed real-time site information via 3D data and IoT data, human intervention can be reduced. Future research should explore integrating digital twin-based safety risk management, management of manned/unmanned zones, and automated construction control.

Mountain tunnel construction involves multiple trades operating within a narrow, extended space, necessitating detailed understanding and meticulous coordination of site conditions. While research on automated construction for mountain tunnels has advanced across many trades, an integrated coordination mechanism is now required. As automation and remote operation advance, we aim to proceed with introducing automated and remote construction while analyzing how many workers will remain in the tunnel for each task and the workflow for progressing each task

Acknowledgment

Field verification of this methodology was conducted with funding from the Ministry of Land, Infrastructure, Transport and Tourism's "Project on the Introduction and Utilization of Innovative Technologies to Dramatically Improve Construction Site Productivity."

Abstract

Earthwork operations are among the most hazardous construction activities due to frequent interactions between heavy machinery and workers in dynamic, constrained environments. Traditional safety practices remain largely reactive and insufficient for real-time accident prevention. This paper presents an IoT-driven real-time risk analysis framework for proactive safety management in earthwork operations. The system integrates machine-mounted telematics, spatial analytics, and dynamic heat-map visualization to assess collision risks at machine and zone levels. A three-week deployment on a construction site identified spatiotemporal risk hotspots and recurring near-miss patterns using meter-level positioning accuracy, demonstrating a shift from reactive control to proactive, data-driven safety management.

Introduction

In European construction, particularly in Denmark, earthwork operations pose a significant hazard due to frequent collisions involving heavy machinery. Confined workspaces amplify these inherent risks, leading to a high rate of severe accidents. Poor on-site conditions and human factors can lead to equipment-worker collisions, jeopardizing safety and operational efficiency (Son and Kim, 2021; Talmaki and Kamat, 2022). Machinery collisions are a significant concern on all construction sites. The close-quarters operation of heavy equipment, combined with poor visibility and miscommunication among operators, frequently leads to serious accidents. The shared workspace between workers and machinery increases the risk of injuries, making it essential to thoroughly investigate mitigation strategies (Kim et al., 2023). Existing methods, which rely on manual supervision and post-incident analysis, are reactive and insufficient for preventing collisions. These approaches often cause costly delays and make safety hazards worse (Soltanmohammadlou et al., 2019; Zhang et al., 2017) Therefore, the motivation to drive this research is to make a transition from reactive to proactive safety management systems that can effectively predict and prevent incidents on construction sites through innovative technology.

Despite advancements, construction safety still relies heavily on manual oversight and post-incident reviews. The use of flagmen and basic rear cameras exemplifies a reactive safety approach, underscoring the need for a shift toward real-time, technology-driven risk management. . There is a notable gap in using real-time data to prevent equipment collisions during rapidly changing earthwork operations (Waqar et al., 2023). Incorporating technologies such as the Internet of Things (IoT), Geographic Information Systems (GIS), and machine learning is crucial for advancing construction safety beyond traditional methods. However, current practices often fail to fully utilize these tools to build a cohesive, real-time monitoring system that adapts to the dynamic nature of construction sites. Existing literature lacks studies that show how to effectively integrate technology into safety systems that both identify risks and provide real-time insights to stakeholders (Talmaki and Kamat, 2022). The absence of real-time, tech-enabled risk assessment frameworks remains a significant barrier to safer construction sites (Häikiö et al., 2020). Dynamic risk assessments that combine real-time data with visualization tools, such as heat maps, enable swift hazard identification, supporting quick, informed decisions (Talmaki and Kamat, 2022). This research presents a novel, integrated IoT framework for construction safety that explicitly addresses the current gap by linking machine telematics, spatial analytics, and dynamic heat-mapping visualization to enable proactive safety management during earthwork operations. This research emphasizes equipment-based risk monitoring and does not address interactions between workers and equipment, which continue to be a major cause of fatal accidents. As a result, the proposed framework should be viewed as a partial safety measure rather than a complete safety system. The proposed system provides continuous, real-time spatial risk awareness, enabling immediate on-site decision-making, unlike traditional post hoc or isolated sensing approaches.

Literature review

State of practice in safety management for earthwork operations

Across the EU, 20% of accidents and deaths occur on construction sites (Hong and Teizer, 2024). Construction remains one of the most hazardous industries in the UK, accounting for 27% of workplace deaths in 2020/21, with 18% caused by moving vehicles (Walker et al., 2021). Earthwork operations, involving heavy machinery like

excavators and bulldozers, pose significant safety risks, particularly collisions, which research shows are a leading cause of injuries (Shen et al., 2016; Teizer, 2015). Sites with multiple heavy equipment units operating simultaneously can create confusion regarding navigation and operational priorities. The presence of numerous personnel can further complicate coordination and increase the likelihood of accidental collisions (Kukoyi and Adebowale, 2021). Trenching and excavation activities are particularly hazardous due to the risk of collapse. OSHA reports that trenching cave-ins are among the top causes of construction-related fatalities, often resulting in severe injuries or deaths (Asadzadeh et al., 2020). The primary causal factors include inadequate protective systems and geological instabilities that are insufficiently assessed before excavation. Furthermore, Poor planning and unclear equipment paths often cause construction accidents. Research has linked inadequate design and maintenance negligence to collisions, highlighting the need for careful planning and regular inspections to ensure safe operation of machinery (Zhang et al., 2017).

Traditional safety management on construction sites during earthwork operations with heavy equipment has primarily relied on manual inspections, visual checks, and physical barriers to reduce the risk of collisions. For Instance, communication methods, such as walkie-talkies or visual signals, are not always effective in ensuring timely warnings, especially in sites with high noise levels or low visibility (Jo et al., 2019). Consequently, the risk of collisions among heavy equipment persists, resulting in serious accidents and injuries. Other methods, such as physical barriers and cones to delineate safe work zones, were prominent but not foolproof; they did not account for all variables that could lead to collisions between equipment and personnel (Kayhani et al., 2018).

Enhancements in communication, such as alarms and visual alerts, were limited and did not provide comprehensive real-time proximity awareness (Jo et al., 2019). Safety performance was largely reactive, focusing on accident responses rather than proactive hazard assessments and preventative measures (Leonardo et al., 2020).

Digital Technologies in Safety Management of Earthwork Operations

Innovative technologies like IoT are transforming construction safety through real-time data collection. Using wearable sensors and environmental monitoring, IoT enables continuous tracking of workers, machines, and site conditions. Similarly, Asadzadeh et al. (2020) discuss how sensor-based safety management integrated with IoT technologies improves responsiveness to dynamic working conditions (Asadzadeh et al., 2020). This shift towards automated, proactive monitoring systems has emerged as a necessity given the inadequacies of passive safety measures traditionally employed in construction settings (Häikiö et al., 2020; Kim et al., 2023). Another key innovation, heat maps, offers visual data representations that enhance decision-making for worker safety and operational efficiency.

Wearable sensors now play a vital role in construction safety by providing real-time monitoring to identify hazards before accidents happen (Zamani et al., 2020). Strategies for sensor placement, such as those by (Talmaki and Kamat, 2022), improve machinery safety. Positioning technologies like Global Positioning System (GPS), Radio Frequency Identification (RFID), Light Detection and Ranging (LiDAR), and computer vision enable real-time tracking of equipment and workflows(Kim and Xiong, 2025). GPS supports spatial awareness on large sites, reducing near-miss incidents (Cheng and Teizer, 2013), while LiDAR offers 3D mapping to identify high-risk zones (Rao et al., 2022). RFID enhances equipment tracking and accountability (Poudel and Assaad, 2025). Together, these technologies create integrated safety systems that improve visibility and hazard detection on construction sites. Golovina et al. developed heat maps that visually represent high-risk areas where worker-equipment interactions are most likely, supporting predictive safety planning (Golovina et al., 2016). These visuals help safety managers identify hazards and develop mitigation strategies by prioritizing areas needing immediate attention. Heat maps are also widely used outside construction, such as in traffic safety management, to analyze accident hotspots and implement preventive measures (Chung et al., 2023). They highlight high-traffic equipment zones, enabling proactive interventions before incidents occur. Managers can modify equipment routes or schedules based on this data to reduce interactions and risks.

A recent perspective by Bęś et al. (2025) highlights the integration of IoT sensors with digital twins, GIS/BIM, and real-time visualization for construction safety. It emphasizes sensor networks, RTLS, and connected systems for dynamic site monitoring, enabling data-driven dashboards and risk visualization (Bęś et al., 2025). Modern safety management combines automation, real-time visualization, and dynamic risk assessment, but fully integrated solutions remain limited. Advances in IoT, digital twins, and AI now allow automated systems to track hazards, assess risks, and support decisions through live dashboards and heatmap-style risk views. An ideal system would unify hazard detection, risk prioritization, and KPI monitoring into a single, scalable platform for real-time safety management (Khajavi et al., 2023)

Research gaps & objectives

The integration of IoT-based monitoring systems with heat map generation holds significant promise for improving safety in earthwork operations, yet several gaps limit its effectiveness. One identified gap is that current systems lack real-time data analytics capable of processing high-volume sensor data quickly enough to provide immediate hazard detection and dynamic heat map updates (Liu et al., 2021; Niu et al., 2019). Moreover, most tools rely on historical data rather than proactive hazard prediction models, thereby limiting their

ability to anticipate collision risks. Machine learning approaches are needed to analyze equipment movement and generate predictive, forward-looking heat maps (Moe et al., 2023). Real-time integration of IoT-based construction safety systems remains constrained by data heterogeneity, latency, and weak governance, which limit the seamless integration of sensor streams (e.g., wearables, RTLS, environmental data) with dynamic heatmap or risk visualization outputs. Even where real-time dashboards exist, they often rely on static thresholds or simplified models, reducing the accuracy and responsiveness of risk prioritization in fast-changing site conditions. Additionally, many solutions lack robust governance frameworks that link sensor data to safety actions, decision logs, and audit trails across the project lifecycle, raising concerns about data reliability and regulatory compliance. While digital twin approaches offer promise for auditable and traceable safety management, their large-scale deployment e,g. With consistent rule versioning and intervention tracking, it remains underdeveloped. Furthermore, existing studies are often limited to specific use cases, with insufficient evidence on how these integrated systems perform across design, procurement, and on-site execution, hindering broader industry adoption (Arya et al., 2025; Catalán et al., 2025). Addressing these gaps calls for research that advances real-time analytics, develops predictive modeling capabilities, and incorporates user-centered design principles to enable practical adoption and enhance the effectiveness of digital safety management in construction. This study contributes by delivering a practical, real-time IoT-integrated safety framework that unifies data, visualization, and actionable risk monitoring, bridging the gap between fragmented tools and scalable, proactive construction safety management

Methodology

This section outlines the core theme of developing a real-time risk management system, including the design framework, data collection methods, and technology integration strategy used to enable proactive safety monitoring in earthwork operations. This study will follow a Design Science Research (DSR) methodology structured into four sequential steps:

1. *Identification of research gaps and system requirements* through a systematic literature review and expert consultation.
2. *Evaluation Metrics for Safety Performance* to evaluate system performance, a set of safety KPIs, including proximity violations, duration of unsafe interactions, near-miss detection, and severity classification based on a risk matrix, was defined.
3. *System design and technical development* of IoT-based heat map solutions integrating real-time analytics and predictive modeling.

Step #1: system requirements:

This stage ensured technical robustness and practical relevance by grounding the system design in two approaches: (1) a systematic literature review (on IoT safety, positioning, and heat maps), and (2) semi-structured interviews with three experienced safety managers to translate theoretical advances into operational needs.

The project requirements spanned three areas: Functional (system capabilities, including continuous tracking and heat map generation), Technical (performance, with a focus on low-latency, real-time processing of diverse data streams), and User-Oriented (practicality for safety managers, requiring an intuitive interface and clear, actionable visuals).

Step #2: evaluation metrics for safety performance

To strengthen the evaluation of the proposed system, a set of quantitative safety performance indicators (KPIs) was defined based on proximity analysis, temporal patterns, and risk severity classification. These indicators provide a structured framework to assess unsafe interactions and interpret safety conditions beyond simple tracking performance. The primary KPIs include: (1) proximity violations per operational hour, representing the frequency of safety threshold breaches between machines or between machines and static hazards; (2) duration of unsafe interactions, capturing the exposure time during which equipment operates within unsafe proximity ranges; and (3) severity classification of safety violations, derived from a dynamic 5 × 5 risk assessment matrix combining likelihood and consequence levels. In this study, near-miss events are defined as interactions occurring within critical distance thresholds (e.g., <5 m), thereby enabling the identification of high-risk situations before actual incidents occur.

Table 1: Assessment of metrics

KPI	Description	Unit
Proximity violations per hour	Number of safety threshold breaches between entities	events/hour
Duration of unsafe interactions	Time spent within unsafe proximity ranges	Seconds
Severity classification	Risk level based on likelihood × consequence matrix	Categorical (1-5)
Near-miss events	Interactions below the critical distance threshold (<5 m)	events

Step #3: system design and implementation:

Employing a Design Science Research (DSR) methodology, this study developed a real-time safety monitoring framework. The system uses IoT sensors on heavy machinery to collect positional and operational data. This data is managed, stored, processed, and analyzed efficiently by a hybrid InfluxDB (time-series database)–AWS architecture, which facilitates dynamic heat map and risk matrix visualization. The system comprises three layers: sensor, database, and visualization (Figure 1).

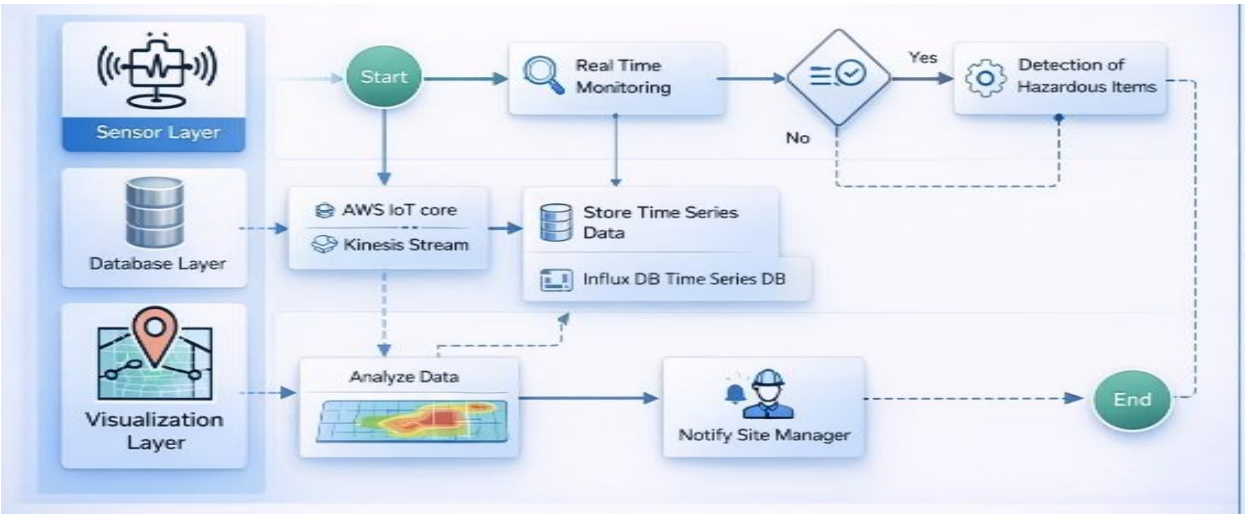

Figure 1:System overview

Sensor layer: IoT devices with GNSS-enabled telematics continuously stream high-frequency positional and kinematic data (location, movement) from heavy machinery. This data enables precise, real-time mapping of equipment trajectories, providing the technical foundation for dynamic heat maps and proactive hazard assessments. These sensors provide latitude–longitude coordinates at approximately 1 Hz, with a typical horizontal accuracy of 0.5-1.5 m under open-sky conditions. Such accuracy is consistent with prior construction safety studies that employ GNSS-based equipment tracking and is sufficient to detect spatial overlaps and proximity risks during earthwork operations.

By incorporating engine RPM and load, the system reliably classifies machine activity, as these variables strongly correlate with operational status (Talmaki & Kamat, 2022). The system distinguishes among idle, down, and active working time, enabling granular monitoring and a more realistic representation of operational risk, both of which are essential for safety management.

Database layer: The database layer uses a hybrid InfluxDB–AWS architecture for scalable, real-time safety. InfluxDB efficiently handles high-frequency data ingestion (via REST APIs) and time-based queries for hazard detection. AWS services (IoT Core, Kinesis, S3) ensure scalability, secure connection management, real-time ingestion, and long-term storage. This setup delivers reliable, low-latency insights crucial for proactive safety visualization management. Machine-installed telematics securely stream GNSS, motion, and engine data via APIs.

Visualization layer: The visualization layer delivers a dynamic spatial and temporal view of machine movements across a specific geofenced earthwork site. This area is defined by GNSS coordinates in the WGS84 reference frame: (55.719581, 9.128638) → (55.719998, 9.126529) → (55.722117, 9.127383) → (55.721882, 9.129044) → (55.722466, 9.129268) → (55.722419, 9.129801) → (55.719581, 9.128638), forming a closed polygon that marks the operational boundary of the jobsite. Machine telemetry is processed as continuous time-series data and refreshed at fixed intervals to maintain current situational awareness. Operational states are classified into time windows based on proximity events and hazard interactions, then mapped to a heatmap layer using color-coded risk indicators: blue (Idle), yellow (Down), and red (Working). Static hazard zones are defined through structured user input, with each hazard characterized by its spatial location, influence radius, and severity classification. These hazards are modeled as persistent spatial entities that serve as fixed reference points against which the movements of live machines are continuously evaluated for proximity violations.

Machine-level safety indicators are derived from live telemetry streams updated at a fixed refresh rate. For each machine, a continuous safety evaluation is performed, capturing the amount of unsafe work it performs at any given time. Unsafe work is identified when the real-time distance between machines, or between a machine and a static hazard zone, falls below predefined safety thresholds.

Zone Safety Status is derived by continuously evaluating unsafe activity within each spatial zone. For a given zone, safety status indicates the level of safety at any time, based on the machines operating within its boundaries and their ongoing proximity violations. A zone is considered increasingly unsafe when multiple machines, or the same machine repeatedly, perform unsafe work—defined by distance-based threshold violations with other machines or static hazard zones—while operating in that zone. The zone safety status is updated in real time and visualized as a zone-level indicator, enabling supervisors to rapidly identify areas where unsafe work is accumulating due to congestion, overlapping tasks, or hazardous spatial configurations. Both machine-level and zone-level safety states are translated into a standardized 5 × 5 risk assessment matrix to support consistent interpretation and prioritization of safety conditions. In this mapping, likelihood is derived from the extent and persistence of unsafe work, as reflected in the machine or Zone Safety

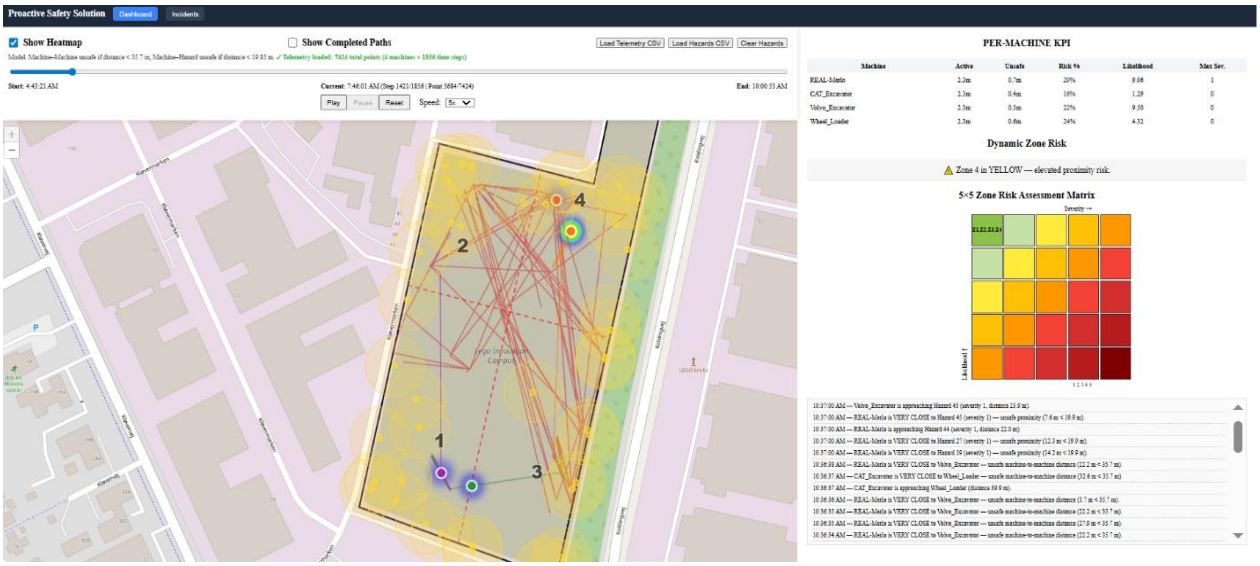

Figure 2: Visualization layer

KPI, capturing how frequently and for how long distance-based safety thresholds are violated. Severity is determined by the classification of the interacting hazards or machines involved in those violations, reflecting the potential consequences of the unsafe condition. By combining these two dimensions, each machine and zone is assigned to a corresponding risk cell that represents its current safety state. The matrix is continuously updated as KPIs evolve and rendered in the visualization interface to provide a clear, comparable view of escalating or diminishing risk across the site. Additionally, live commentary is provided to enhance the system's decision-making robustness.

The visualization layer is implemented as a fully client-side JavaScript dashboard using Vue 3 for reactive state management and Leaflet for heat plugin, for geospatial rendering. Vue components maintain live state for machine telemetry, static hazard definitions, safety KPIs, and risk states, while Leaflet renders the geofence polygon, 2 × 2 zone partitions, machine markers, trajectories, static hazard zones, and a continuously updated risk heat map. The heat map visualizes the spatial accumulation of unsafe activity by projecting machine- and zone-level safety KPIs onto the map surface, thereby highlighting areas of elevated risk. Telemetry and hazard data are ingested via browser-based CSV parsing and replayed at a fixed refresh rate using a JavaScript timing loop. Distance-based proximity evaluation and safety status updates are computed in JavaScript and propagated through Vue's reactivity system, triggering synchronized updates of the heat map, map layers, machine and zone KPIs, and the 5 × 5 risk assessment matrix. This fully browser-based architecture enables continuous, low-latency visualization of evolving safety conditions without server-side processing.

Step #3: System implementation:

The system was implemented and evaluated on a live construction site in Billund, Denmark, covering approximately 19,000 m² and involving intensive earthwork activities, including excavation, grading, and site preparation. For this pilot study, four machines were instrumented and monitored simultaneously: a telescopic handler (13013-MerloP40.17), two excavators (Volvo and CAT), and a wheel loader (Figure 2). These machines are the primary sources of dynamic interaction and collision risk on earthwork sites, owing to overlapping workspaces and frequent material-handling operations. The system was deployed over a three-week monitoring period, providing a realistic operational context for continuous telemetry acquisition and for evaluating real-time hazard detection, zone-level risk accumulation, and heat-map-based visualization within a space-constrained, dynamically evolving site. In addition to mobile equipment, predefined static hazardous items (Table 1) were incorporated prior to system execution and remained fixed throughout the monitoring period, serving as continuous reference points for distance-based safety evaluation.

Table 2: Static hazardous items in jobsite with severity

Group Name	Total Items	Severity Level (Out of 5)
Access & Road	15	3
Perimeter & Boundary	11	2
Storage & Stockyard	9	4
Cranes, Panels & Heavy Machinery	8	5
Facilities	2	1

The system captured live location, movement, and engine performance data, enabling accurate machine tracking. This data was integrated with a digital jobsite map (including obstacles/boundaries) to create dynamic heat maps. These maps moved beyond simple movement tracking to identify actual collision risks, significantly enhancing safety awareness (see Figure 3, which highlights high-risk zones).

Results and discussion

During the three-week monitoring period, the machines continuously streamed high-frequency GNSS data (location, movement, status). This positioning information was integrated with the site's digital boundaries. The data's consistency with planned routes and physical constraints confirmed its reliability for proximity-based safety analysis, even without ultra-high precision. This study focuses on equipment-centric risk monitoring and does not capture worker–equipment interactions, which remain a primary source of fatal incidents; therefore, the proposed framework should be interpreted as a partial safety solution rather than a comprehensive systemThe system successfully tracked equipment movement patterns across 504 operational hours, generating comprehensive telemetry records that captured real-time positioning and operational status. Analysis of this data revealed distinct patterns of spatial clustering and temporal risk concentration. Machine activity was visible in the heatmap, including down periods (equipment powered off during breaks and end-of-shift), idle states (engine running but stationary during excavation or loading work), and active movement between work locations. This operational state classification, derived by combining GNSS positioning with RPM and load-sensor data, proved essential for accurate risk assessment.

Dynamic heatmaps clearly visualized equipment activity and identified spatiotemporal safety hotspots near excavation fronts, loading zones, access routes, heavy machinery areas, and excavation perimeters. These high intensity clusters showed elevated collision risk caused by dense machine movement and repeated machine to hazard proximity violations, with extreme cases recording minimum distances below 1 m. The analysis also revealed that risks increased during peak operational periods when multiple machines worked in confined spaces, allowing the framework to distinguish hazardous zones from safer staging areas and provide a live, transient safety assessment beyond static safety methods

Additionally, the dynamic heat map visualization provides situational awareness superior to fixed zones or manual checks. By continuously displaying shifting risk patterns and congestion clusters, it enables safety managers to visually identify emerging hazards and facilitate timely, targeted interventions (e.g., rerouting). This shifts safety management from post hoc analysis to real-time, proactive spatial intelligence. The system's capacity to update visualizations in near-real-time (refresh intervals under 30 seconds) allowed supervisors to observe evolving safety conditions and respond before critical thresholds were breached.

The proposed system is designed to support safety managers or designated personnel in monitoring and managing safety risks in earthwork operations in real time. When the dashboard detects unsafe proximity between machines or hazards, risks are immediately visualized through heat maps, KPI dashboards, risk matrices, and live commentary, enabling rapid identification and communication to operators and nearby workers via tools such as walkie-talkies, radios, or mobile devices, or through public announcement systems when necessary. If no corrective action is observed, the system supports escalation by continuously monitoring the condition, triggering repeated alerts, and enabling stronger interventions such as issuing urgent warnings, halting machinery, or clearing workers from risk zones. In critical situations involving high-severity hazards, operations may be paused entirely until safe conditions are restored. By combining real-time detection, communication, and escalation mechanisms, the system facilitates a structured response process that enhances situational awareness, supports timely intervention, and enables continuous improvement of safety practices through the analysis of recurring risk patterns

This study presents the methodology for an integrated IoT safety monitoring system based on commercial telematics and cloud infrastructure. Our findings indicate that meter-level positional consistency is adequate for proactive safety decision-making and identifying hazardous zones, effectively overcoming the limitation of lacking quantitative accuracy validation. The system's reliance on industry-standard GPS accuracy (typically 2–5-meter precision) proved sufficient for safety zone monitoring, confirming that sub-meter precision is not a prerequisite for effective proximity-based risk assessment in open earthwork environments. Future work is necessary to integrate predictive analytics and model complex multi-equipment interactions for broader applicability.

The analysis revealed that unsafe interactions were not uniformly distributed but concentrated in specific spatial zones and time periods. Temporal risk analysis revealed high-risk operational periods, while spatial clustering identified recurring hotspots near excavation fronts and in high-traffic areas. Additionally, machine-specific risk profiles indicated that certain equipment types exhibited higher frequencies of proximity violations, highlighting opportunities for targeted safety interventions. While no historical baseline or incident logs were available for direct comparison, the system detected multiple proximity violations and near-miss patterns over 504 operational hours, demonstrating its ability to uncover latent safety risks that are typically not observable with traditional monitoring approaches. These results support the system's role in enabling proactive safety management by providing real-time, data-driven insights into hazardous interactions. Future work will focus on validating these indicators through longitudinal studies and integrating incident records and near-miss reporting systems to establish quantitative links between detected risk patterns and actual safety outcomes.

Limitations and conclusions

The proof-of-concept system was tested for only three weeks at a single site, limiting generalizability. Machine telematics lacked survey-based validation, so it supports relative risk identification rather than precise localization. GPS positioning also introduces accuracy uncertainty, especially near obstructions, though this was minimal at

the study site. The absence of baseline safety records limits the ability to quantify absolute reductions in incidents, and future work will address this through before–and–after comparative analysis.

Finally, the study was limited to two machine types and omitted critical factors like worker-on-foot interaction, multi-machine dynamics, and environmental/behavioral context. The absence of worker tracking represents a significant limitation, as pedestrian-equipment interactions constitute a major source of construction site accidents. Additionally, the system did not account for visibility conditions, operator experience levels, or communication patterns among crews, all of which influence real-world safety outcomes.

Despite these constraints, the system demonstrates strong technical feasibility and practical value by integrating IoT telemetry with dynamic heat maps for proactive safety management. Continuous risk visualization reveals high-risk spatiotemporal patterns, providing actionable insights beyond traditional static plans. Its reliance on operational context confirms the effectiveness of real-time spatial analytics, while hazard detection and visual risk zones address key safety gaps.

From an implementation perspective, the system uses commercially available telematics and cloud infrastructure, making it accessible without major customization. Its compatibility with existing fleet systems, along with standard data formats and open-source tools, supports easy adoption, scalability, and site-specific customization

The research demonstrates that IoT-enabled proximity monitoring can transition construction safety from reactive incident response to predictive hazard prevention. By providing continuous spatial awareness and enabling early intervention before accidents occur, the system exemplifies how digital construction technologies can fundamentally enhance worker safety. The framework's capacity to identify recurring risk patterns also supports organizational learning, allowing firms to refine operational procedures and training programs based on empirical evidence of actual site behavior rather than theoretical hazard assessments.

To advance this work, future efforts must quantitatively validate positioning accuracy and assess system robustness across various sites. Research should incorporate new data sources, including worker tracking and multi-equipment modeling. Expanding the framework to include wearable sensors for workers on foot would enable comprehensive monitoring of all site personnel, thereby addressing the current limitation of equipment-only tracking. Integration of computer vision systems could complement GPS-based positioning, particularly in confined spaces or in areas with degraded GPS signal. Crucially, the integration of machine learning for predictive risk forecasting will be key to transitioning construction safety management from reactive to a predictive practice. Advanced analytics could leverage historical proximity patterns to forecast collision probabilities from current operational configurations, enabling preemptive interventions when risk thresholds are projected to be exceeded.

Long-term deployment across multiple sites can establish industry benchmarks and validate risk patterns. Integrating BIM and construction schedules can contextualize proximity data, enabling a scalable, data-driven approach to improving construction safety and preventing accidents.

PERCEIVED BENEFITS OF 5D BIM IN CONSTRUCTION COST MANAGEMENT: A EUROPE-WIDE SURVEY

Enes Gönen and Semra Çomu
Boğaziçi University, Istanbul, Türkiye

Abstract

Examining contextual factors shaping the success of 5D BIM implementation in Europe, results reveal that while 91.5% utilize the technology for QTO and deep adoption remains limited, satisfaction increases significantly when a critical value threshold is exceeded, moving from single-use tasks to integrated workflows. Contractors are less satisfied by 5D BIM due to commercial risk, while medium-sized organizations and moderately complex projects exhibit a transition trap, resulting in lower satisfaction. Conversely, high national BIM maturity and Integrated Project Delivery amplify success. 5D BIM provides optimal value only when implemented as a comprehensive system, not merely as a standalone tool.

Introduction

The construction industry, despite its massive contribution to the global economy, has long been recognized as one of the least digitized sectors, characterized by stagnant productivity and a slow pace of technological adoption (Agarwal et al., 2016; Naji et al., 2024). However, the sector is currently undergoing a significant shift towards digital transformation to overcome these historic inefficiencies and modernize project lifecycles (Naji et al., 2024). Building Information Modeling (BIM), specifically its fifth dimension (5D BIM), offers a paradigm shift by integrating cost-related data with 3D models to improve efficiency, accuracy, and decision-making. The uses (features or functionalities) of 5D BIM include automated quantity takeoffs, cost estimation linked to model, cost planning and forecasting, change management, value engineering, cash flow analysis, cost control, progress payment validation, lifecycle cost analysis and claims management, delivering substantial advancements over traditional methods (Aibinu and Venkatesh, 2014; Charef et al., 2018; Kehily and Underwood, 2017; Lu et al., 2016; Stanley and Thurnell, 2014; Vigneault et al., 2020).

Despite these capabilities, the industry's perceptions of 5D BIM are divided. Enthusiasts praise it as a revolutionary tool that simplifies cost management, increases accuracy, and promotes collaboration, while skeptics argue that traditional tools are sufficient for similar tasks without the need for a BIM model, claiming that 5D BIM is overhyped. This divide highlights the need for robust empirical evidence to validate the benefits of 5D BIM and clarify its value proposition.

Existing research on 5D BIM has largely focused on technical case studies addressing the practical benefits of 5D BIM or developing frameworks and tools to support its adoption, with little research on which contextual factors shape practical outcomes. A critical gap persists in the literature: empirical studies investigating how specific factors influence the benefits of 5D BIM are scarce.

The motivation for this study stems from the lack of comprehensive research examining how project characteristics, user profiles, and features used affect the perceived success of 5D BIM in various construction projects. By addressing this gap, the study aims to provide actionable insights to optimize 5D BIM implementation. Through a survey of European construction professionals, it aims to provide evidence-based recommendations for developing 5D BIM adoption strategies.

Methodology

Data collection

A questionnaire survey was designed to collect data on respondent information, project characteristics, 5D BIM implementation, and perceived benefits of 5D BIM in construction projects. The survey targeted construction professionals with experience in projects where BIM was utilized in cost management processes across the European regions as defined by the Publications Office of the European Union (2026), excluding Russia and the Caucasus countries. This geographical scope was selected due to the widespread adoption of 5D BIM within the region and the researcher's ability to leverage an established professional network, which facilitated access to relevant and high-quality contacts.

The survey was structured into four sections. The first section, "Respondent Information", gathered demographic and professional data. Respondents were asked to specify their age, gender, total years of experience in the construction industry, BIM and 5D BIM, their current role/title and stakeholder category (e.g., client/owner, contractor, designer, consultant) with respect to both their current position and the reference project.

The second section, "Project Characteristics", collected specific details regarding the reference project. Respondents were asked to identify the project type (commercial, residential, metro, etc.), budget, duration, location, delivery method (design-bid-build, design-build, IPD, etc.), contract type (lump-sum, unit price, etc.), project's com-

plexity, BIM maturity level of the project country, and the BIM expertise level of the project team.

The third section, "5D BIM Implementation", examined the practical application and workflow of BIM in cost management processes. Respondents were asked to describe their workflow processes through an open-ended question, and to select the 5D BIM uses employed in the reference project and the software tools utilized for implementation.

The final section, "Benefits of 5D BIM in Cost Management", assessed the extent to which respondents agreed that 12 different expected benefits were observed in their reference projects using a 5-point Likert scale (ranging from 1-Strongly Disagree to 5-Strongly Agree). Respondents were asked to select "Not Relevant" if a specific outcome was not a targeted project goal. Additionally, an open-ended question was included to invite participants to share specific examples or anecdotes, adding qualitative depth to the analysis.

The survey was hosted on Google Forms, with settings configured to collect email addresses to ensure non-anonymous responses, allowing verification of respondents' identities and relevance.

A targeted survey was conducted with construction professionals experienced in 5D BIM within Europe. A multi-channel sampling approach, primarily utilizing targeted LinkedIn searches (e.g., "5D BIM cost") and professional referrals, built an initial pool of 236 potential participants. Candidates were screened against strict eligibility criteria requiring the practical use of at least one 5D BIM functionality (detailed in Figure 1) on a construction project in Europe. Excluding unreachable or ineligible contacts yielded 163 qualified invitees. Eligible professionals were invited via multiple communication channels, with information provided on the study scope and confidentiality. In total, 59 valid responses were collected between April and May 2025, corresponding to a response rate of 36.2% among qualified invitees. While this network-driven sampling ensured relevance, it inherently introduces a potential selection bias regarding professionals inactive on such platforms.

Data analysis

Survey data were initially screened and preprocessed using Microsoft Excel. Categorical responses were reviewed, consolidated where necessary, and infrequent categories were grouped under a general "Other" label. Project location data were aggregated into regional groupings based on EuroVoc classifications. For analysis, multiple-selection items were converted into binary variables, and two summary indicators were derived to capture the extent of 5D BIM adoption: the number of different 5D BIM functionalities used and the number of distinct software tools reported by each respondent.

Following preprocessing, the dataset was transferred to the Python programming environment for statistical analysis and visualization, utilizing the Pandas library for data manipulation and Matplotlib for generating figures.

Firstly, the extent of utilization was analyzed, where the frequency of use for each 5D BIM feature was calculated. The features were ranked based on the number of respondents utilizing them, and the results were visualized using a horizontal bar chart with a "progress-bar" style to clearly display the adoption rates relative to the total sample size.

Secondly, the perceived benefits were analyzed, where the industry's perception of 5D BIM benefits was assessed based on the 12 Likert-scale items. A diverging stacked bar chart was generated to illustrate the distribution of sentiments, separating positive (agree/strongly agree) and negative (disagree/strongly disagree) responses centered around the neutral option. Responses marked as "Not relevant" were excluded from the percentage calculations to ensure the analysis accurately reflected the views of those with direct experience.

Finally, to evaluate how different contextual factors impact the perceived success of 5D BIM, a composite metric termed "Overall Perceived Benefits" (OPB) was defined. This score was calculated for each respondent by averaging the numerical values of the 12 benefit items (scale 1–5), excluding "Not relevant" responses from the calculation. The distribution of OPB scores across various groups was analyzed using variable-width box plots, which display the median, quartiles, and range of the data. In these plots, the width of each box is proportional to the sample size of the respective subgroup, allowing for a simultaneous assessment of distribution and frequency. Given the total sample size of 59 and the resulting smaller subgroup populations, inferential statistical testing would lack the adequate statistical power to reliably detect effect sizes. Therefore, this descriptive visual approach was chosen over calculating precise confidence intervals. For visualization purposes, nominal categorical variables were sorted by median OPB score in descending order, while ordinal variables were sorted by their natural descending order. Even in cases where no significant relationship was observed, variables were presented to utilize the box widths representing frequency of the group as a descriptive tool, thereby providing essential context regarding the profile of the respondents and the characteristics of their referenced projects.

Open-ended responses regarding specific project experiences, challenges, and benefits were subjected to thematic analysis to identify recurring narratives. Relevant qualitative evidence was interwoven directly into the discussion of quantitative results, enabling recurring themes to serve as a corroborative context that offers explanatory depth to the statistical observations.

Results and discussion

A total of 59 valid responses were collected from professionals who utilized BIM for cost management in their reference projects located in 19 European countries. Figure 1 illustrates the adoption rates of various 5D BIM functionalities. The data reveals a striking disparity between the most common use case and all other functionalities. An overwhelming majority of respondents (91.5%) utilize

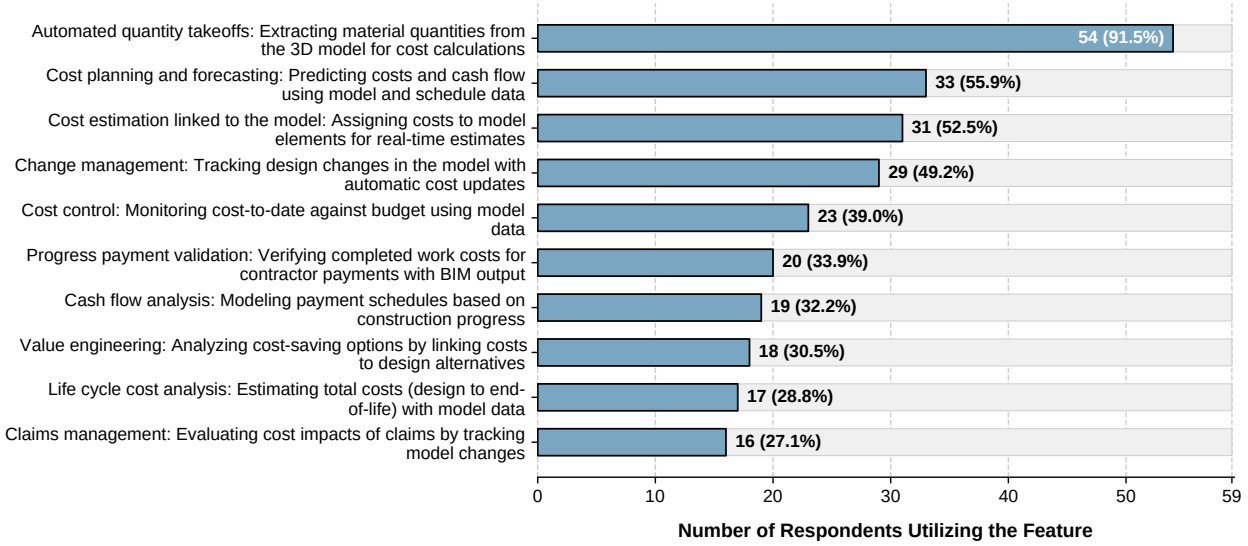

Figure 1: Utilization frequencies of 5D BIM features in reference projects (n=59)

5D BIM for ”Automated quantity takeoffs” making it the foundational, and for many, the only application of the technology.

In sharp contrast, the second most cited use drops significantly to 55.9%, indicating that many professionals equate 5D BIM solely with geometry-based quantity extraction rather than integrating cost data directly into the model environment or leveraging it for further financial analysis. This limited scope aligns with established literature; Mitchell (2012) observed that 5D is frequently reduced to the ”simple one-liner of Quantity Take Off” while Moses et al. (2020) confirmed that industry efforts have predominantly focused on using technologies for quantity extraction rather than fully integrated cost management. This exposes a prevalent definitional ambiguity: although Charef et al. (2018) identify a theoretical consensus defining 5D BIM as the ”cost” dimension, practical application reveals a stark divergence in what the cost dimension actually entails.

This quantitative observation is corroborated and critiqued by the qualitative findings from the open-ended survey questions. Several respondents argued that automated quantity extraction is merely a prerequisite but not the definition of 5D BIM. One respondent explicitly stated that ”true 5D BIM begins only after going beyond the quantity takeoff” implying that those who stop at quantity takeoff cannot claim to be fully utilizing 5D BIM. This dichotomy suggests that the industry is currently operating with a ”two-tier” definition of 5D BIM: a broad, entry-level tier focused on quantity takeoff (QTO), and a narrower, mature tier focused on comprehensive cost management.

Beyond automated quantity takeoffs, adoption rates cluster at moderate to low levels. Approximately half of the respondents reported using 5D BIM for ”Cost planning and forecasting” (55.9%), ”Cost estimation linked to the model” (52.5%), and ”Change management” (49.2%), indicating partial integration beyond geometry-based counting. All remaining functions including ”Cost control” (39.0%),

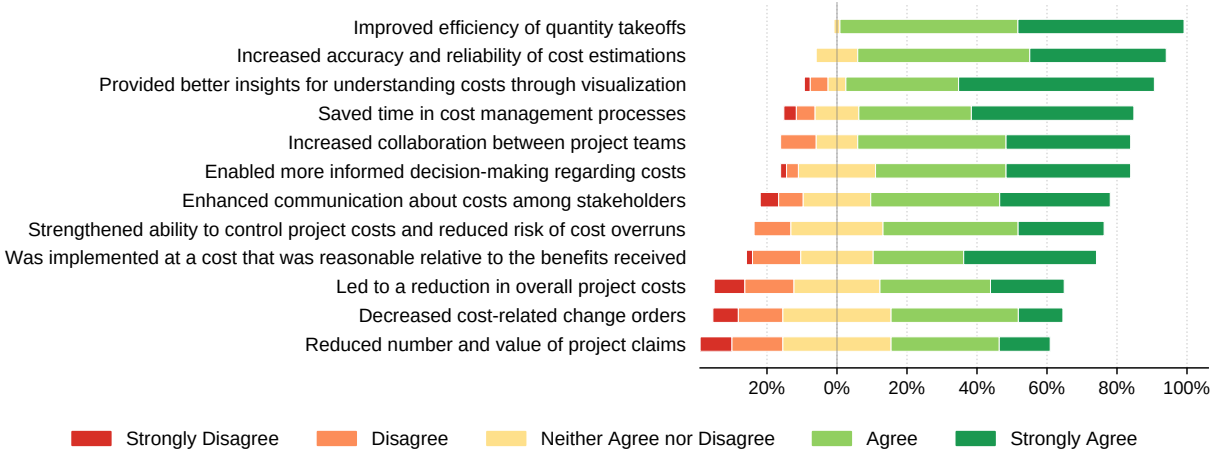

Figure 2: Perceived benefits of 5D BIM implementation (sorted by level of agreement)

”Progress payment validation” (33.9%), ”Cash flow analysis” (32.2%), and ”Value engineering” (30.5%) and ”Lifecycle cost analysis” (28.8%) and ”Claims management” (27.1%) were reported by fewer than 40% of respondents, reflecting that these specialized downstream tasks are currently the least common implementations of 5D BIM.

Turning from the breadth of adoption to the perceived impact, Figure 2 illustrates a predominantly positive reception of 5D BIM, based on the survey responses. Across all twelve queried benefits, the proportion of respondents expressing agreement (combining ”Agree” and ”Strongly Agree”) consistently outweighs those expressing disagreement. This consensus suggests that, despite the variations in adoption maturity discussed earlier, the technology delivers tangible value to those who implement it.

The most significant gains are perceived in the foundational tasks of cost management. ”Improved efficiency of quantity takeoffs” emerged as the top-rated benefit, followed closely by ”Increased accuracy and reliability of cost estimations.” This statistical finding is strongly corroborated by the qualitative feedback; respondents repeatedly emphasized that linking the Bill of Quantities (BOQ) directly to the 3D model creates an ”objective and consistent dataset” thereby accelerating the process and significantly reducing the risk of human error associated with manual calculations. This aligns with recent findings by Mohd Saupi and Ismail (2024), who reported that improved cost estimation remains a primary driver for adoption, with professionals emphasizing 5D BIM’s capacity to produce more precise and reliable financial projections compared to traditional methods.

Complementing these foundational gains, the literature emphasizes that 5D BIM extends its value into the dynamic phases of project delivery by enhancing decision-making and collaboration. Eldin et al. (2024) highlight that the technology facilitates real-time visualization and analysis of cost data, which allows for continuous financial forecasting and proactive risk mitigation rather than mere reactive corrections. Furthermore, Pishdad and Onungwa (2024) argue that integrating cost data into the model fosters a more transparent collaborative environment, effectively shifting cost management from isolated, convoluted spreadsheets to a shared, visual 3D format where assumptions can be easily challenged and verified by the entire project team.

To evaluate the impact of contextual factors on 5D BIM success, Overall Perceived Benefit (OPB) scores were analyzed using variable-width box plots. These figures simultaneously illustrate the statistical distribution of scores along the horizontal axis and the relative sample size of each subgroup through the vertical width of the boxes.

Figure 3 displays the distribution of OPB scores categorized by experience levels and Figure 4 by respondent age. The average age of the sample is approximately 35 years old, with 12 years of experience in construction, 8 years in BIM, and 6 years in 5D BIM, calculated based on the weighted mean of range midpoints. Both figures show stable medians and overlapping ranges across all groups,

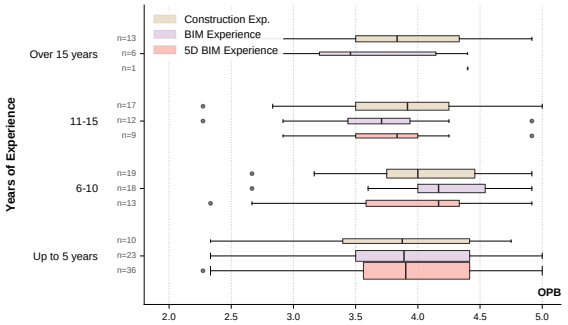

Figure 3: Distribution of OPB by experience in construction, BIM and 5D BIM

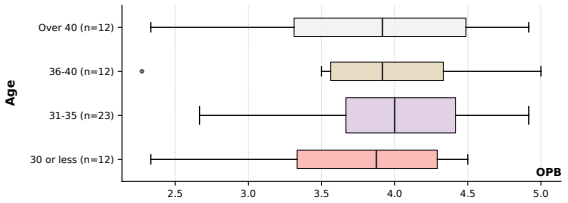

Figure 4: Distribution of OPB by respondent age

indicating that the positive perception of 5D BIM benefits remains consistent regardless of the length of professional experience and age.

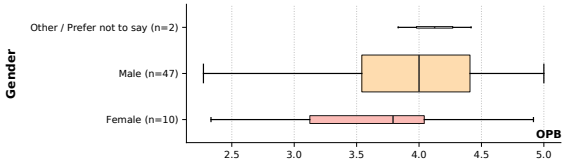

Figure 5: Distribution of OPB by gender

Figure 5 presents OPB scores by gender, reflecting a sample distribution with a larger male cohort (n=47) compared to the female group (n=10). While the male subgroup exhibits a slightly higher median, the notable difference in group sizes suggests that this observation should be interpreted within the context of the sample’s demographic composition, rather than as a definitive indicator of gender-based divergence in 5D BIM perception.

Figure 6 characterizes the respondents’ professional profiles at the time of the survey. The sample is notably dominated by ”BIM & Digital Construction” group (n=23), reflecting that 5D BIM is still largely a specialized discipline driven by domain experts rather than general project management staff. While smaller groups like ”Project Managers & Site Engineers” (n=10) and ”Executive Leadership & Founders” (n=7) suggest higher satisfaction, the BIM specialist group exhibits a wider range of OPB scores.

Figure 7 reveals a ”benefit asymmetry” across stakeholder roles. Although Contractors constitute the largest group in the reference project (n=22), they report a lower median OPB score compared to other groups. Qualitative findings further suggest that this lower perception among Contractors may be linked to commercial sensitivities rather than technical implementation alone. The high level of cost transparency required by 5D BIM may conflict with com-

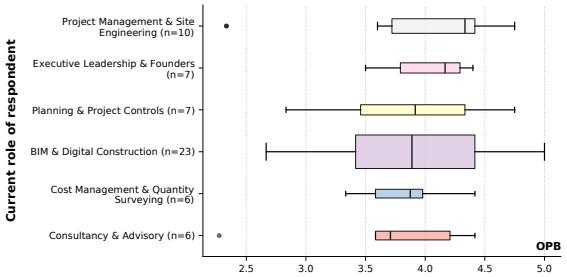

Figure 6: Distribution of OPB by current role of the respondent

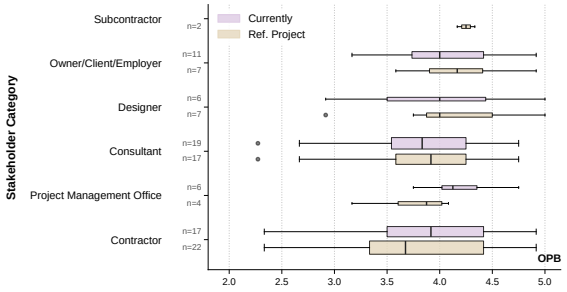

Figure 7: Distribution of OPB by current stakeholder category of the respondent and the stakeholder category in the reference project

petitive contracting environments where profit margins are guarded, and the requirement to share granular cost data within a shared model can be viewed as a commercial risk rather than a benefit, potentially tempering the enthusiasm for 5D adoption among contractor organizations. This stance is substantiated by Guo et al. (2019), who demonstrated that BIM-enabled transparency can directly impact contractors' interests by exposing proprietary resource allocations and cost structures that previously served as hidden sources of profit.

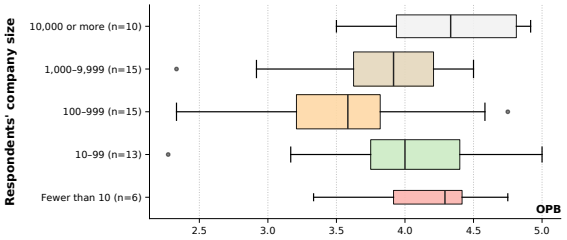

Figure 8: Distribution of OPB by the number of employees of the company that the respondent was/is working in the reference project

Figure 8 and Figure 9 illustrate a striking non-monotonic, U-shaped relationship across both company size and project complexity, where perceived benefits peak at the extremes and dip significantly in the intermediate categories. In terms of company size, the high satisfaction among small firms suggests organizational agility, while the success of large corporations (over 10,000 employees) likely stems from the resource abundance required to enforce standardization and specialized training, aligning with a resource-based view of firm capabilities.

Conversely, mid-sized firms (100–999 employees) appear caught in a "transition trap" facing the interoperability challenges of scaling without the institutional capacity of larger

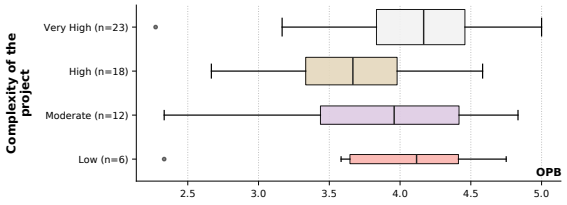

Figure 9: Distribution of OPB by project complexity

entities. This aligns with Bosch-Sijtsema et al. (2017), who argue that medium-sized contractors often face a specific disadvantage; they are compelled to compete with larger firms on complex projects yet lack the comparable in-house R&D resources and financial buffer to overcome the high investment costs and knowledge barriers of BIM implementation. A parallel U-shaped pattern in project complexity reinforces this observation, suggesting that while 5D BIM offers quick wins for simple projects and becomes indispensable for high-complexity ones, intermediate projects occupy a "zone of friction" where the implementation effort is felt most acutely relative to the rewards.

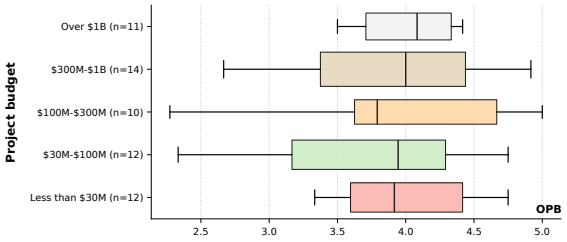

Figure 10: Distribution of OPB by project budget

Figure 10 displays the relationship between project budget and OPB scores. Within the studied sample, no significant trend was observed; the median OPB scores appeared consistent across all financial tiers.

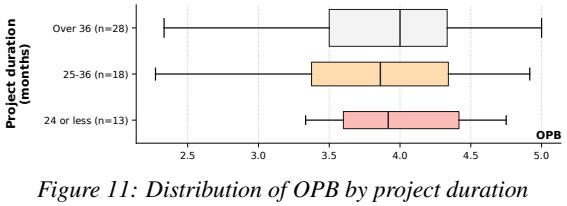

Figure 11: Distribution of OPB by project duration

Figure 11 presents the analysis regarding project duration. Due to data skewness, where nearly half the respondents (n=28) concentrate in the "Over 36 months" category, no meaningful relationship was observed.

Figure 12 demonstrates a clear positive correlation between the national BIM maturity level and the perceived benefits of 5D BIM. Unlike the variable project characteristics discussed earlier, the national environment shows a linear progression: as the maturity level rises from "Emerging or Low" (n=14) to "High" (n=8), the median OPB score steadily increases. This empirical finding supports the macro-micro relationship established by Prabhakaran et al. (2021), who argue that a mature national ecosystem characterized by established mandates and standardized protocols significantly amplifies organizational implementation suc-

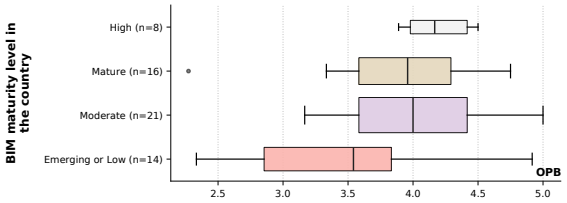

Figure 12: Distribution of OPB by BIM maturity level in the project country

cess by reducing external friction, reflecting the impact of institutional logics on technology adoption.

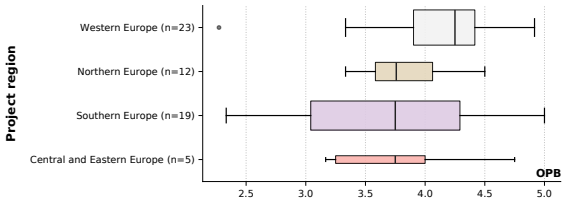

Figure 13: Distribution of OPB by project region

Figure 13 corroborates this finding through a geographical lens, highlighting Western Europe as the region with the highest perceived benefits. This group, which constitutes the largest segment (n=23) and includes respondents from the United Kingdom (14), Germany (5), Luxembourg (2), the Netherlands (1), and Austria (1), exhibits the highest median score. This superior performance can be attributed to the mature BIM adoption landscape in these countries, particularly the UK and Germany, where rigorous standards and widespread engineering familiarity create a conducive environment for 5D integration. In contrast, the remaining regions report comparatively lower median scores, likely reflecting varying degrees of market maturity. These include Southern Europe (n=19), dominated by respondents from Turkiye (16) alongside Portugal (2) and Italy (1); Northern Europe (n=12), comprising Lithuania (4), Denmark (2), Finland (2), Norway (2), Latvia (1), and Sweden (1); and Central and Eastern Europe (n=5), consisting of respondents from Hungary (1), Kosovo (1), Romania (1), Serbia (1), and Slovenia (1).

Qualitative insights from these regions suggest that these lower outcomes are driven by systemic barriers rather than individual lack of skill. Respondents specifically pointed to the absence of established national cost databases and a specialized BIM education as primary obstacles. This observation is empirically supported by the case of Türkiye, the dominant constituent of the Southern Europe group, where the lack of official government mandates and standardized cost data has been identified as a critical barrier, keeping adoption at a ”nascent” stage compared to the mature, policy-driven ecosystem of the UK (Sari and Pekeriçli, 2020; Omotayo et al., 2025). This validates the correlation between a supportive national infrastructure and the successful realization of 5D benefits.

Figure 14 examines the influence of the project team's BIM expertise on OPB scores. A visual inspection does not indicate a distinct, linear trend across all categories

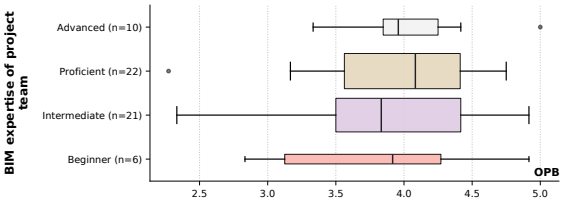

Figure 14: Distribution of OPB by BIM expertise of the project team

(from ”Beginner” to ”Advanced”). However, a closer look at the two largest subgroups, ”Intermediate” (n=21) and ”Proficient” (n=22), reveals a noticeable positive shift; the ”Proficient” group exhibits a higher median score compared to the ”Intermediate” cohort. This observation suggests that while the overall relationship remains complex across the spectrum, the transition from an intermediate to a proficient level of collective expertise serves as a discernible factor in realizing higher perceived benefits.

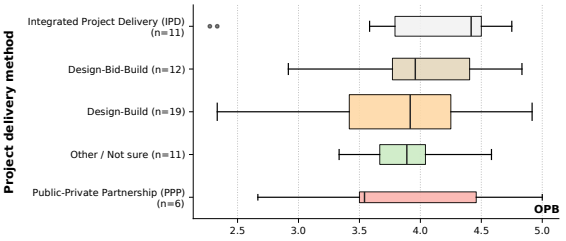

Figure 15: Distribution of OPB by project delivery method

Figure 15 displays the relationship between project delivery methods and OPB scores. The Integrated Project Delivery (IPD) group (n=11) demonstrates the highest median score with a relatively compact distribution. This aligns with the expectation that the collaborative structure of IPD creates a favorable environment for 5D BIM implementation compared to traditional methods such as Design-Bid-Build, Design-Build, Public-Private Partnership (PPP). This pattern is consistent with the broader literature, which identifies IPD as the optimal delivery method for BIM; its multi-party risk-sharing structure and reward mechanisms align commercial interests, helping to mitigate the financial transparency risks feared by contractors, thereby fostering early contractor involvement and seamless data integration, whereas traditional methods often fragment the very information flows that 5D BIM relies upon (Piroozfar et al., 2019; Karasu et al., 2022).

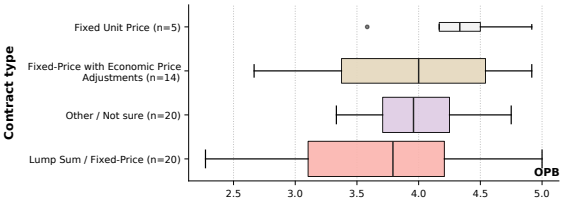

Figure 16: Distribution of OPB by contract type

Figure 16 examines OPB scores across contract types, revealing that despite minor variations between categories such as 'Fixed Unit Price' and 'Lump Sum / Fixed-Price,' the overall distribution patterns remain largely overlapping

with similar medians; consequently, no distinct relationship could be established between the specific pricing mechanism and the perceived benefits of 5D BIM.

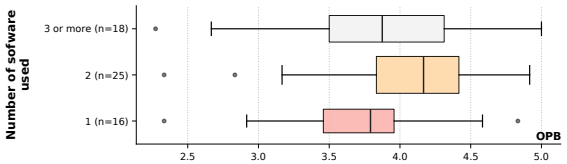

Figure 17: Distribution of OPB by the number of software programs each respondent mentioned using for 5D BIM

Figure 17 correlates the diversity of the software toolkit with OPB scores, revealing that the highest and most consistent satisfaction is found in the ”2 software” category (n=25). This suggests an optimal workflow often pairs a primary design tool, most notably Autodesk Revit (mentioned by 40 respondents), with a specialized coordination or estimation platform. In contrast, the ”1 software” group (n=16) reports a notably lower median score, likely reflecting the limitations of performing 5D tasks solely within a design authoring tool, while the ”3 or more” group (n=18) shows diminished returns, potentially due to complexity. Following Revit, the most frequently cited tools were Navisworks (29), RIB CostX (11), Synchro (10), Bexel Manager (8), Tekla (4), RIB iTWO (4), and Solibri (3), with 24 other programs mentioned by one or two respondents.

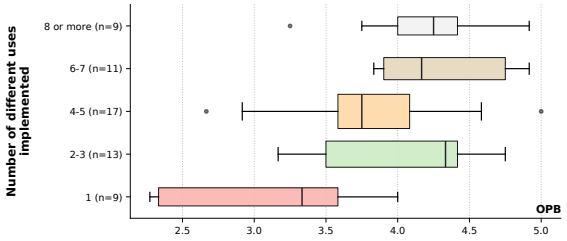

Figure 18: Distribution of OPB by the number of 5D BIM uses implemented

Figure 18 stands as the empirical validation of the ”True 5D BIM” concept, offering perhaps the most critical insight of the entire study. It establishes a robust positive correlation between the depth of implementation and perceived success. The group implementing only ”1 use” (n=9) reports the lowest median satisfaction, reinforcing the earlier observation from Figure 1 that limiting 5D BIM to a single function (predominantly quantity take-off) fails to unlock the technology’s potential.

However, the data reveals a dramatic ”value threshold” immediately after this initial stage. The jump to the ”2-3 uses” category (n=13) results in a sharp increase in the median OPB score, surpassing even the intermediate groups. This indicates that moving beyond isolation, by integrating just one or two additional functions (e.g., coupling QTO with Cost Estimation or Progress Monitoring), creates a synergistic effect that instantly amplifies value. This aligns with the findings of Disney et al. (2022) and Sun et al. (2024), who demonstrate that the interdependence of multiple BIM uses creates a ”systemic” benefit where the whole is greater than the sum of its parts, leading to significantly higher user satisfaction and project performance compared to fragmented tools. The trend continues to favor holistic application, with the ”8 or more” group (n=9) maintaining high satisfaction. This confirms that 5D BIM is not merely a tool for a specific task but a systemic methodology; the more comprehensively its diverse functions are utilized, the greater the return on investment.

Conclusions

This paper examined the contextual factors influencing the perceived success of 5D BIM in the European construction sector. By analyzing responses from 59 professionals across 19 countries, the research bridges the gap between theoretical potential and practical reality. The findings reveal a critical dichotomy: while most practitioners equate 5D BIM with simple quantity take-offs (QTO), the data confirms that this limited approach yields the lowest satisfaction. Instead, a distinct ”value threshold” exists where integrating cost estimation or progress monitoring via a dual-platform workflow significantly amplifies success, validating 5D BIM as a systemic, integrated methodology rather than a singular task.

Contextual analysis highlights that success follows a nonlinear, U-shaped pattern; mid-sized firms and intermediate projects often face a ”transition trap” lacking both the agility of small firms and the institutional resources of large corporations. Furthermore, a ”benefit asymmetry” emerges among stakeholders; contractors report lower satisfaction levels, likely due to the commercial risks associated with 5D BIM’s high transparency, which can conflict with competitive contracting norms by exposing proprietary cost structures. Conversely, the results confirm that a supportive ecosystem, characterized by high national BIM maturity and collaborative delivery methods like Integrated Project Delivery (IPD), is a fundamental catalyst for realizing the full potential of 5D BIM.

These results should be considered in light of several limitations. Most notably, the sample size, constrained by the specialized nature of the domain, reduces the statistical power for subgroup analyses, as small frequencies within certain subcategories preclude the calculation of robust effect sizes and result in wide confidence intervals. Furthermore, the analysis relies on perceived benefits as a surrogate for objective performance, a measure that indicates technological acceptance but does not necessarily equate to quantifiable financial profitability or hard project metrics. Additionally, the geographic distribution of the sample introduces potential geographic bias. Specifically, the heavy dominance of Turkish respondents in the Southern Europe category, while providing valuable context regarding emerging market barriers, may limit the generalizability of regional comparisons and mask country-specific differences, particularly regarding applicability to non-European regulatory contexts. Future studies should address these limitations by applying weighted benefit criteria and complementing perception-based surveys with quantitative case

studies that incorporate actual cost variance data and schedule performance metrics. This approach would validate the perception-behavior link and strengthen causal inference, while also expanding the assessment of return on investment (ROI) to encompass the operational stage of the facility's life cycle.

Abstract

The selection of construction methods is a critical factor in linear infrastructure projects, yet current practice remains largely experience-driven. As is evident from the extant literature, multi-criteria decision-making, rule-based and algorithmic approaches are applied to support method selection. The present systematic literature review analyses these approaches with respect to input parameters, output structures, and validation strategies. The findings indicate a predominance of project-level ranking models and limited spatial resolution. Key deficiencies identified include inadequate scalability, deficient integration of costs and restricted applicability to corridor-scale decision-making. The review identifies these gaps as central challenges for future data-driven decision-support systems.

Introduction

The accelerated expansion of energy transmission infrastructure is a key prerequisite for achieving climate and energy policy goals in many countries. In Germany, too, the expansion of transmission grids poses a particularly complex planning challenge. This complexity along underground transmission routes arises from heterogeneous environmental conditions, dense existing infrastructure and highly variable geotechnical conditions along the routes (Ahmels & Bruns, 2016; TenneT TSO GmbH, 2025). In particular, soil conditions, groundwater conditions, intersection types, access restrictions or environmental restrictions can change significantly over short distances. Consequently, the construction methods selected in response to these conditions along the corridor significantly influence costs and time, environmental impacts and technical risks. Inadequate choices can increase costs, prolong construction periods and intensify environmental-related constraints (Neuling, 2013). In this context, the selection of suitable construction methods, such as open-cut excavation or horizontal directional drilling (HDD), plays a decisive role in project execution. Linear infrastructure projects are typically realised along extended corridors with spatially varying boundary conditions, where construction-related constraints may change over short distances. As a result, construction method selection is not a single project-level decision but a sequence of locally constrained choices made along the corridor. Figure 1 illustrates such a construction context by showing an open-cut excavation along a linear infrastructure corridor. Furthermore it highlights the spatial setting in which construction method selection translates into locally constrained execution decisions along the route.

Figure 1: Open-cut construction method along a linear infrastructure corridor (source: Max Bögl Group)

Despite their relevance, the selection of construction methods for linear infrastructure projects is still predominantly based on expert judgement, experience-based heuristics, and manually prepared feasibility studies. While such approaches benefit from domain expertise, they are difficult to standardise, reproduce, or scale across long corridors with heterogeneous boundary conditions. In contrast, a data-driven construction method selection approach could have the potential to support spatially resolved, segment-oriented decision-making. Construction methods would be assessed locally along the corridor, enabling more transparent and reproducible decision-making.

Against this backdrop, digital planning tools are increasingly being explored to operationalise such spatially resolved decision-making in infrastructure projects. Therefore research and practice have made significant progress in the digitalisation of infrastructure planning. Geographic information systems (GIS) have become a core technology for the integration and analysis of spatial data in corridor and route planning, enabling the systematic consideration of environmental constraints, topography and existing infrastructure (Schito & Grassi, 2015).

GIS-based approaches are widely used for route optimisation, spatial conflict analysis, and corridor evaluation, often in combination with resistance-based models or multi-criteria decision analysis (MCDA) (Malczewski, 2006; Steuer & Donaubauer, 2012). Within the context of digital construction, these developments form part of a broader convergence of geospatial modelling and simulation-based planning and increasingly shape research in construction informatics (Linner, 2024). They primarily address the question of *where* infrastructure should be located, while higher levels of automated or algorithmic decision support for construction-related decisions remain limited in practice (Pan M. et al., 2018).

However, once a route has been determined due to approval decisions, land use restrictions or agreements with stakeholders, the focus of planning shifts from route selection to construction. At this stage, the key question is *how* the infrastructure should be built along heterogeneous corridor segments. While tunnel construction and microtunnelling research has extensively addressed method and machine selection under geological uncertainties, the systematic transfer of such decision-making concepts to corridor-based linear infrastructure remains limited (Pan M. et al., 2020; Borrmann, 2024). Existing GIS-based planning tools and digital planning environments predominantly support data management, visualisation, and documentation of route alignments, while providing limited support for the automated derivation of construction methods or execution variants (Pan M. et al., 2020; Borrmann, 2024). Similarly, BIM and simulation-based approaches increasingly enable detailed modelling of construction processes, but they often lack integration with large-scale geodata sets or the segment-by-segment decision logic required for long linear projects (Borrmann A. et al., 2015; Borrmann, 2024; Arashpour, M. et al., 2025). Consequently, planning and execution data remain fragmented, and decisions about construction methods are rarely supported by transparent, reproducible, and data-driven models that work along entire corridors.

Recent research highlights the growing potential of integrated, model-based decision support systems that link geospatial data, geotechnical information and execution-related parameters within a unified analytical framework (König, M. et al., 2021; Pache, Scharun, & Hochmuth, 2024). At the same time, several authors emphasise the ongoing challenges associated with data heterogeneity, expert dependency and limited interoperability between planning and execution models (Schito & Grassi, 2015; Arashpour, M. et al., 2025). These limitations are particularly evident in the selection of construction methods, which remains one of the least standardised and most experience-driven steps in linear infrastructure planning. Against this backdrop, a systematic understanding of existing data- and model-based approaches to the selection of construction methods is needed.

On the one hand, individual studies propose decision support models based on multi-criteria evaluation, rule-based logic or hybrid algorithmic approaches. On the other hand, there is still a lack of a consolidated overview of these methods, their input specifications and output structures, and their validation strategies.

This study addresses this need by conducting a systematic literature review and deriving a structured taxonomy of decision-support approaches for construction method selection in linear infrastructure projects.

Building on the identified gaps, ongoing research aims to develop GIS-based, segment-oriented decision-support workflows that translate corridor-scale constraints into transparent method assignments and link them to cost and schedule evaluation.

Research Objective and Questions

The objective of this systematic literature review is to identify data- and model-based approaches for selecting construction methods in linear infrastructure projects. These approaches will then be classified and summarised. The review focuses on methodological contributions that support the selection of construction methods under heterogeneous segment conditions. Beyond identifying families of methods, the overview aims to systematically consolidate the types of input parameters used for decision-making. Moreover, the different forms in which decision results are provided in the existing approaches are consolidated. In the final step, validation strategies and frequently reported limitations are to be evaluated.

To achieve this goal, three specific research questions were formulated.

RQ1: Which data- and model-based approaches for the selection of construction methods in linear infrastructure projects are described in the scientific literature?

RQ2: Which input parameters (e.g. geotechnical, geometric, ecological or economic factors) and which output structures (e.g. rankings, suitability assessments, cost or time indicators or method assignments) are used in these approaches?

RQ3: How are the proposed decision models validated and what methodological limitations are discussed in literature?

Methodology – Systematic Review Design

In order to address the research objective and the three research questions defined in Chapter 2, a systematic literature review was conducted. The methodological design enables a structured and transparent analysis of data- and model-based approaches to construction method selection in linear infrastructure projects. It further ensures the reproducibility of both the synthesis and the underlying selection process. The review follows established guidelines for systematic reviews in civil engineering research and is aligned with the PRISMA framework (Page, M. et al., 2021).

Review Protocol and Analytical Framework

The methodological workflow of the review is divided into five consecutive phases: definition, search, selection, analysis and synthesis. Figure 2 provides an overview of the analytical workflow used in this study.

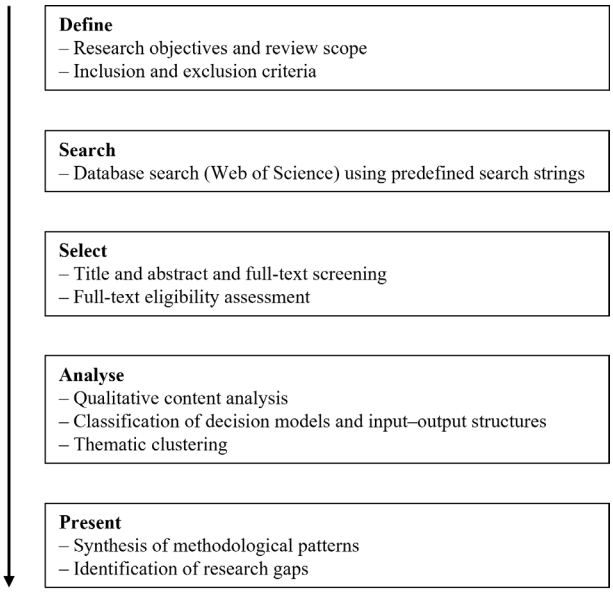

Figure 2: Methodological workflow of the systematic literature review

Literature Search Strategy

The literature search followed a transparent and reproducible procedure in accordance with the PRISMA framework and comprised literature identification, scope restriction, full-text eligibility assessment, and qualitative synthesis. The search was performed using the Web of Science Core Collection and limited to peer-reviewed journal articles and conference proceedings published in English between 2016 and January 2026.

Web of Science was selected as the primary database due to its structured indexing and broad coverage of engineering and construction-related outlets, supporting a consistent and reproducible review process.

Grey literature, such as technical reports or non-peer-reviewed project documentation, was not systematically included.

A predefined search strategy was applied on 12 January 2026 using three thematic keyword groups addressing (i) construction method selection, (ii) decision-support approaches, and (iii) linear infrastructure contexts. Keywords were combined using Boolean operators (OR within groups; AND between groups).

The search query was conducted using a topic search (TS), covering title, abstract, and author keyword fields. All search terms are summarised in Table 1. On top, subject-category filters were defined to restrict the results to relevant research fields. The selected categories included Engineering Civil, Construction & Building Technology, Materials Science Multidisciplinary, Physics Applied, Environmental Sciences, Computer Science Information Systems, Engineering Multidisciplinary and Geosciences Multidisciplinary. These categories were deliberately defined beyond the core field of civil engineering to ensure a broader coverage of related research domains and to capture potentially relevant methodological approaches from adjacent disciplines. Additional records were assigned to further categories but were not explicitly considered as primary filters.

After applying these filters, 177 publications remained from the initial 284 records for further screening.

Table1: Keyword groups and associated search terms used for the literature search

Keyword group	*Associated keywords*
Construction method selection	*construction method; construction technique; method selection; installation method; trenchless; horizontal directional drilling; HDD; tunnell; TBM selection*
Decision-support approaches	*decision support; select; multi-criteria; multicriteria; MCDA; MCDM; AHP; TOPSIS; ELECTRE; PROMETHEE; fuzzy; rule-based*
Linear infrastrucure context	*linear infrastructure; corridor; route; alignment; pipeline; cable; utility; underground infrastructure; transmission line*

This was followed by a two-stage screening process. First, titles and abstracts were reviewed for thematic relevance. Records that did not relate to civil engineering or construction or that did not focus on construction methods or processes were excluded at this stage. The full-text articles were then reviewed for suitability in terms of their methodological relevance. Studies were excluded in the full-text phase if they did not contain an explicit selection or comparison of construction methods, did not have a formal decision-making or evaluation model, or were purely descriptive case studies without transferable methodological contributions. The entire screening and selection process is summarised in the PRISMA flow diagram shown in Figure 3.

Data Extraction and Synthesis Approach

A structured data extraction scheme was used for the final selection of the included studies. Each publication was analysed with regard to (i) the type of decision support approach, (ii) the input parameters considered, (iii) the structure of the decision results, and (iv) the validation strategy applied. The extracted information was summarised using qualitative content analysis and thematic clustering. This process enabled the classification of decision support methods into methodological families, the identification of frequently used parameter categories, and the evaluation of validation practices and methodological limitations.

Results – Classification and Synthesis of Approaches

This section synthesises the results of the systematic review in accordance with the three research questions. The included studies were analysed with respect to their underlying decision-support approaches (RQ1), considered input parameters and output structures (RQ2), and applied validation strategies and methodological limitations (RQ3).
Table 2 provides an overview of the studies included in the qualitative synthesis.

Types of Decision-Support Approaches (RQ1)

The reviewed literature reveals three dominant families of decision-support approaches for construction method selection in linear infrastructure projects: (i) multi-criteria decision-making (MCDA) methods, (ii) rule-based and knowledge-based models, and (iii) hybrid or algorithmic decision approaches (Aschilean & Giurca, 2018; Matthews J. et al., 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Parka, A. et al., 2020; Alinizzi, M. et al., 2020; Lin, S.S. et al., 2023; Leu, S.S. et al., 2025).

In terms of digital decision support, the identified method families can be interpreted as distinct digital decision-support paradigms, ranging from expert-driven rule-based knowledge models to algorithmic and hybrid approaches with increasing degrees of automation (Pan M. et al., 2018; Pan M. et al., 2020).

MCDA-based approaches constitute the largest group of identified methods. These studies typically employ established techniques such as the Analytic Hierarchy Process (AHP), the Analytic Network Process (ANP) or fuzzy extensions to rank alternative construction methods based on weighted evaluation criteria (Aschilean & Giurca, 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Alinizzi, M. et al., 2020; Lin, S.S. et al., 2023). MCDA approaches are predominantly applied at the project level and aim to support early-stage decision-making under multiple, often conflicting criteria.
While these methods provide transparent and structured rankings, they generally rely on predefined weights and are sensitive to expert judgement (Aschilean & Giurca, 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Alinizzi, M. et al., 2020; Lin, S.S. et al., 2023).

Rule-based or expert-driven approaches formalise expert knowledge in the form of deterministic rules or decision trees (Matthews J. et al., 2018; Parka, A. et al., 2020). These models are commonly applied in more detailed planning or design stages and focus on technical feasibility and constraint satisfaction (Marinos V. et al., 2018; Parka, A. et al., 2020). Although such approaches enable consistent decision logic, their transferability is often limited by context-specific rule sets (Marinos V. et al., 2018; Parka, A. et al., 2020).

Hybrid and algorithmic approaches combine rule-based feasibility checks with optimisation or simulation techniques (Matthews J. et al., 2018; Leu, S.S. et al., 2025). These models are typically applied at a segment based decision level and explicitly account for spatial variability along linear infrastructure corridors (Matthews J. et al., 2018; Leu, S.S. et al., 2025).

Compared to purely MCDA-based methods, hybrid approaches allow the assignment of different construction methods to individual segments and thus offer a higher degree of operational realism (Matthews J. et al., 2018; Leu, S.S. et al., 2025).

Input Parameters and Output Structures (RQ2)

Across the reviewed studies, input parameters can be grouped into four main categories: geological and geotechnical conditions, geometric characteristics, economic factors, and environmental or social aspects (Aschilean & Giurca, 2018; Matthews J. et al., 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Alinizzi, M. et al., 2020; Ma, P. et al., 2023; Lin, S.S. et al., 2023; Leu, S.S. et al., 2025).

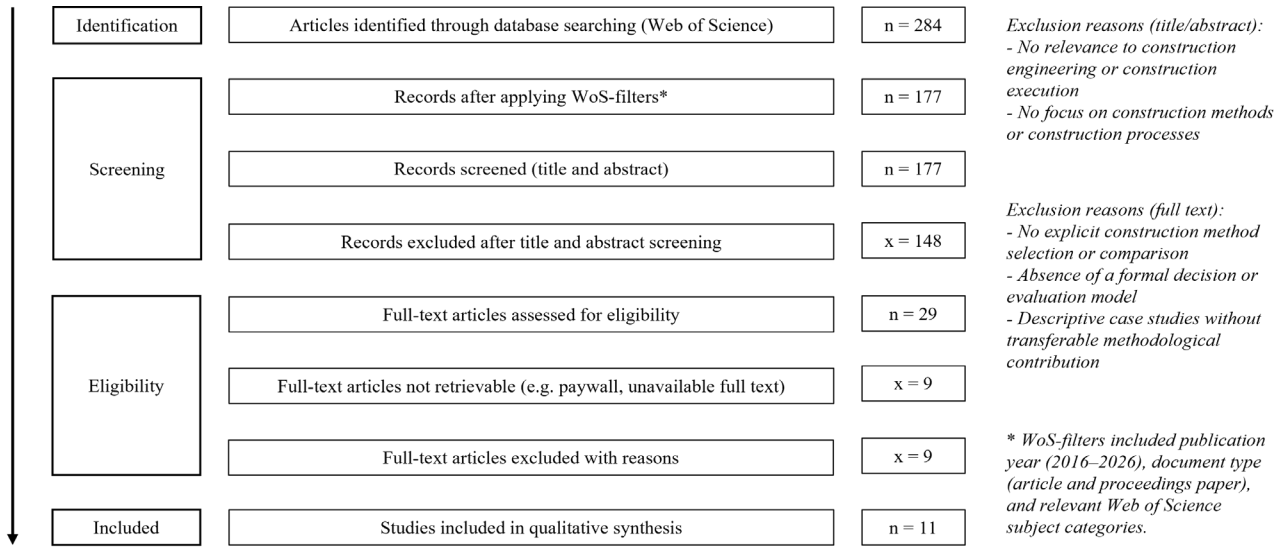

Figure 3: PRISMA flow diagram illustrating the literature search, screening, and study selection process

Geological and geotechnical parameters, such as soil type, groundwater conditions, and geomechanical properties, are considered in the majority of technically oriented models (Marinos V. et al., 2018; Matthews J. et al., 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Ma, P. et al., 2023; Leu, S.S. et al., 2025).

Geometric inputs typically include pipeline diameter, installation depth, alignment length, and crossing conditions (Aschilean & Giurca, 2018; Matthews J. et al., 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Ma, P. et al., 2023; Lin, S.S. et al., 2023).

Economic parameters, including construction cost and duration, are widely used across all methodological families (Aschilean & Giurca, 2018; Matthews J. et al., 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Parka, A. et al., 2020; Alinizzi, M. et al., 2020; Lin, S.S. et al., 2023; Leu, S.S. et al., 2025). Environmental and social criteria, such as emissions, traffic disruption, or societal impacts, are incorporated less consistently and are mainly addressed in sustainability-oriented MCDA studies (Zwierzchowska & Kuliczkowska, 2019; Alinizzi, M. et al., 2020; Rokstad, M. et al., 2025).

Regarding output structures, most approaches generate ranked lists or suitability scores for alternative construction methods (Aschilean & Giurca, 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Alinizzi, M. et al., 2020; Lin, S.S. et al., 2023). Some studies provide a single recommended method, while others report relative performance indicators or Pareto-optimal solutions (Marinos V. et al., 2018; Parka, A. et al., 2020; Leu, S.S. et al., 2025). Only a limited number of models explicitly assign construction methods at a segment level along a predefined alignment (Matthews J. et al., 2018; Leu, S.S. et al., 2025).

The findings highlight a clear dominance of ranking-based outputs and a lack of models that produce directly implementable, spatially explicit construction method assignments (Aschilean & Giurca, 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Alinizzi, M. et al., 2020; Lin, S.S. et al., 2023; Leu, S.S. et al., 2025).

Validation Strategies and Methodological Limitations (RQ3)

Validation strategies across the reviewed literature predominantly rely on illustrative case studies and scenario-based analyses (Aschilean & Giurca, 2018; Marinos V. et al., 2018; Matthews J. et al., 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Parka, A. et al., 2020; Alinizzi, M. et al., 2020; Ma, P. et al., 2023; Lin, S.S. et al., 2023; Leu, S.S. et al., 2025). Many studies demonstrate their proposed methods using single real-world projects or hypothetical examples (Aschilean & Giurca, 2018; Matthews J. et al., 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Parka, A. et al., 2020; Alinizzi, M. et al., 2020; Lin, S.S. et al., 2023; Leu, S.S. et al., 2025).

Simulation-based validation is applied in algorithmic and risk-oriented approaches, whereas sensitivity analyses are commonly used in MCDA-based models to assess robustness against weighting assumptions (Aschilean & Giurca, 2018; Matthews J. et al., 2018; Kwast-Kotlarek & Hełdak, 2019; Leu, S.S. et al., 2025).

Despite these validation efforts, several methodological limitations are recurrent. A strong dependence on expert input remains a key challenge, particularly in weighting criteria and defining rule sets (Aschilean & Giurca, 2018; Zwierzchowska & Kuliczkowska, 2019; Kwast-Kotlarek & Hełdak, 2019; Parka, A. et al., 2020; Lin, S.S. et al., 2023). Data availability and quality constraints limit the applicability of many models beyond their original case contexts (Marinos V. et al., 2018; Matthews J. et al., 2018; Ma, P. et al., 2023; Leu, S.S. et al., 2025).

Furthermore, most approaches lack integration with scheduling, cost control, or digital planning systems, which restricts their practical adoption in real-world project environments (Aschilean & Giurca, 2018; Matthews J. et al., 2018; Alinizzi, M. et al., 2020; Lin, S.S. et al., 2023; Leu, S.S. et al., 2025).

Discussion

Interpretation of Results and Methodological Trends

The results of the systematic review show that research on data- and model-based construction method selection for linear infrastructure projects is methodologically diverse but limited in operational depth. Although numerous decision-support approaches have been proposed, most outputs remain project-level rankings or suitability assessments.

They primarily support the decision-making process in the early stages and rarely reflect the spatial variability of real-world corridors. Multi-criteria decision-making approaches dominate the literature, offering transparent evaluation structures and enabling the integration of technical, economic, and environmental criteria. Their outcomes strongly depend on expert-defined weights and project-specific assumptions.

Rule- and knowledge-based models provide more detailed feasibility assessments but often suffer from limited transferability due to context-specific rule sets. Against this background, a small number of core contributions represent a methodological advancement by addressing construction method selection at a segment or corridor level. Matthews J. et al. (2018) demonstrate how rule-based feasibility constraints combined with optimisation logic enable differentiated method assignment along pipeline corridors. Leu, S.S. et al. (2025) extend this perspective by incorporating risk and robustness considerations through Pareto-optimal solution spaces. In contrast, Alinizzi, M. et al. (2020) and Lin, S.S. et al. (2023) provide structured multi-criteria assessment frameworks that largely remain within ranking-based decision paradigms.

Identified Research Gaps

In spite of these advances, several persistent research gaps emerge from the synthesis.

First, construction method selection is rarely conceptualised as a spatially distributed decision problem along predefined alignments. Most approaches abstract from corridor geometry and do not provide explicit segment-level method assignments.

Second, a gap exists between the availability of detailed geospatial and geotechnical data and their systematic integration into decision-support models. Although such data are frequently cited as inputs, they are seldom combined within modular, rule-based frameworks that enable automated and consistent method selection along entire corridors.

Third, the operational integration of decision models remains limited. Most studies provide rankings or qualitative recommendations without translating them into quantitative indicators for cost, duration, or resource demand, thereby constraining their applicability within scheduling, cost control, or digital planning systems.

When interpreted through an AI and digital construction lens, the reviewed approaches distinguish between knowledge-driven decision-support models, such as rule-based systems, and more data-driven or algorithmic approaches. Whereas knowledge-based models offer transparency and traceability, they exhibit limited scalability and adaptability to changing boundary conditions. Automated and hybrid approaches remain rare and are often constrained by data availability, interoperability challenges, and limited uncertainty handling (Pan M. et al., 2020; Linner, 2024). This highlights construction method selection as a promising yet underexplored application field for AI-enabled decision-support within integrated digital construction workflows.

Although this review focuses on peer-reviewed journal articles and conference proceedings to ensure methodological transparency and reproducibility, practice-oriented knowledge documented in grey literature is not systematically reflected. Technical guidelines, industry reports, and project documentation often contain detailed procedural knowledge on construction method selection.

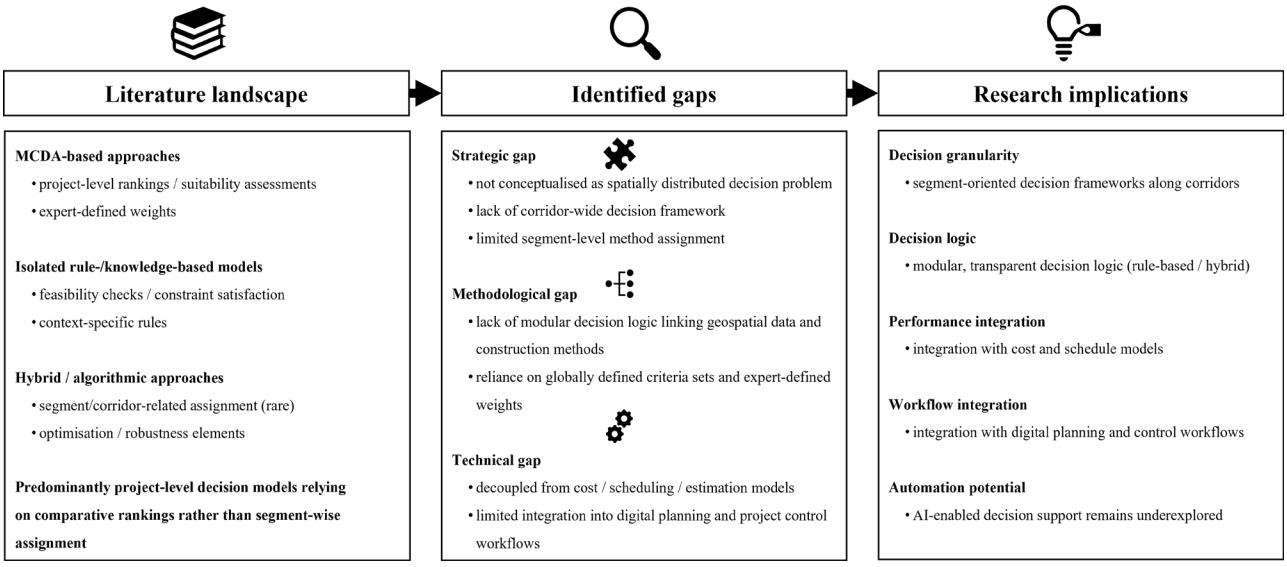

Figure 4: Conceptual synthesis framework derived from the systematic review

However, heterogeneous quality, limited traceability, and a lack of formal validation complicate systematic synthesis. From a scientific perspective, grey literature could be incorporated in complementary research designs, such as structured expert elicitation or qualitative case studies. While such approaches may support the transfer of practice-driven knowledge into reproducible decision-support models, they fall outside the scope of this systematic literature review.

Furthermore, another methodological limitation of this review lies in the restriction of the literature search to a single bibliographic database. While this supports consistency and reproducibility, relevant studies indexed exclusively in other databases (e.g., Scopus or Engineering Village) may not be fully captured. Future reviews could extend the search to additional databases and, where appropriate, complement peer-reviewed sources with structured evidence from practice-oriented outlets.

Methodological Implications for Decision-Support Approaches

Figure 4 summarises the review synthesis by linking the identified families of decision-support approaches, recurring limitations, and resulting methodological implications. Based on the findings of this systematic review, decision-support approaches for corridor-based projects should

(1) treat construction method selection as a segment-oriented decision problem with explicit spatial granularity rules,
(2) operationalise reusable and transparent decision modules linking ground and crossing conditions to feasible methods, and
(3) connect method assignment to cost, schedule, and resource evaluation through consistent data interfaces.

Building on these implications, the author's ongoing research focuses on integrating spatial segmentation, modular decision logic, and quantitative evaluation within a GIS-enabled framework. Accordingly, validation needs to extend beyond single-case demonstrations and include sensitivity analyses and validation against empirical project data to assess model behaviour under varying boundary conditions.
Complementing this, Figure 5 positions the systematic review within an end-to-end decision-support workflow.

Conclusions and Outlook

By categorising existing decision-support approaches and analysing their input parameters, output structures, and validation strategies, the review establishes a transparent reference framework for comparative analysis and future research. The synthesis identifies a central structural limitation in current research: construction method selection is predominantly addressed through project-level or ranking-oriented models and remains weakly integrated with geospatial information and quantitative cost or scheduling perspectives. As a result, decision-support concepts are often fragmented and offer limited applicability for corridor-scale, segment-oriented planning.

Overall, the findings underline that construction method selection represents a critical yet underdeveloped component of digital infrastructure planning. Addressing the identified integration deficit is essential for improving transparency and reproducibility in the planning and execution of linear infrastructure projects. In this context, the review provides a structured foundation for the author's research, which develops a modular hierarchy for construction method selection (e.g., open-cut and trenchless families and module types derived from soil and terrain conditions) and translates corridor constraints into reproducible module-based outputs (e.g., €/m and production rates). Such a framework aims to enable scalable, auditable, and quantitatively informed decisions along the entire alignment and to facilitate integration with downstream cost and schedule evaluation in digital planning workflows.

ONTOLOGY-BASED COST MANAGEMENT IN PUBLIC INFRASTRUCTURE PROJECTS: A CASE STUDY ON TRANSFERABILITY AND APPLICABILITY

Anna Nast[1], Jacopo Cassandro[2], Claudio Mirarchi[2], and Jürgen Melzner[1]
[1]Chair of Construction Engineering and Management, Faculty of Civil and Environment Engineering, Bauhaus-Universität Weimar (BUW), Weimar, Germany
[2]Department of Architecture, Built Environment, and Construction Engineering (DABC), Polytechnic of Milan, Milan, Italy

Abstract

Cost management in infrastructure projects is complex due to evolving cost information, multiple estimation methods, and national regulations. Ontology-based approaches combined with Building Information Modeling (BIM) can improve cost consistency and decision-making; however, their transferability and applicability across domains and countries remain insufficiently investigated. This paper examines how an existing ontology-based cost management approach can be transferred to German railway infrastructure projects. A case study explores the reuse of cost ontologies across construction domains and under a different national regulatory framework. The results suggest that ontology-based cost structures support cost development and semantic consistency in standardized infrastructure projects.

Introduction

Cost management is one of the most critical and challenging tasks in infrastructure project management. Total project costs are often unknown until after the conceptual design phase and, in some cases, even after construction completion (Moses, 2020; Ashworth & Perera, 2018). The use of different estimation methods, cost indicators, and classification systems throughout the project lifecycle frequently leads to inconsistencies, limited transparency, and error-prone decision-making (Cassandro et al., 2025).

Digital methods such as Building Information Modeling (BIM) have significantly improved the availability and integration of project data. In parallel, ontology-based approaches have been proposed to formalize cost knowledge, enable semantic interoperability, and support structured cost analyses. Previous studies indicate that ontologies enhance consistency and traceability in cost management by providing a shared semantic framework across disciplines and phases (Signorini et al., 2025).

Nevertheless, current ontology-based cost management approaches exhibit two main limitations. First, they often focus on highly detailed and static cost calculations without explicitly considering the evolution of cost information across different project phases. Second, most approaches are developed and validated within a single domain or national context, raising concerns regarding their transferability, applicability, scalability, and generalizability. This paper specifically addresses the second limitation by examining the application of an existing ontology-based cost management approach in the context of German railway infrastructure projects.

In this study, *transferability* refers to the reuse of the ontology-based cost model in a different construction domain, such as infrastructure instead of buildings, without fundamental changes to its core ontological classes and their relationships (Korstjens & Moser, 2018). *Applicability* refers to the feasibility of implementing the approach in a different regulatory and organizational context, including national cost management rules, such as the German instead of the Italian context. *Scalability* denotes the capability of the approach to support different project sizes and work types, for example small-scale rather than large-scale projects or demolition rather than new construction. *Generalizability* addresses the extent to which findings can be applied beyond a single case study, for example through the development of a reference project based on a larger project sample.

Following the recommendations of Farghaly et al. (2023), this paper emphasizes the reuse of existing ontologies rather than the development of new, isolated models. Specifically, it builds on the ontology-based cost management approach proposed by Cassandro et al. (2023), which has so far been validated primarily in building projects within the Italian regulatory framework, while its conceptual structure is designed to support multiple domains and national standards.

The objective of this paper is to explore the transferability and applicability of the ontology-based approach to infrastructure projects and to a distinct national context, namely the German railway sector. German railway infrastructure projects are characterized by specific cost management rules, standards, regulations, and organizational features that differ substantially from those applied in prior case studies in the Italian construction industry, making this context a suitable testbed for assessing cross-national applicability and methodological robustness.

While cost management procedures, aggregation methods, and regulatory requirements vary across national contexts and application domains, the underlying *cost items* – defined as price components and their

technical descriptions – remain conceptually comparable. In infrastructure projects, however, unit prices are often unstable and not directly reusable, as they strongly depend on site-specific conditions, construction sequences, access constraints, and track closures.

Therefore, the objective of ontology-based cost management is not to standardize prices, but to semantically structure cost item descriptions in a way that enables consistent association, comparison, and updating of cost values across projects. This study is based on the assumption that variations across contexts primarily affect how cost data are structured, interpreted, and managed, rather than the cost data themselves. By semantically structuring cost items and their descriptions through an ontology-based approach, cost information becomes machine-interpretable, verifiable, and consistently comparable across projects and national frameworks.

By transferring the existing ontology-based cost structure to the German railway context, this paper demonstrates its scalability, semantic depth, and ability to support cost data management despite differences in national regulations and industry practices. The case study of standardized German railway infrastructure projects therefore offers an exploratory validation of ontology reuse in a cross-domain and cross-national setting.

Background

Cost management

Cost management encompasses the processes of planning, estimating, budgeting, and controlling costs to ensure that projects remain financially viable and achieve their intended objectives (Project Management Institute, 2021). These activities enable practitioners to forecast expenditures, establish cost baselines, evaluate cost performance, and implement corrective actions when deviations occur.

In the construction sector, cost management spans the entire project lifecycle and addresses direct and indirect costs, including labor, materials, equipment, subcontractors, contingencies, overheads, and life-cycle expenditures (Ashworth & Perera, 2018; Smith, 2016). Effective cost management relies on structured mechanisms such as cost breakdown structures, detailed budgets, real-time cost tracking systems, and change control procedures (AACE International, 2022). Despite their maturity, these practices often remain dependent on manual processes, fragmented data sources, and heterogeneous classification systems.

The increasing adoption of the BIM technology has enabled more integrated 5D cost workflows. However, commercial 5D BIM tools typically rely on proprietary cost structures and require extensive manual mapping between model elements and cost items. This limits transparency, interoperability, and the systematic verification of consistency between geometric, quantitative, and cost domains (Cassandro et al., 2023). As a result, cost management processes rarely achieve the level of robustness required to meet public procurement, standardization, and auditability requirements, particularly in small-scale public works, where limitations in time, expertise, and budget hinder the adoption of complex digital ecosystems (Nast & Koch, 2023).

Ontology-based approaches

Ontologies, defined as “an explicit specification of a conceptualization” (Neches et al., 1991), have gained traction in the Architecture, Engineering, and Construction (AEC) sector as a means to address interoperability challenges and integrate heterogeneous datasets (Pauwels & Terkaj, 2016). They determine domain-specific concepts and relationships (Farghaly et al., 2023) and enable machine-interpretable knowledge representations using languages such as OWL (Web Ontology Language) and RDF (Resource Description Framework), supporting semantic interoperability, rule-based reasoning, and knowledge reuse. Recent systematic reviews confirm the growing adoption of ontology-based applications across AEC domains to address interoperability issues, although practical applications remain fragmented and constrained by data heterogeneity and scalability limitations (Farghaly et al., 2023; Palihakkara et al., 2025; Speiser et al., 2025).

In the cost domain, early research focused on representing work items, construction methods, and work conditions through ontologies to enable automated cost estimation from BIM models. Lee et al. (2014) proposed a BIM- and ontology-based cost-estimation approach that uses ontological reasoning to infer appropriate work items from BIM-derived work conditions, incorporating contextual information such as room usage and material attributes. Subsequent studies expanded the formalization of specifications and cost rules (Ma et al., 2016) or represented cost classification systems, such as the New Rules of Measurement (NRM), using ontological engineering approaches (Abanda et al., 2017). Similarly, Liu et al. (2016) developed a construction-oriented product ontology for quantity take-off (QTO) in light-frame construction, extending BIM schemas with domain-specific terms and enabling automated reasoning for QTO extraction. Zhang et al. (2022) used an ontological approach to conceptualize knowledge for budgeting real estate developments.

More recent research focuses on integrating cost ontologies with IFC-based models and Linked Building Data to enable semantic links between geometric entities, cost items, and resource information (Hagedorn et al., 2025). These approaches show that ontologies can support automated matching between BIM elements and cost structures, improve the transparency of cost logic, and reduce manual effort in traditional 5D BIM workflows. Further studies demonstrate how ontology-based models support the assessment of IFC class reliability for cost estimation and enable standardized digital cost representations for public procurement (Cassandro et al., 2023).

Infrastructure projects

Transportation infrastructure is typically grouped into asset classes such as roads and highways, railways, bridges, and related asset types (Bradley et al., 2016). However, the research literature offers no widely accepted, sector-wide thresholds for classifying project size. Accordingly, project size is usually defined case-by-case by the contracting authority or the implementing organization. Building on Nast & Koch (2023), this study operationalizes small-scale infrastructure projects primarily based on the physical scale of the asset. Examples include single-sided railway platforms, bus stops, rest areas, and service stations.

In the European infrastructure context, small-scale construction measures are particularly relevant. For example, in Germany, approximately 80–90 % of railway stations are small-scale facilities with side platforms (around 9,300 assets) (DB InfraGO AG, 2025). Additionally, railway infrastructure is selected as the focus of this study, as it represents a highly standardized yet cost-critical domain with substantial cost overruns compared to other infrastructure sectors, such as road construction (Flyvbjerg et al., 2003).

Standardization in AEC

Like other manufacturing industries, the AEC sector relies on standards, guidelines, and codes of practice to ensure safety and reduce errors. Standardization is widely recognized as a prerequisite for BIM implementation (Moses et al., 2020), for effective 5D BIM-based cost planning and management, and for the development of domain-specific ontologies (Signorini et al., 2025). In this context, standardization provides the base for semantic interoperability, and BIM aligns closely with the componentization and integration of building elements.

Cost management challenges in public projects

Public-sector projects must comply with standardized measurement rules, regional price lists, and strict auditability requirements. However, cost information is often encoded in natural language or non-interoperable software formats, hindering automated verification and cross-project reuse (OECD, 2017). Fragmentation is further exacerbated by the coexistence of diverse standards, such as NRM, UniClass, MasterFormat, and national or regional price books. Although classification systems are recognized as essential in both international and national contexts (Pupeikis et al., 2022), current digital workflows for estimation, budgeting, and cost control frequently lack semantic consistency, particularly in public projects where transparency, standardization, and reproducibility are mandatory.

This study aims to extend the use of existing ontology-based cost management approaches to the domain of small-scale public infrastructure projects. In doing so, it addresses the specific challenges of cost management in infrastructure projects while also helping to close a gap in the practical application of current ontology-based approaches.

Methodology

This study adopts a qualitative research design to investigate the transferability and applicability of existing ontology-based approaches for cost management. In line with Yin (2018), document analysis and expert interviews were used as primary sources of evidence. A representative small-scale railway project was first defined on the basis of publicly available documents from DB InfraGO AG, Business Unit Passenger Railway Stations, expert interviews, and anonymized project data. This reference case was then used to evaluate the ontology-based cost management approach proposed by Cassandro et al. (2023) during the procurement phase. Selected items from the Bill of Quantities (BoQ) were used in the experiment, and the approach was assessed with respect to transferability, applicability, scalability, and generalizability. Finally, the results were discussed and directions for future research were derived (see Fig. 1).

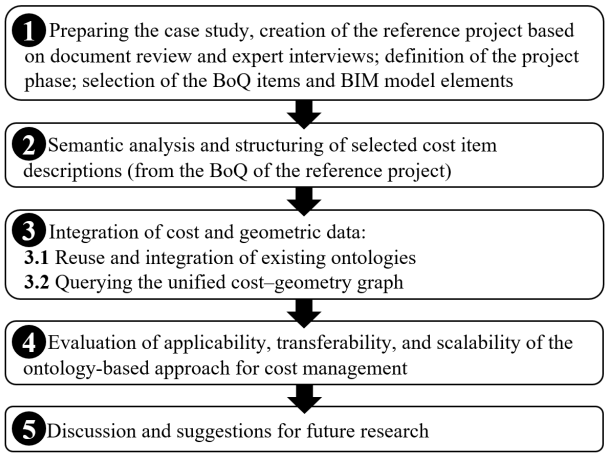

Figure 1: Overview of the research process

The adopted ontology-based approach explicitly separates the semantic definition of cost items from their associated economic values. While cost item descriptions remain stable and reusable across projects, cost values are modeled as context-dependent attributes that vary according to project-specific conditions, construction phases, and estimation scenarios. This distinction is particularly relevant for railway infrastructure projects, where cost estimation is largely driven by construction sequencing, logistics constraints, and site access conditions rather than standardized unit prices.

Case study

To address one of the key limitations of existing ontology-based approaches for cost-related activities – namely the insufficient validation and extension of existing ontologies – a case study was conducted in the German AEC context. The railway station sector was selected because it exhibits a high degree of standardization (DB InfraGO AG, 2025), remains underrepresented in research despite its practical relevance (Bawono et al., 2020), and combines both building and infrastructure construction characteristics.

The German railway infrastructure company DB InfraGO AG has established comprehensive construction standards for major facilities within the railway station domain (DB InfraGO AG, 2025). These standards govern planning, engineering, and construction activities at passenger stations and include standard drawings and details, sample service specifications (BoQ), structural design calculations, technical specifications, planning manuals, and approved building components.

A reference project was developed as a case study representing the typical characteristics of small-scale railway stations. The core scope comprises the construction of a new side platform, elevated and extended to ensure accessibility and improve infrastructure performance. In Germany, railway stations are rarely developed on greenfield sites. Therefore, the reference project involves the complete dismantling and reconstruction of the existing platform at the same location. All structural components, including platform edges, foundations, surface covering, and underground cabling, will be removed and replaced by new installations (see Fig. 2).

Figure 2: A typical railway station project

A key characteristic of the reference project is the strong influence of track closures, logistics constraints, and site conditions on cost calculation, particularly with respect to the selection and quantity of resources such as equipment, labor, and materials. Compared with typical building projects, construction scheduling must be considered much more explicitly when estimating costs for railway stations during the tender phase. Consequently, standardized unit prices are generally of limited applicability. In addition, railway infrastructure projects are subject to a large number of nationally specific guidelines, regulations, and approval procedures.

However, the main challenge is not limited to the coexistence of different national standards and classification systems. Cost information is also fragmented across heterogeneous document types and is often encoded in natural language or stored in non-interoperable formats. As a result, ontology-based representation and querying require concepts, quantities, and rules to be semantically disambiguated and formalized before they can be consistently linked across domains. Moreover, construction cost items are typically defined at a relatively high level of abstraction and do not adequately support resource-based cost analysis, which further complicates detailed semantic modeling.

Results

Based on the methodological steps illustrated in Figure 1, the results are organized to reflect the sequential application of the ontology-based approach to the selected cost items. Each result corresponds to a distinct phase of the research process, ranging from the semantic analysis of cost item descriptions to the integration of cost and geometric data and the evaluation of transferability and applicability.

Due to the limited scope of this paper, the procurement phase, based on the definitive estimate, was selected as the starting point for transferring the ontology-based approach to the infrastructure context. To ensure a focused analysis, the approach was applied to a selected subset of the BoQ items. Specifically, five representative cost items were examined, referring to three key construction elements that are fundamental to most railway station projects and include both construction and demolition activities: the precast foundation element, the precast platform edge, and the precast corner element (see Fig. 3). Despite the limited number of cost items analyzed, the selected elements represent standardized components of railway station projects and therefore provide a suitable basis for assessing the applicability, transferability, and scalability of the approach.

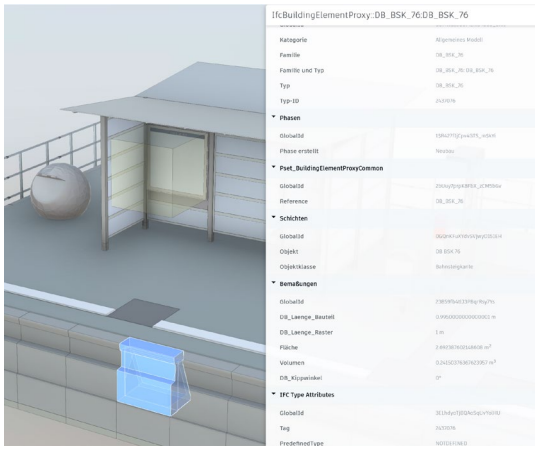

Figure 3: Selection of construction elements

Semantic structuring of cost items

In the first step, the case study focuses on the semantic analysis of railway cost items as defined in the project documentation. As illustrated in Figure 4, individual cost item descriptions typically combine heterogeneous information related to construction work, material resources, activities, and technical specifications within a single unstructured textual entry.

By adopting the ontology-based approach proposed in Cassandro et al. (2025) and Signorini et al. (2025), these cost items can be decomposed into semantically well-defined components, including:

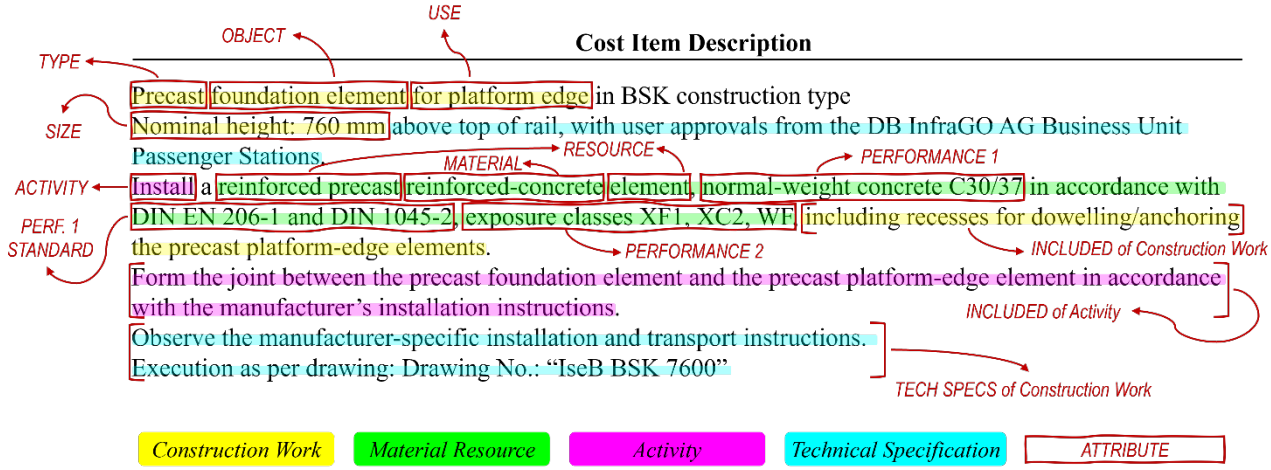

Figure 4: Semantic structuring of cost item 'Precast foundation element for platform edge'

- Construction Work Object (e.g., precast foundation element)
- Activity (e.g., installation)
- Material Resource (e.g., reinforced precast element)
- Technical and performance specifications (e.g., compliance with manufacturer-specific instructions).

This semantic structuring reveals several recurring issues in traditional cost descriptions, such as semantic overlap, implicit assumptions, and ambiguities between objects, processes, and requirements. By making these distinctions explicit and structuring the information into well-defined attributes (e.g., object, type, material, use, and performance), the ontology provides a clearer and more coherent definition of cost items while preserving their original meaning and enabling machine interpretability.

Reuse and integration of existing ontologies for cost – geometry linkage

In a second step, the study demonstrates how existing ontologies can be reused and integrated to structure cost items and establish semantic links to geometric data. Following ontologies were selected:

- *ifcOWL* is employed to generate an RDF representation of the IFC model, enabling access to geometric objects and their properties.
- *Cost Item Ontology (CI)* is used to formalize cost items and their internal structure based on the previously semantic structuring.
- *Construction Resource Ontology (CR)* is used to establish explicit relationships between geometric objects and cost items.

These ontologies were selected because they enable explicit semantic structuring of cost items and their direct linkage to geometric data. Many alternative ontologies focus on process automation or isolated knowledge representation and lack the semantic granularity required to jointly model and evaluate relationships between cost information and geometry (see Chapter 'Background'). In the cost domain, this explicit linkage is essential, as quantities, construction logic, and resource requirements are directly derived from geometric definitions.

Through the integration of these ontologies, a unified knowledge graph is generated in which each cost item is explicitly linked to one or more corresponding geometric objects (see Fig. 5). This linkage enables automated QTO extraction directly from IFC-derived data and their consistent association with cost items within a shared semantic framework.

As a result, quantities, cost item definitions, and unit prices are no longer managed as separate artifacts but are integrated into a single machine-interpretable model. This enables the generation of a computable and extensible BoQ, in which cost values can be updated, revised, or compared across scenarios, provided that such variations are driven by external cost factors that do not affect the semantic definition of cost items, their resource composition, or measurement rules. Typical examples include variations in labor, equipment, and material costs due to geographic location, market conditions, or alternative construction and procurement scenarios, rather than changes in construction logic or resource structure.

The absence of standardized unit prices in German railway projects does not affect the validity of the proposed approach. Project-specific unit prices can be assigned, updated, and modified independently of cost item definitions and object relationships, as long as such modifications reflect contextual cost variability rather than changes in quantity take-off logic or resource breakdown, thereby demonstrating the scalability, adaptability, and reuse potential of the ontology-based cost structure.

Querying the unified cost – geometry graph

Finally, the resulting knowledge graph is queried using SPARQL to demonstrate its practical applicability. The SPARQL queries are not intended for statistical analysis but are employed as a verification mechanism to demonstrate the internal consistency and operational applicability of the ontology-based model.

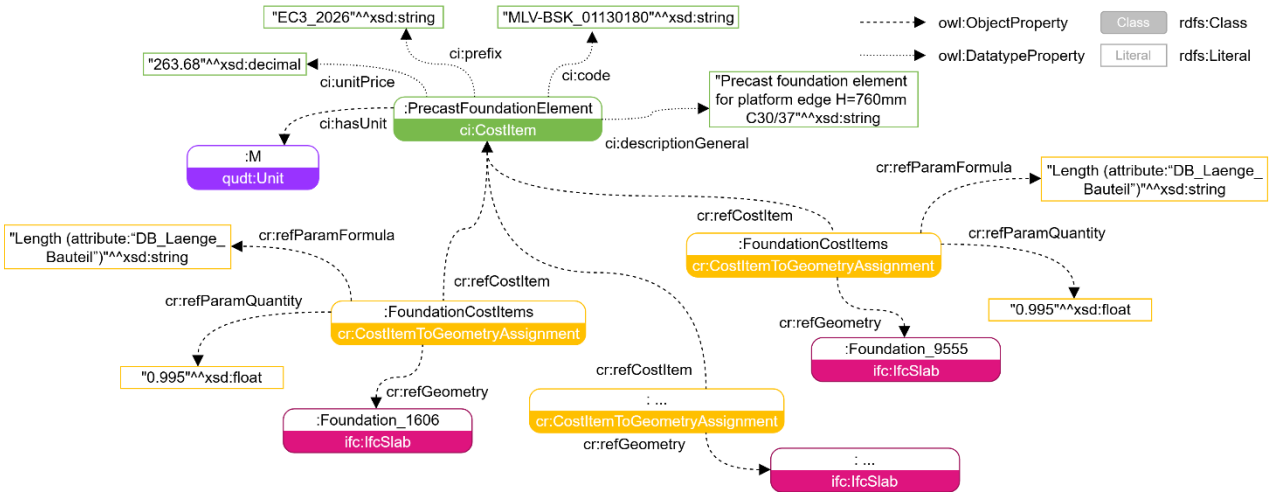

Figure 5: Unified knowledge graph for precast foundation element

The query shown in Listing 1 interrogates the integrated knowledge graph by explicitly crossing the semantic relationships between construction objects (`?obj`), cost assignments (`?assign`), and cost items (`?costItem`). It retrieves all construction objects (`?obj`) participating in a `cr:CostItemToGeometryAssignment`, independent of their specific IFC class. For each object, the query extracts its globally unique identifier (`?guid`) through the `ifc:globalId_IfcRoot` relationship and the associated `IfcGloballyUniqueId` literal (`express:hasString`), ensuring object-level traceability across geometric, cost, and quantity domains.

```

  ?costItem ci:code ?code .
  ?costItem ci:unitPrice ?unitPrice .
  ?costItem ci:hasUnit ?measureCost .
  }
ORDER BY ?obj
```

Listing 1: SPARQL query

Cost information is accessed via the `cr:CostItemToGeometryAssignment` node, which acts as a semantic mediator between geometry and cost data. Through this assignment, the query retrieves:

- the referenced cost item (`cr:refCostItem`),
- the quantity parameter used for cost calculation (`cr:refParamQuantity`),
- and the applied cost formula (`cr:refParamFormula`).

From the linked cost item, the query extracts:

- cost code (`ci:code`), enabling classification and aggregation of cost items,
- the unit price (`ci:unitPrice`),
- and unit of measurement (`ci:hasUnit`).

The resulting dataset consolidates each cost – geometry association in a single row, explicitly linking a construction object to its cost item, quantity reference, unit price, unit of measurement, and calculation formula. By ordering the results by construction object, the query facilitates systematic object-level inspection and validation.

Unlike traditional document-centric cost management approaches (e.g., Excel files and IFC data) with rigid data schemas, ontologies and knowledge graphs enable an explicit, machine-interpretable representation of the semantic relationships between cost items, construction objects, and quantities. The query results demonstrate that cost and geometric information – traditionally distributed across separate documents, spreadsheets, and software systems – can be consistently retrieved from a single integrated model.

Evaluation of the ontology-based approach

The reuse of the selected ontology-based approach to cost data management would not be feasible if cost items could not be described in a sufficiently structured manner or if their semantic characteristics could not be mapped to the core ontological classes and properties, such as object, material, function, and form. In the present study, however, the cost item descriptions reveal a high degree of semantic consistency, while the alignment with the generic ontology classes is preserved, demonstrating the applicability and robustness of the approach.

Discussion

This case study shows that the ontology-based cost structure remains applicable and robust in German railway projects, even in the absence of standardized unit prices. Project-specific cost values can be assigned, updated, and compared independently of the underlying cost item definitions, which confirms the validity of separating semantic meaning from monetary values. Although pricing mechanisms differ between building construction and infrastructure projects, the study shows

a fundamental commonality in cost calculation: the semantic structure, granularity, and progressive development of cost information are consistent across domains, irrespective of national or organization-specific cost management practices.

The prior standardization of railway station projects proved to be a crucial prerequisite for transforming cost information into machine-interpretable structures. This finding further underlines the role of standardization as a fundamental enabler of digitalization and process automation in the AEC sector, particularly in the context of transparent and traceable cost management (Signorini et al., 2025). Establishing a reliable benchmark therefore requires the initial definition of a standardized project typology, followed by the incremental integration of cost information reflecting project-specific conditions.

The mapping between project data and ontology classes is performed manually. While this increases the workload and therefore constitutes a current limitation of the ontology-based approach, the mapping process could be automated using AI-based methods. However, such automation would require appropriate training data to ensure reliable mapping quality. Since sufficiently annotated datasets are not yet available, automated mapping was beyond the scope of the present study.

This paper focuses on the ontology-based approaches using BIM data, which typically represents the detailed stage of an infrastructure project. Early project phases are not covered, as they rely on other geometric data sources, and should be considered in future studies.

Conclusion

While Farghaly et al. (2023) emphasize the importance of testing, reusing, and transferring existing ontologies to new contexts, this paper extends the application of ontology-based cost management approaches to the domain of small-scale public infrastructure projects. In doing so, it explores the scalability, semantic depth, and robustness of the ontology-based cost structure under varying project characteristics, national regulations, and organization-specific cost management practices.

This study builds on previous research by Cassandro et al. (2025) and Signorini et al. (2025) on ontology-based approaches for structuring cost information and improving cost management, particularly with regard to transparency and decision-making. More specifically, it investigates the reuse of the Cost Item Ontology and the Construction Resource Ontology in the context of a German railway infrastructure, including both the representation of cost definitions and the queryability of the encoded data. In this way, the case study addresses one of the key limitations of current ontology-based approaches, namely their restricted applicability due to the lack of validation across different domains and national contexts.

Transferability was demonstrated by applying the ontology-based cost model to both building construction and infrastructure projects without requiring fundamental changes to its core ontological classes and relationships between them. *Applicability* was ensured by adapting the approach to a different national and organizational context, such as the German instead of the Italian context. *Scalability* was supported through the selection of small-scale projects relevant for industry adoption, as well as by including different construction activities such as prefabricated construction and demolition works. *Generalizability* was achieved through the use of a reference project derived from approximately 9,300 railway station platforms.

Across the case study, cost information for the reference project was represented in a structured, consistent, and transparent manner. The results confirm that cost values can be modified, compared, and reassigned without affecting the semantic integrity of cost items, directly supporting the methodological assumption of separating meaning from monetary value.

A limitation of this study is that only a subset of items from the reference BoQ was examined. Accordingly, the findings should be regarded as preliminary evidence of structural similarities between the Italian and German cost management contexts under investigation, as well as of the potential transferability of the ontology-based approach, rather than as confirmation of broad cross-context validity. Future studies should therefore expand the analysis to cover all construction trades.

Another limitation of this paper is its focus on detailed cost estimation during the procurement phase, which was necessary to assess transferability based on fully specified cost descriptions. Future research should extend the ontology-based approach to early cost estimation and demonstrate the dynamic growth and evolution of cost information across the project lifecycle.

GRAPH-BASED GENERATIVE SCHEDULING IN CONSTRUCTION PROJECT MANAGEMENT

Jianpeng Cao[1], Hisham Said[2]
[1]The University of Hong Kong, Hong Kong S.A.R., China
[2]Santa Clara University, Santa Clara, CA, United States

Abstract

Factory-based modular construction resembles manufacturing systems, but production scheduling remains challenging due to design variability, product heterogeneity, and design–production coupling. Existing construction scheduling methods rely on predefined task structures and adapt poorly to design changes. This paper presents a graph-based generative scheduling framework that derives production plans directly from modular designs. A design graph is transformed through graph rewrite rules to generate tasks, resources, precedence constraints, and task durations. The resulting job shop scheduling problem is solved using constraint programming. Case studies demonstrate automated schedule generation, reveal resource bottlenecks, and support early-stage production capacity planning.

Introduction

The increasing adoption of modular and prefabricated construction has intensified the need for advanced production planning and scheduling methods that can effectively manage complex task precedence, resource constraints, and design variability (Said and Kandimalla 2018). Factory-based construction environments share many characteristics with manufacturing systems, yet construction-specific uncertainties, heterogeneous products, and tight coupling between design and production continue to limit the effectiveness of traditional scheduling approaches (Ballard and Howell 1998; Gibb and Isack 2003). In particular, translating design information into executable production schedules remains a largely manual and error-prone process.

Job shop scheduling models have been widely applied to prefabrication and industrialized construction to optimize makespan, resource utilization, and workflow reliability. Specifically, job shop scheduling has been applied to the fabrication of pipe spools (ElMenshawy et al. 2025; Karim et al. 2024; Liu et al. 2017; Safarzadeh et al. 2018), precast concrete elements (Anvari et al. 2016; Xie et al. 2023), and sheet metal assemblies (Said and Kandimalla 2018). However, most existing approaches rely on predefined task structures and static process models, which restrict adaptability to design changes and limit scalability across different module configurations. Recent research has highlighted the potential of graph-based representations to model production systems more flexibly, capturing both structural and operational relationships in a unified framework.

This paper proposes a graph-based generative scheduling methodology that directly links modular design representations with production planning through graph rewrite rules. By transforming a parametric module design graph into a task and resource graph, the approach enables automated formulation of a job shop scheduling problem with design-dependent task durations and constraints. While the underlying optimization follows standard job shop scheduling (JSP) formulations, the innovation lies in the automated, graph-based generation of the constraint space, a process that traditionally relies on manual, error-prone expert input. In this context, the constraint space encompasses the set of logical dependencies (such as precedence, resource availability, and spatial conflicts) that bound the feasible solutions for a project. By serving as a generative engine, the proposed graph transformation process maps architectural topology directly onto these constraints. The framework is demonstrated through a modular production case study and solved using constraint programming to generate optimized schedules.

Literature review

Production planning and scheduling for prefabricated and modular construction has been extensively studied using job shop and flexible job shop formulations. Early and foundational work adapted manufacturing-oriented models to construction fabrication contexts, including steel components, bridge girders, precast elements, and pipe spools, often focusing on minimizing makespan and balancing resource utilization (Hasan et al. 2019; Hu et al. 2014; Liu et al. 2017). Genetic algorithms, memetic algorithms, and heuristic methods have been commonly employed to address the computational complexity of these problems (Meng et al. 2018; Moghadam et al. 2017; Xie et al. 2023).

More recent studies have expanded these models to incorporate multi-objective optimization, distributed production, and just-in-time constraints, reflecting the increasing complexity of industrialized construction systems (Anvari et al. 2016; Flamini and Nicosia 2024; Wang et al. 2024). Data-driven and learning-based approaches have also emerged, leveraging historical production data to forecast labor hours and improve scheduling performance (ElMenshawy et al. 2025; Karim et al. 2024; Said and Kandimalla 2018).

Graph-based representations have been recognized as a powerful abstraction for scheduling problems, particularly through disjunctive graph formulations that explicitly encode precedence and resource conflicts (Błażewicz et al. 2000; Otala et al. 2021). Besides, these scheduling advancements, an increasing number of

studies have explored graph-based modeling for building design in offsite and modular construction, particularly due to its effectiveness in representing the physical topology and spatial relationships of prefabricated modules (Cao et al. 2024; Gan 2022). While these approaches offer strong theoretical foundations for both design and production independently, their application in construction has largely focused on modeling production processes rather than integrating upstream design information. Consequently, the linkage between modular design attributes and schedule generation remains weak.

The present study addresses this gap by employing graph rewriting to generatively derive task, resource, and constraint structures from a design graph, enabling automated, design-consistent job shop scheduling for modular construction.

Methodology

Graph Representation

The design of a prefabricated building module design is modeled as an undirected graph in which nodes represent rooms and walls. Room nodes indicate spaces with geometric attributes (width, length, area), while wall nodes are attributed by one of three types (internal, external, or partition wall) and are annotated with the wall's dimensional properties (height and length) and the presence of doors or windows. The edges between room and wall nodes capture boundary relationships, indicating which walls define the perimeter of each room. On the other hand, the edges between room nodes indicate the adjacency and accessibility between two rooms without the existence of a partition wall. This graph-based representation captures efficiently the room–wall topology of a module design that can be informative for production planning.

Rule Definition

This framework relies on a rule repository that bridges architectural design and production planning. To ensure the scalability of the generative approach, the framework categorizes rules into a multi-level hierarchy.

Element Level: At this granular level, rules specify the tasks and associated resources for individual components (e.g., interior walls, MEP fixtures). This ensures that every physical part of the parametric design triggers a corresponding manufacturing requirement.

Room Level: These rules capture the aggregated activities required for specific functional spaces, such as dry rooms versus wet rooms. This level introduces broader finishing tasks, including ceiling installation, flooring, and specialized commissioning.

Module Level: At the highest level of the hierarchy, the rules introduce an abstract "module node." This node associates the entire unit with holistic tasks such as structural assembly, final quality inspection, and logistics.

By organizing rules in this manner, the framework effectively deconstructs the fabricator's production expertise into a reusable Rule Library. While the initial formulation of these rules requires input from the fabricator crew to ensure the "constraint space" accurately reflects the reality of the shop floor, the resulting templates can be applied to new designs with minimal intervention. This reduces the user's burden from "creating logic" to "selecting appropriate rule sets," thereby enhancing the system's usability for non-expert project managers.

Design-to-Production Transformation using Graph Rewriting Rules

Graph rewriting, also known as graph transformation, is a rule-based approach for modifying graph structures by adding, removing, or reconfiguring nodes and edges according to predefined rules. In engineering design, it provides a structured yet flexible mechanism for automating complex transformations, encoding domain knowledge, and systematically exploring design alternatives (Kolbeck et al. 2022). Recent advances have demonstrated its effectiveness in modular and parametric design contexts, where rule-based transformations enable automated generation of design variants and support early-stage decision-making (Aksamija et al. 2010; Voss et al. 2023). Graph grammars extend this concept by offering a formal framework for design synthesis, allowing valid configurations to be generated through well-defined transformation rules while ensuring consistency and correctness through metamodels or type graphs (Campbell 2009; Schmidt and Rudolph 2016).

For the proposed design-production framework, graph rewriting rules are used to link process knowledge, including task, resources and constraints, to design graph. As such, there are two production-related nodes that are added to the design graph by the graph rewriting rules: 1) task nodes represent a discrete production activity with uninterrupted duration; and 2) resource nodes represent the production crews or equipment used to accomplish one task or more. Task assignment to each module design element (wall and room nodes) is created by adding edges "constructs" from task nodes to the design elements. Resource assignment is created by adding edges "uses" from task nodes to resource nodes representing required production capabilities. Afterwards, constraint assignment is created by adding edges "precedes" between task nodes to represent the logical sequencing between the fabrication tasks.

Graph Rule Assignment

Rule assignment is performed by iteratively matching the left-hand side (LHS) patterns of the graph rewrite rules against the module design graph. When a valid matching is found, the corresponding rule is applied by augmenting the graph with the right-hand side (RHS) components. The RHS introduces task nodes, resource dependency links, and task–task precedence relations, while preserving the original design entities and their topological relationships.

After the rule assignment, task durations are computed by associating the unit of the design entity with a predefined unit production rate stored in the task node. For example, the duration of the task "Light-gauge wall framing (studs

& door/window frames, exterior)" is calculated by multiplying the wall surface area extracted from the design graph by the corresponding production rate (hours per square meter of wall). This approach ensures the task durations are design-dependent and adapt to the design changes automatically, ensuring the consistency between design and production planning.

Scheduling Formulation

After the task assignment, the production planning is formulated as a job shop scheduling problem, where each module to be produced is modeled as a job. The input is the graph generated from the graph rewrite process, which defines the set of tasks, their precedence relationships, required resources, and design-dependent durations. Besides, two additional inputs, including the number of modules to be produced and the number of stations (resources), are defined according to order demand and factory production constraints. In traditional job shop models, stations are fixed in location. However, this proposed framework models them as moveable resources (crews) as most prefabricated volumetric modules are stationary and the fabrication crews move between them to execute the tasks. The scheduling objective is to minimize the overall makespan of the module production process.

Implementation

The proposed methodology is implemented as a Python-based computational pipeline that integrates graph modeling, task graph generation, and constraint-based scheduling. To demonstrate the methodology, a sample module design is used as a case study (Figure 1), which was obtained from a large building fabricator in Asia. In total, the analyzed module includes three exterior walls (EW), four interior walls (IW), two interior wet walls (WW), one dry room (R), and two wet rooms (WR). The differentiation between EW, IW, and WW wall elements is needed due to their different compositions and layers (partition material, insulation, existence of mechanical and electrical M&E systems, and finish material. A similar justification exists for the differentiation between dry and wet rooms (R and WR).

Wall Data

Wall	Dimension	Doors	Windows
EW1	3 x 2.12	-	1
EW2	3 x 2.51	-	1
EW3	3 x 4.63	-	2
IW1	3 x 6.88	1	-
IW2	3 x 6.88	-	-
IW3	3 x 4.10	-	-
IW4	3 x 4.10	1	-
WW1	3 x 2.12	-	-
WW2	3 x 4.10	-	-

Room Data

Room	Area
R1	4.63 x 6.88
WR1	2.12 x 4.10
WR2	2.51 x 4.10

EW = Exterior Wall
IW = Interior Wall
WW = Wet Wall
R = Room
WR = Wet Room

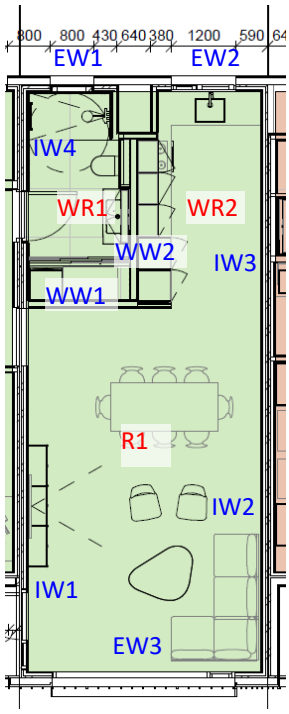

Figure 1: A sample module design

In addition to the prefabricated module design, it was critical to formulate a product-process recipe for each element in the module to facilitate the generative schedule process. Table 1 lists the product-process recipes for each element and aspect of a module, including production tasks, station/resource, unit type, duration, and precedence constraints. These recipes reflect the fabrication of the overall structural system of the module (structural steel post-beam with a concrete floor) and the fabrication tasks and resources needed to realize the different wall and room types. The recipes were formulated by the researcher by examining the production plan that were shared by the building fabricator. It should be noted that the fabricator shared a generic schedule for all their standard modules, which was useful to strategically outline the production process and resources but this generic schedule did not enable reliable scheduling and control of the production process. This observation confirms the need for this study and the proposed framework for generative scheduling of prefabricated building modules.

Table 1. Module production process

Element	ID	Production Task	Station / Resource	Unit	Duration (hrs)	Preceding Tasks

The implementation leverages *ReGraph* and *NetworkX* as the core graph modeling and transformation engines. *NetworkX* ("NetworkX" 2026) is used to construct and manage the underlying design and task graphs, providing a flexible data structure for representing nodes, edges, and associated attributes such as geometry, resources, and production parameters. *ReGraph* ("ReGraph" 2026) is employed to define and execute graph rewrite rules, enabling rule-based pattern matching and transformation of the design graph into a task and resource graph. Through left-hand-side pattern matching and right-hand-side graph augmentation, *ReGraph* supports the systematic addition of tasks, precedence relations, and resource dependencies while preserving the original design topology. This combination allows the implementation to separate graph data management from transformation logic, ensuring that design-dependent task generation is modular, extensible, and computationally efficient within the Python-based pipeline.

The task graph is then converted into a job shop scheduling problem and solved using Google OR-Tools CP-SAT ("OR-tools" 2026). The objective of the experimental evaluation is to analyze how the generative framework supports production planning through three key performance metrics: makespan, busy time, station saturation, and queue time. For the initial analysis, the production of a single module is examined under the assumption of deterministic task durations and fixed station capacities. Production station capacities are assumed based on typical factory conditions, including three framing stations, two M&E stations, two insulation stations, one doors-and-windows station, two painting stations, two flooring stations, one carpentry station, two structural workstations, and one closeout station.

Results

This section presents the outputs generated by the proposed framework. Figure 2 shows the graph representation of the sample module design. Rooms and walls are modeled as nodes, with edges capturing their topological relationships. Wall nodes store geometric properties such as dimensions and the number of doors and windows, and room nodes store the width, length and area. These geometric attributes are used to derive the duration calculation for each task.

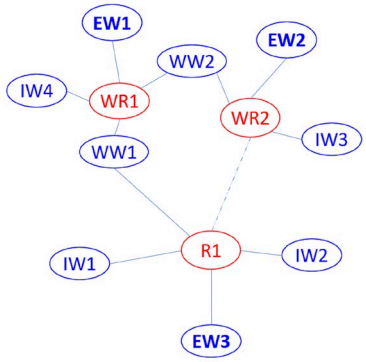

Figure 2: Graph representation of sample module design

Built upon the product-process recipes (Table 1), graph rewrite rules are applied to transform the design graph into a task graph, as illustrated in Figure 3. The resulting task graph represents design entities (blue circular nodes), production tasks (green squares) and resources/stations (orange diamonds). Solid edges represent task–entity and task–resource associations, while dashed edges indicate precedence constraints between tasks.

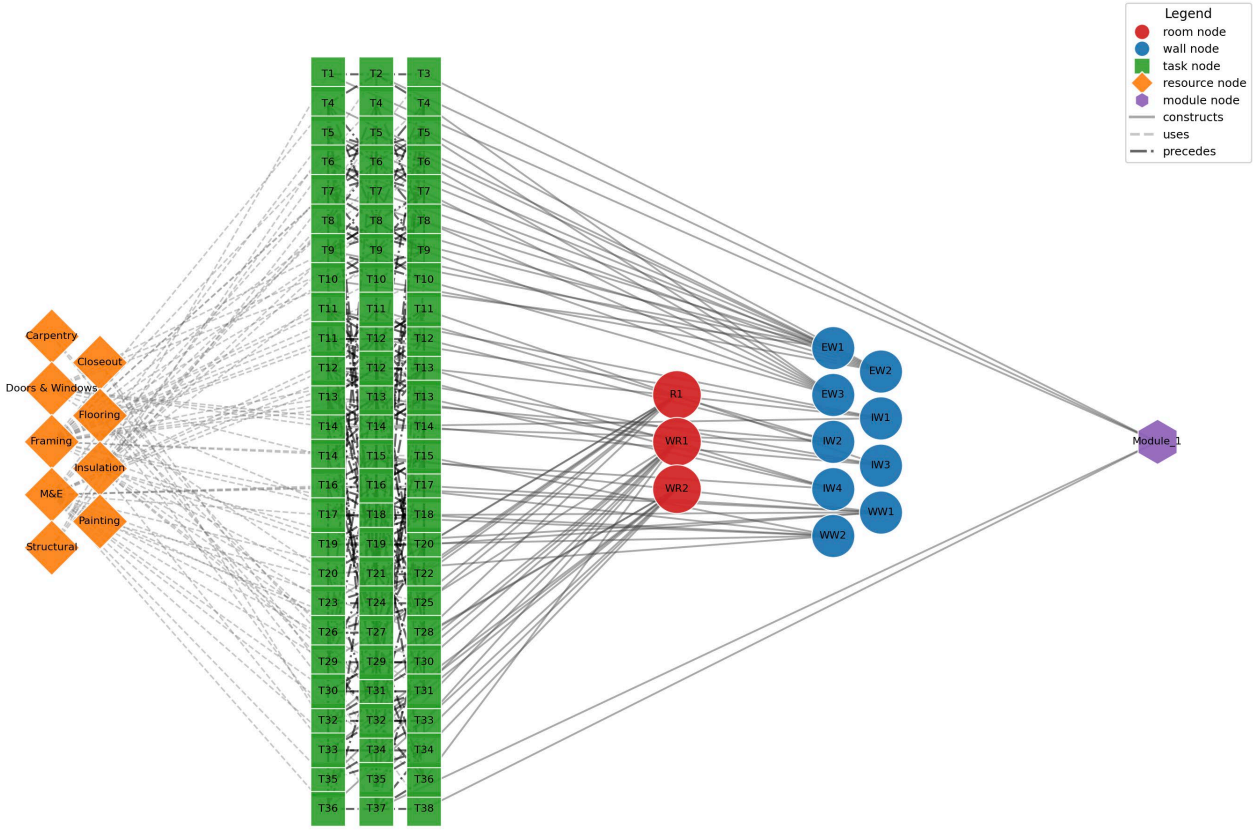

Figure 3: Task graph representation

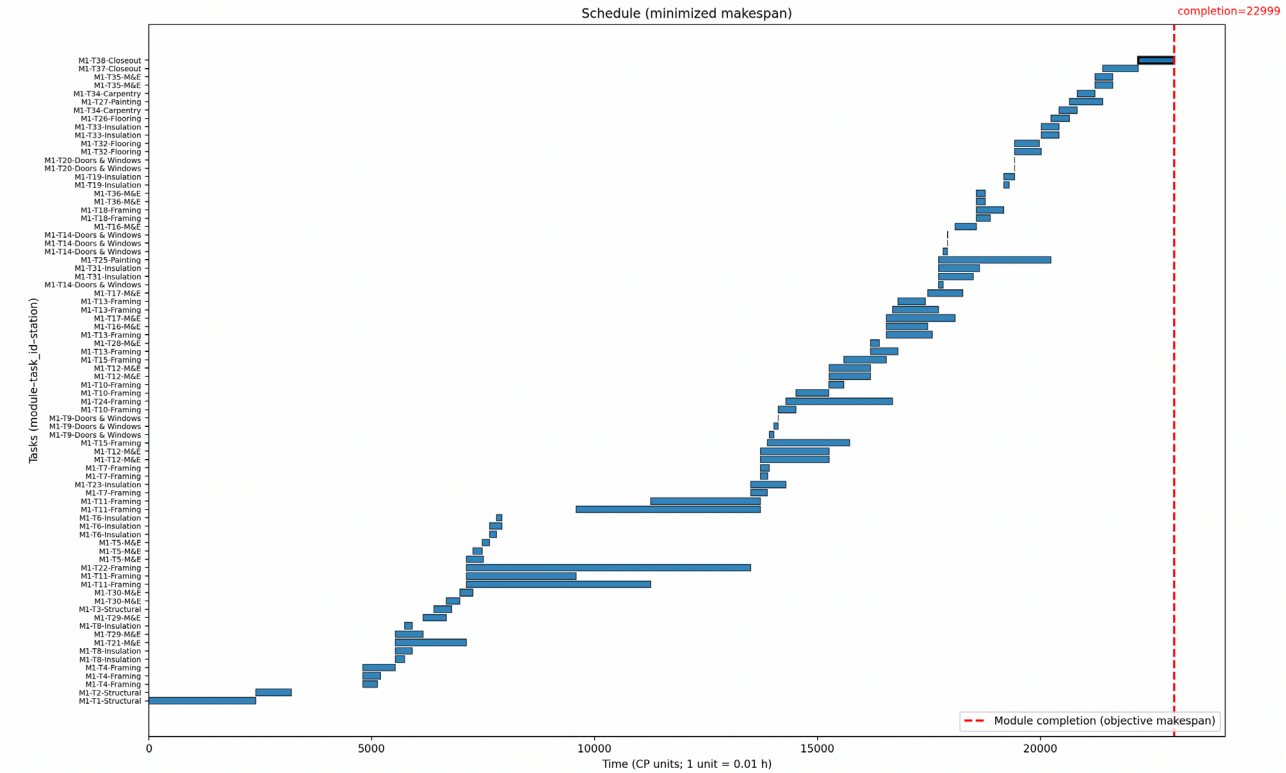

Figure 4: Optimized job shop schedule for modular production

The optimized schedule is presented as a Gantt chart (Figure 4) obtained by solving the job shop scheduling problem derived from the task graph. The vertical axis lists individual tasks, while each bar represents the corresponding task start and finish times. The dashed vertical line indicates the optimized makespan (230 hours), which corresponds to the module completion time.

Discussion

The results demonstrate the ability of the proposed graph-based generative scheduling framework to automatically translate a parametric modular design into a feasible and optimized production schedule. Beyond the single-module demonstration, additional experiments were conducted to derive important insights for the system scalability, resource bottlenecks, and the interaction between design-driven task generation and factory production constraints.

In contrast, professionals are enabled by the proposed generative framework to be more efficient by automating the mapping of architectural topology to scheduling constraints, the system eliminates manual "linking" errors, ensuring that the generated schedule is logically consistent and adheres strictly to design dependencies.

Expanding the analysis beyond the scheduling of a single module revealed the scalability limitation and the diminishing marginal efficiency of the modeled production system. Table 2 shows the resulting total makespan and the average module makespan for fabricating different numbers of modules. The multi-module experiments reveal a clear non-linear relationship between production volume and total makespan. While increasing the number of modules leads to economies of repetition in early stages, the average completion time per module eventually increases as shared resources become saturated. This diminishing marginal efficiency is a well-known phenomenon in prefabrication environments, where parallelism is constrained by finite station capacities and reentrant workflows. The observed reduction in average module time from three to approximately twelve modules indicates improved utilization of parallel stations, whereas the subsequent increase reflects congestion effects and resource contention. Importantly, these dynamics emerge naturally from the generated task and resource graph without manual adjustment of precedence logic or capacity rules. This highlights a key advantage of the proposed approach over traditional scheduling models that rely on static, predefined workflows. Because task durations and precedence relationships are derived directly from the design graph and rule assignments, the scheduling model remains consistent as production volume changes, allowing emergent system behavior to be analyzed rather than imposed.

Table 2: The resulting total makespan and average module makespan under different number of modules

Number of Modules	Total Makespan (hr)	Average Module Makespan (hr)
1	230.00	230.00
3	413.65	137.88
5	634.23	126.85
10	1,180.79	118.08
11	1,293.16	117.56
12	1,402.08	116.84
13	1,650.35	126.95
14	1,802.5	128.75
15	1,960.00	130.67
20	2,655.12	132.76

The station-level performance analysis further illustrates the explanatory power of the graph-based formulation. The framework was utilized to analyze the resource utilization and bottlenecks under the scenario of fabricating 20 modules. Three metrics were tracked for each station: 1) busy time: measures total processing workload executed on station; 2) saturation percentage: represents the fraction of time during which the station operates at full capacity, indicating how frequently the station constrains task execution; and 3) queue time: measures the cumulative waiting time of tasks assigned to a station before processing, capturing upstream congestion effects. Tables 3 lists the values of these metrics and the capacities for three sample stations: framing, mechanical and electrical, and insulation. Framing stations exhibited the highest busy time and saturation percentage, confirming their role as the primary bottleneck in the examined production configuration. This finding is consistent with practical observations in modular factories, where framing activities often dominate early production stages and constrain downstream flow. In contrast, insulation and finishing-related stations showed relatively low saturation, suggesting underutilized capacity and potential opportunities for rebalancing or task reallocation. Queue time metrics provided additional insight into upstream congestion effects that are difficult to capture using aggregate performance indicators alone. High queue times at framing and M&E stations indicate that delays propagate through the system not merely due to task durations, but because of structural dependencies encoded in the task graph. From a managerial perspective, this suggests that capacity expansion decisions should prioritize stations with both high saturation and high queue accumulation, rather than focusing solely on busy time.

Table 3: The station performance analysis results

Station	Capacity	Busy Time	Saturation %	Queue time
Framing	3	6531.2	81.3	255570.4
M&E	2	2830.6	53.0	46339.9
Insulation	2	993.0	17.6	6247.52

Conclusion

This study illustrates how graph rewriting can serve as an effective bridge between design representation and production scheduling. By separating design topology, process knowledge, and scheduling constraints into distinct but interoperable graph layers, the approach maintains both flexibility and interpretability. The use of constraint programming further ensures that the generated schedules are globally optimized with respect to the defined objective, rather than relying on heuristic sequencing alone. More broadly, the results suggest that graph-based generative scheduling can function not only as a planning tool, but also as an analytical instrument for understanding the systemic consequences of design and capacity decisions in industrialized construction.

A key contribution of this study lies in demonstrating how tight coupling between design and production can be operationalized rather than abstracted away. Because task generation and duration calculation are driven by geometric attributes extracted from the design graph, even minor design changes, such as wall lengths, room configurations, or the number of openings—would propagate automatically into the production schedule. This capability contrasts with most existing job shop scheduling approaches in construction, which assume fixed task sets and rely on manual updates when designs evolve. The experimental results suggest that such coupling is particularly valuable in early-stage design evaluation and production planning. Designers and production planners can use the framework to explore "what-if" scenarios, assessing how design decisions influence makespan, station saturation, and bottleneck severity before committing to detailed fabrication plans. In this sense, the framework supports a shift from reactive scheduling toward proactive, design-informed production optimization.

Nevertheless, the current implementation also has limitations. The experiments assume deterministic task durations and station capacities, whereas real-world factory environments are subject to stochastic disruptions, learning effects, and workforce variability. In addition, the case study focuses on a single module type, and while the framework is generalizable, heterogeneous module families and mixed-model production were not explicitly examined. These factors may amplify congestion effects and introduce additional scheduling complexity.

The findings from the extended experiments point to several promising avenues for future research. First, incorporating stochastic task durations and probabilistic disruptions would allow the framework to support robustness and resilience analysis. Second, extending the graph rewrite rules to handle multiple module typologies within a single production line would enable mixed-model scheduling studies. Third, coupling the scheduling outputs with cost, labor, or energy metrics could support multi-objective optimization and decision-making at the factory planning level. Fourth, the framework successfully transforms a parametric module design into a feasible schedule without manual intervention. Future work can leverage this capability to identify design features that have the greatest impact on production performance.

INTEGRATED MANY-OBJECTIVE OPTIMIZATION FOR DECISION-MAKING AND DYNAMIC PROJECT CONTROL

Aman Shukla, and Sahil Garg
Indian Institute of Technology Delhi, New Delhi, India

Abstract

Construction projects involve conflicting objectives beyond time and cost, including quality, safety risk, resource stability, and environmental impact. Many-objective optimization (MaOO) helps address this complexity in planning, but it provides limited support for decision-making during execution, and selecting one solution from Pareto-sets often depends on human judgment. To overcome these gaps, this paper proposes an integrated planning and control framework combining Opposition-Based NSGA-III (OBNSGA-III) for six-objective optimization, an Entropy-based-VIKOR model for compromise solution selection, and a Dynamic-MaOO re-optimization mechanism for execution control. A case study based on 25-activities is used to demonstrate effective decision support from planning to execution.

Introduction

Construction projects operate as short-term complex production systems that involve multiple stakeholders with different and competing objectives (Ward et al. 1991). Construction industry is one of the rapidly growing industries in developing nations that supports socio-economic development by contributing infrastructure growth and employment generation. (Fu & Zhang, 2016). Construction projects involve large number of individual but interlinked activities. (Singh and Ernst, 2011). Traditional construction projects focus only on optimization of Time and cost. But Construction projects involve large number of objectives such as Quality, safety risk, resource moment, and environmental impact due to construction. These are important objectives for stakeholders and have direct impact on the project.

Traditional multi-objective algorithms struggle to maintain solution diversity and convergence to optimize more than three objectives. Thus, simultaneously optimization of these objectives requires many objective optimizations model (MaOO). NSGA-III and its variants address this issue through reference-point-based selection mechanisms, enabling efficient search in high-dimensional objective spaces.

MaOO model gives pareto optimal solution sets. Decision makers often use subjective weighted-sum methods to select one solution from the Pareto solution sets for the project. This includes human factor and limiting reproducibility. Current construction MaOO research, optimize the project objectives during planning phase assuming that selected solution will remain valid during execution phase.

The proposed framework integrates Opposition-Based NSGA-III (OBNSGA-III) model, an Entropy-based-VIKOR model, and Dynamic-MaOO re-optimization mechanism. This integrated framework contributes as a new methodology in selection of single solution set from sets pareto-optimal solution and plays a key role in project control during execution phase as it moves beyond one-time optimization and supports planning as a continuous process and enables both initial decision-making and execution-stage adaptation.

Literature Review

Early research in construction projects optimization was largely focused on the optimization of time–cost and finding the relationship between project duration and direct cost. Abbasnia et al. (2008) applied fuzzy logic model to find uncertainty in time–cost relationships, while Zareei and Hassan-Pour (2015) introduced a resource-constrained formulation to improve the schedule feasibility. These studies showed that deterministic planning approaches are insufficient for realistic construction decision making. As research progressed, it is found that considering only two objectives are not sufficient, particularly in projects where schedule acceleration adversely affected other performance dimensions.

To address this, quality was introduced as a third optimization objective. El-Rayes and Kandil (2005) demonstrated that minimization of time and cost alone can significantly degrade the construction quality and used an integrated time–cost–quality optimization model. The emergence of evolutionary algorithms further enabled the treatment of such multi-objective problems. Deb et al. (2002) proposed a NSGA-II algorithm. This model was widely adopted in construction scheduling as it provides elitist selection, and it has ability to generate diverse Pareto-optimal solutions. Subsequent studies applied genetic algorithms and particle swarm optimization to incorporate additional constraints and objectives, including safety risk and resource utilization (Afshar, A., and Dolabi, 2014; Elbeltagi, E., 2016).

As construction performance evaluation expanded, researchers have studied the effects of optimization of

safety and environmental impact with time and cost. Afshar, A., and Dolabi (2014) showed that time–cost-optimized schedules often lead to higher safety risks and came with a time-cost-safety risk optimization model, while Ozcan-Deniz et al. (2012) demonstrated a significant trade-off between productivity and environmental impact. Further, multi-mode, resource-constrained formulations highlighted the conflict between stability of execution and traditional performance measures of project (Ghoddousi, P., et al., 2013; Kim, K., et al., 2015). At this stage, most models address three objectives, typically combining time, cost and either safety or environmental criteria.

However, as the number of objectives increased beyond three, the conventional dominance-based algorithms such as NSGA-II, the effectiveness and diversity of selected solutions decreased. To overcome this, Deb and Jain (2014) proposed a reference-based NSGA-III algorithm. This algorithm uses a reference-point-based non-dominated sorting to maintain diversity in high-dimensional objective spaces. Development of this method marked a transition from multi-objective optimization to many-objective optimization in construction research. Arya et al. (2024) and Behera et al. (2025) applied NSGA-III to balance time, cost, quality, and sustainability-related objectives, while Zhan et al. (2024) demonstrated its effectiveness in generating well-distributed Pareto fronts for construction project management problems.

Recent studies have explicitly acknowledged the need for five-objective optimization frameworks. Panwar and Jha (2019) formulated a many-objective construction scheduling model integrating time, cost, resources and environment impact and Sharma and Trivedi (2022) integrated time, cost, quality, safety, and resource constraints using NSGA-III-based approaches. Panthi and Hussain (2025) further extended this line of research by proposing an OBNSGA-III framework incorporating time, cost, quality, safety, and environmental sustainability. Similarly, Sharma and Trivedi (2023) modelled trade-offs among time, cost, quality, safety risk, and environmental impact using opposition-based NSGA-III. These studies collectively demonstrate that most existing construction MaOO models converge at five objectives, reflecting both computational complexity and modelling challenges.

Despite of these advances, construction research optimization models are rarely used to optimize six-objectives simultaneously. In particular, the simultaneous integration of time, cost, quality, safety risk, environmental impact, and resource moment within a single optimization framework has received limited attention. Resource moment objectives are often treated separately from safety or environmental criteria, even though all three directly influence production stability and execution reliability. The absence of six-objective formulations restricts the ability of planners to evaluate comprehensive trade-offs inherent in complex construction systems.

Another limitation in literature is the decision-making to select one solution from Pareto-optimal sets. Although NSGA-III-based models generate diverse solution fronts, most studies rely on subjective weighting or visual inspection to select final execution plans. Zhan et al. (2024) explicitly noted that post-optimization decision selection remains weak in construction optimization research. While entropy-based weighting and compromise ranking methods such as VIKOR have been suggested to reduce subjectivity, their systematic integration with many-objective optimization models is still limited.

The majority of existing many-objective construction optimization studies are static and focusing exclusively on the planning stage only. Once project execution starts, the deviations in objective values are typically managed through heuristic rescheduling not from the original optimization logic.

In summary, the literature reveals three interrelated gaps: (1) most construction optimization studies are limited to five objectives, (2) decision-making from many-objective Pareto fronts remains weak and often subjective, and (3) optimization frameworks rarely extend into execution-stage control. The present research addresses these gaps by formulating a six-objective many-objective optimization model, integrating objective decision selection using Entropy–VIKOR, and embedding the model within a dynamic planning-and-control framework suitable for construction production systems. re-optimization.

From a lean construction point of view, construction projects are similar to production systems where planning and control must be continuously aligned to manage variability and improve the workflow reliability. Foundational lean construction studies emphasize the importance of reduction of uncertainty from the production and adapting plans that are based on execution feedback rather than relying on static schedules (Koskela, 1992; Ballard and Howell, 1998). The existing optimization literature remains focused only on planning-stage solutions. The proposed framework responds to this gap by supporting adaptive decision-making during execution phase of project.

Methodology

This research adopts a planning–control perspective to address construction projects as dynamic production systems rather than static optimization problems. The proposed methodology integrates three complementary components:

1. Many objective planning by using OBNSGA-III
2. Objective compromise decision selection using Entropy–VIKOR
3. Dynamic re-optimization during execution.

The proposed framework integrates optimization, decision selection, and re-optimization into a single workflow. The study shows how these can be used together to support planning and control decisions in multimode construction projects.

This model integrates structure existing optimization and decision-making tools into a coherent framework that supports both planning and execution-stage control. This approach aligns with lean construction principles, where plans are continuously optimized and adjusted based on execution feedback instead of being fixed at the outset. This structure explicitly links planning and control, addressing a major limitation of static construction optimization models.

In this study, the VIKOR method is employed to support compromise decision-making under conflicting criteria. The method determines a compromise solution by maximizing group utility and minimizing individual regret, thereby balancing both overall performance and the worst-case criterion. Other techniques, such as TOPSIS, rely on distances to ideal and negative-ideal solutions without considering their relative importance, which may affect the ranking results in certain decision situations (Opricovic, S., and Tzeng, G. H., 2004). As a result, VIKOR provides a more reliable and decision-relevant solution, particularly in situations where poor performance in a critical criterion cannot be ignored.

Many-Objective Optimization Model

Decision Variables and Project Representation

The construction project is modelled as a **precedence-constrained activity network** consisting of n activities. Each activity A has multiple execution modes m, where each mode represents a distinct combination of:

- Activity completion time (ACT_A)
- Activity completion cost (labour, material, equipment) (ACC_A)
- Activity Quality index (AQI_A)
- Activity Safety risk (ASR_A)
- Activity Environmental impact (AEI_A)
- Activity Resource moment (R_t^k)
- A candidate solution is defined as a vector of execution modes, one for each activity.

Objective Function Formulation

The model simultaneously optimizes six project-level objectives, the formulation of objectives are as below:

Objective 1: Minimize Project Completion Time (PCT)

$$PCT = \sum_{A \in CP} A\,CT_A \tag{1}$$

Where, CP denotes the set of activities on the critical path.

Objective 2: Minimize Project Completion Cost (PCC)

$$PCC = \sum_{A=1}^{n} D\,C_A + (IDC \times PCT) \tag{2}$$

Where, DC_A is the direct cost of activity A and IDC is the indirect cost per day.

Objective 3: Maximize Project Quality Index (PQI)

$$PQI = \frac{1}{n}\sum_{A=1}^{n} A\,QI_A \tag{3}$$

Where, AQI_A represents the quality achieved during first-time execution of activity A.

Objective 4: Minimize Project Safety Risk (PSR)

$$PSR = \sum_{A=1}^{n} A\,SR_A \tag{4}$$

Where, ASR_A aggregates safety risks related to labor injury, material wastage, and equipment failure for activity A.

Objective 5: Minimize Project Environmental Impact (PEI)

$$PEI = \sum_{A=1}^{n} A\,EI_A \tag{5}$$

Where, AEI_A is the CO_2-equivalent emission associated with activity A.

Objective 6: Minimize Project Resource Moment (PRM)

$$PRM = \sum_{A=1}^{n} A\,RM_A \tag{6}$$

here, $ARM_A = M_x + M_y$ $M_x = \sum(R_t^k)^2$, $M_y = \sum(R_t^k \cdot t)$

This formulation penalizes resource fluctuation and uneven resource distribution over time.

OBNSGA-III Optimization Procedure

The many-objective optimization problem is solved using Opposition-Based NSGA-III (OBNSGA-III).

The algorithm proceeds as follows:

1. Generate an initial random population of size N based on execution modes.
2. Generate an opposition-based population by computing opposite solutions and selecting the fittest N individuals.
3. Generate structured reference points using: $H = \binom{N+p-1}{p}$; where $N = 6$ objectives and $p = 6$ divisions per objective.
4. Apply simulated binary crossover (SBX) and polynomial mutation to generate offspring. And combine parent and offspring populations and perform non-dominated sorting.
5. Normalize objective values and associate solutions with reference directions.
6. Apply niche-count-based selection using perpendicular distance to reference points.
7. Perform opposition-based generation jumping.
8. Repeat until convergence criteria are met.

This process yields a diverse Pareto-optimal solution set without requiring subjective preferences during optimization.

Entropy–VIKOR Decision-Making Model

To identify a single actionable solution from the Pareto sets, an **Entropy-based VIKOR** model is employed.

Formulation of Entropy–VIKOR Decision-Making Model

Let the Pareto-optimal solution set obtained from OBNSGA-III be denoted as:

$$\mathcal{P} = \{P_1, P_2, \dots, P_m\}$$

Each solution P_i is evaluated against M objectives, forming a decision matrix F:

$$\mathrm{F} = [f_{ij}], \quad i = 1,2, \dots, m; \; j = 1,2, \dots, M$$

where f_{ij} represents the value of the j^{th} objective for the i^{th} Pareto solution.

Entropy-Based Objective Weighting

To eliminate subjective bias in assigning objective importance, entropy theory is applied.

Step 1: Normalization of Decision Matrix

Since the objectives are measured in different units and possess different optimization directions, the decision matrix must be normalized.

For each objective j, the normalized performance value p_{ij} is computed as:

$$p_{ij} = \frac{f_{ij}}{\sum_{i=1}^{m} f_{ij}} \tag{7}$$

Step 2: Entropy Calculation

The entropy value E_j of the j^{th} objective is calculated as:

$$E_j = -\frac{1}{ln(m)} \sum_{i=1}^{m} p_{ij} \, ln(p_{ij}) \tag{8}$$

The entropy value reflects the degree of dispersion of information associated with an objective across Pareto solutions.

Step 3: Objective Weights

The entropy-based weight w_j of the j^{th} objective is then obtained as:

$$w_j = \frac{1 - E_j}{\sum_{j=1}^{M} 1 - E_j} \tag{9}$$

Objectives exhibiting greater variability across Pareto solutions are thus assigned to higher importance.

VIKOR Compromise Ranking

The VIKOR method is employed to rank Pareto-optimal solutions and identify a compromise solution.

Step *1*: Determination of Best and Worst Values

For each objective j, the best and worst values are defined as:

$$f_j^* = \begin{cases} \min\limits_i f_{ij}, & \text{for cost-type objectives} \\ \max\limits_i f_{ij}, & \text{for benefit-type objectives} \end{cases}$$

$$f_j^- = \begin{cases} \max\limits_i f_{ij}, & \text{for cost-type objectives} \\ \min\limits_i f_{ij}, & \text{for benefit-type objectives} \end{cases}$$

Step 1: Group Utility and Individual Regret Measures

The **group utility measure** for solution i is computed as:

$$S_i = \sum_{j=1}^{M} w_j \frac{f_j^* - f_{ij}}{f_j^* - f_j^-} \tag{10}$$

The **individual regret measure** is defined as:

$$R_i = \max_j \left[w_j \frac{f_j^* - f_{ij}}{f_j^* - f_j^-} \right] \tag{11}$$

Step 2: VIKOR Compromise Index

The compromise ranking index Q_i is calculated as:

$$Q_i = v \frac{S_i - S^*}{S^- - S^*} + (1 - v) \frac{R_i - R^*}{R^- - R^*} \tag{12}$$

where:

$S^* = min_i S_i$, $S^- = max_i S_i$

$R^* = min_i R_i$, $R^- = max_i R_i$

v represents the weight of group utility (taken as $v = 0.5$ for this study)

The Pareto solution with minimum Q_i, satisfying acceptable advantage and stability conditions, is selected as the **baseline execution plan**.

Dynamic Many-Objective Optimization Model for project control

To address execution-stage uncertainty, a Dynamic MaOO re-optimization model is introduced. The dynamic MaOO model extends the static planning optimization into the execution phase by incorporating real-time project progress.

At each decision point

- Lock the completed activities and remove from the decision space.
- Partially completed activities contribute only to the remaining work.
- Remaining activities are re-optimized using OBNSGA-III.
- Normalization of new Pareto solutions is done along with the planned solution
- In the normalized plane, calculated the distance between re-optimized solutions.
- The solution having minimum deviation from the planned solution is selected to continue the execution.

This mechanism ensures adaptability while preserving consistency with the original compromise plan.

During project execution, the model incorporates actual obtained objective values for completed activities. If deviations are observed between planned and achieved values, the optimization is re-executed using the updated data. The model then recommends revised execution modes for the remaining activities, ensuring alignment with the original project objectives with minimum deviation from the planned objective values. The model works on OBNSGA-III algorithm with updated input data obtained during execution.

Model Flow Chart is shown in Figure-1.

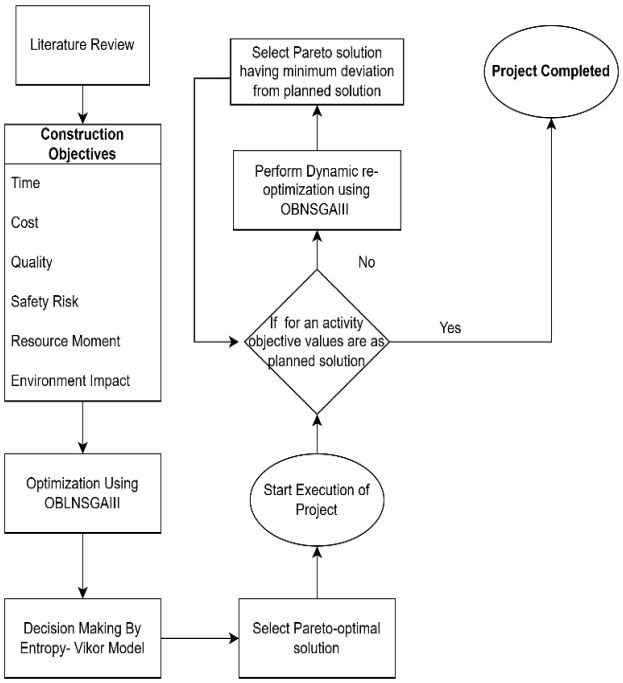

Figure 1: Flow Chart of Proposed Model

Case Study and Result

The case study involves 25 activities with various execution modes, yielding a combinatorial search space of over 53 million alternatives related to a construction project. Optimization of this project is done on OBNSGAIII model, and 78 Nos of pareto-optimal solutions are obtained. The Multi-Objective Trade-off based on normalized values is shown below as Figure 2.

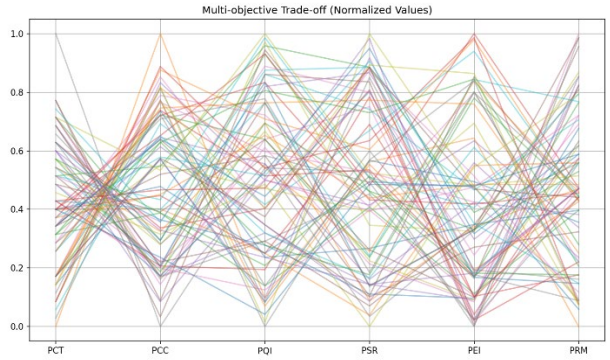

Figure 2 : Multi-Objective Trade-off based on normalized values

After this the multi-criteria decision making was done based on Entropy based VIKOR model to select a solution set for the project execution.

Results of Entropy weight calculated from model for objectives are: PCT: 0.166, PCC: 0.134, PQI: 0.177, PSR: 0.210, PEI:0.160, PRM:0.153. And selected solution set after Entropy VIKOR model- Pareto Index-23, selected modes of execution for 25 activities (A1-A2-…-A25) are: 1-2-1-1-1-1-3-3-2-3-3-1-1-2-1-2-2-1-2-2-1-1-2-1-1 and project objective values are: PCT: 243 days, PCC: 723900 Rs., PQI: 0.86, PSR: 75.22, PEI: 70.92, PRM 1855.

This Pareto solution is used for execution of project. After completion of first two activities, it is found that objective values are deviated as per planned due to resource unavailability at project site. So, dynamic re-optimization model is used to re-optimize the project and 38 pareto solutions are found. The solution having minimum deviation from planned solution, modes are used for re-execution of project.

The achieved values of objectives and deviation from the planned solution are shown in Table-1.

Table 1: Planned vs Achieved Project Performance

Objective	Planned	Achieved	Deviation (%)
PCT	243	230	-5.35
PCC	723900	815700	12.68
PQI	0.8564	0.8676	1.31
PSR	75.22	74.435	-1.04
PEI	70.92	82.295	16.04
PRM	1855	1995	7.55

The dynamic re-optimization results illustrate how planning decisions can be revised in response to resource unavailability without discarding the original planning rationale. This model is similar to lean construction thinking, which emphasizes maintaining plan reliability while accommodating inevitable execution variability through continuous control rather than complete re-planning.

Conclusion and Future Work

This study proposed an integrated many-objective framework for construction planning and control by combining OBNSGA-III optimization, Entropy–VIKOR decision making, and a dynamic re-optimization mechanism. Unlike most existing studies that limit analysis to five objectives and static planning, the proposed approach explicitly considers six project-level objectives—time, cost, quality, safety risk, environmental impact, and resource moment thereby providing a more complete representation of construction production behaviour.

From the case study we can say that OBNSGA-III can effectively manage a large combinatorial decision space and generate a diverse set of Pareto-optimal solutions. However, the results also confirmed that Pareto optimization alone is insufficient for practical decision-making. The Entropy–VIKOR model enabled objective selection of a balanced compromise solution without relying on subjective weighting, producing an execution plan with acceptable performance across all six objectives.

The dynamic re-optimization results further showed that construction plans must adapt during execution. When deviations occurred due to resource unavailability, the proposed dynamic model successfully re-optimized the remaining activities and identified revised execution

modes with minimum deviation from the original plan. This demonstrates that many-objective optimization can function as a control-oriented decision-support tool, rather than a one-time planning exercise.

The explicit inclusion of resource moment as a sixth objective proved critical, as it revealed differences in execution stability that were not visible through time–cost–quality–safety–environment trade-offs alone. Overall, we can say that the proposed framework supports more reliable planning and controlled adaptation during execution of project, and the framework aligns well with lean construction principles.

From a lean construction point of view, the proposed framework contributes to planning–control integration by enabling structured adaptation of production decisions in response to variability, supporting more reliable execution without relying on rigid or static plans.

Future work can also be done on real-time data integration through BIM-enabled progress tracking and site data acquisition systems. By linking this proposed optimization model with live data streams would allow automatic updating of activity status, resource usage, and performance indicators, transforming the framework into a decision-support system that operates throughout the project lifecycle.

PRINCIPLES FOR THE INDUSTRIALISATION OF THE INFRASTRUCTURE RENOVATION AND REPLACEMENT ASSIGNMENT

Irfan Pottachola, Alexander Bletsis, and Trijntje Verschuuren
Netherlands Organisation for Applied Scientific Research (TNO), Delft, The Netherlands

Abstract

The Netherlands faces an unprecedented infrastructure renewal assignment that cannot be addressed through traditional project-based delivery. Although industrialisation is widely promoted as a solution, its adoption remains limited due to a lack of system-level understanding of the conditions required for scaling. This study positions industrialisation as a coordinated transformation of infrastructure asset management and develops a principles-based perspective to support this transition. Using thematic analysis of literature and expert validation, five principles are identified. Together, these principles clarify why isolated technological initiatives struggle to scale and establishes a foundation for developing action perspectives and policy directions to guide industrialisation.

Introduction

The Netherlands faces an urgent and complex challenge in the renewal (renovation and replacement) of its aging civil infrastructure (TNO, 2023). Approximately 40% of bridges and viaducts are approaching or have exceeded their intended service life, with annual renewal costs projected to rise from €1.1 billion in 2021 to €2.4 billion between 2021 and 2030, and further to €2.9 billion annually between 2031 and 2040 (TNO, 2023). Delivering this scale of intervention requires a significant increase in the pace and efficiency of infrastructure projects.

However, the Dutch construction sector, as currently organised, lacks the capacity and supporting ecosystem to respond effectively (Bletsis, 2020). The sector remains structured around bespoke, one-off projects, characterised by fragmented procurement practices, limited standardisation, and temporary supply chains. This "loosely coupled" structure limits knowledge transfer and learning across projects (Dubois and Gadde, 2002), constraining productivity improvements relative to the wider economy. As a result, existing delivery models remain heavily reliant on labour-intensive, on-site activities, which are associated with inefficiencies such as cost overruns, delays, and waste (Eriksson et al., 2014). At the same time, increasing pressures related to sustainability, resource efficiency, and a shrinking workforce further intensify the need for more productive ways of working (Pottachola, 2024).

Taken together, the scale and urgency of the renewal assignment render the prevailing one-to-one, project-based delivery model increasingly untenable. Without a fundamental shift in how infrastructure renewal is organised and coordinated, the sector will struggle to meet demand (TNO, 2023), making the search for scalable, efficient solutions, and the delivery models that enable them, not only necessary but inevitable.

In response to such systemic challenges, the construction sector has increasingly sought to adopt principles originating from manufacturing, such as standardisation, mechanisation, and automation (Lessing, 2015). These developments are collectively referred to as the industrialisation of construction. Initially, industrialisation in construction was primarily understood as the use of off-site manufacturing as technical means to relocate work away from the unpredictable construction site (Lessing, 2015). Over time, this interpretation has evolved into a more holistic perspective, where industrialisation is framed as a systematic, process-oriented approach characterised by standardisation, continuous improvement, and long-term supply chain integration (van Ee, 2022; van Groesen, 2022; Pottachola, 2024).

Within the Dutch infrastructure sector, industrialisation is widely regarded as a promising solution direction for addressing the renewal assignment. Initiatives such as Industrial, Flexible, and Demountable (IFD) bridge concepts illustrate this potential through reduced project lead times, faster on-site construction with less disruption, and designs that enable disassembly and long-term reuse (EIB, 2022). Feasibility studies in the Dutch context estimate a potential market for IFD of € 3.3 billion for decentralised asset owners between 2025 and 2035, with an associated economic benefit of approximately €300 million (EIB, 2022).

Despite this recognised potential and the availability of supporting technologies, the adoption of industrialised solutions in infrastructure renewal remains limited. This limited uptake cannot be attributed to technological immaturity, but rather to the fragmented way in which industrialisation is pursued, often through isolated instruments or technologies, without a coherent understanding of the organisational conditions required to support industrialised production (Bletsis, 2020). The infrastructure sector operates in an extremely demand-driven environment, reinforcing the central role of asset

owners in enabling or constraining industrialised production. In the Dutch context alone, nearly 370 decentralised public authorities are responsible for infrastructure assets. While efforts on industrialisation heavily focuses on the market side, the role of asset management organisations in this transition is frequently overlooked. Yet, it is precisely the upstream decisions made by asset owners, such as structuring demand to create continuity, defining project requirements that support standardisation, and designing procurement frameworks that incentivise long-term investment, that largely shape the conditions under which industrialised solutions can emerge and scale (EIB, 2022).

The complex nature of infrastructure construction, coupled with the systemic and multifaceted character of industrialisation, requires supporting frameworks capable of structuring and coordinating action across diverse actors (Brouwer, 2024). Although frameworks for industrialised construction have been developed in the housing sector (e.g., Lessing, 2015), these are not fully transferable to the infrastructure domain due to differences in asset characteristics, governance structures, and demand dynamics (Eriksson et al., 2014). Moreover, these frameworks are grounded in an implicit assumption that enabling conditions for industrialised construction such as stable demand and aligned procurement and governance structures are already in place. However, this assumption does not hold in the infrastructure sector, which is characterised by its demand-driven nature and complex product systems. Here, the conditions required for industrialisation are not given, but must be actively created, particularly through asset management practices. Consequently, existing frameworks provide limited guidance for coordinating industrialisation efforts in the infrastructure sector, leaving actors without a shared perspective to align decisions, organise actions, and assess progress.

This study addresses this gap by developing a principles-based framework for the industrialisation of infrastructure asset management, derived through thematic analysis of literature and validated with expert input. By identifying the fundamental principles that characterise industrialised infrastructure systems, the study provides a foundation for aligning and coordinating industrialisation efforts across actors as a system-level transformation of infrastructure asset management.

The remainder of this paper is structured as follows. First, the paper builds its theoretical foundation by drawing on existing industrialisation literature mostly from the building context and adapting these insights to the specific context of infrastructure asset management. Next, the research is described that was conducted to derive principles. The findings section presents the five derived principles. This is followed by a discussion of the implications for asset owners, governance, and sector-wide coordination. Finally, the paper concludes with key insights, limitations, and directions for future research.

Theoretical Foundation – Industrialisation of Asset Management

Industrialisation of construction represents a shift from a traditional design-to-product mindset, where each project is treated as inherently unique, toward a product-to-design perspective that emphasises system-oriented thinking (van Ee, 2022). This shift aims to enable construction companies to achieve economies of scale through integrated value and supply chains across projects (van Groesen, 2022). This transition has been most visibly advanced in the housing sector, where industrially produced modular homes are increasingly regarded as a viable response to the European affordable housing crisis (van Ee, 2022). The growing adoption of prefabricated and modular housing solutions reflects an acceptance of industrial approaches as alternatives to so-called traditional construction methods.

The transition to a product-based mindset in infrastructure sector is not yet advanced. Infrastructure projects are frequently characterised as complex product systems (CoPS) that are unique in nature, which has contributed to a reluctance to adopt standardisation and platform-based approaches due to site-specific conditions and varying client requirements (Stout, 2016). As a result, industrialisation in infrastructure often manifests as isolated technological interventions rather than as a coordinated reorganisation of production and decision-making processes across the value chain. Recent studies, however, demonstrate that even complex civil engineering structures such as bridges can be decomposed into standardised modules and subsystems (EIB, 2022). This perspective is particularly relevant in the context of infrastructure renewal, where the dominant task is no longer greenfield construction but the large-scale renewal of existing assets.

To build on this shift in perspective, industrialisation of construction in this study is positioned not as the application of isolated methods or technologies, but as a coordinated transformation of infrastructure asset management that creates the conditions for the effective adoption and scaling of productivity-enhancing approaches across the value chain (Brouwer, 2024). The definition adopted in this study is synthesised from recurring elements in the literature and subsequently contextualised to the Dutch renewal assignment, where fragmented demand, temporary coalitions, and high transaction costs inhibit productivity improvement. The formulation deliberately emphasises organisational restructuring, scale creation, and the enabling of process-oriented technologies, as these dimensions repeatedly emerged as prerequisites for industrial performance (Lessing, 2015; Stout, 2016; Bletsis, 2020; EIB, 2022; Brouwer, 2024). In line with this perspective, and tailored to the specific dynamics of the Dutch infrastructure renewal assignment, we define industrialisation as:

'The reorganisation of (specific parts of) the infrastructure sector, to reduce its inherent project-based and demand-driven nature, in order to implement and enhance process-oriented technologies, for the

purpose of achieving economies of scale and reducing transaction costs, and eventually to mitigate the productivity challenges in the renewal assignment.'

Industrialisation therefore implies a shift from a purely project-based logic toward a more project-independent or product-oriented approach, in which commonalities across projects are systematically identified and leveraged through product platforms and standardised solution spaces (van Groesen, 2022). Such a shift enables organisations to move from reactive forms of production towards more proactive forms, including mass customisation, where project-specific variation is accommodated within a stable, standardised system (van Groesen, 2022). By aligning supply and demand more effectively, industrialisation creates the conditions under which repetition, learning, and optimisation across projects become possible (Bletsis, 2020).

The reorganisation of the sector is also a prerequisite for the effective implementation of process-oriented technologies, which form the operational backbone of industrialisation (Lessing, 2015). Technologies such as automation, mechanisation, and digital configurators enable the transition from craft-based, labour-intensive practices to manufacturing-led production processes. However, without the process stability and organisational alignment provided by industrialisation, advanced technologies cannot be effectively deployed at scale (Pottachola, 2024). In this sense, industrialisation is not the result of technological adoption, but rather a necessary condition for technologies to deliver productivity gains.

Operationally, industrialisation aims to realise economies of scale and economies of repetition, which are currently difficult to achieve in the infrastructure sector due to fragmented and unpredictable demand (Brouwer, 2024). Standardisation and the aggregation of demand into programs or portfolios enable the production volumes required to justify investments in industrial facilities and tools, thereby reducing unit costs (EIB, 2022). In parallel, a shift from transactional, lowest-price procurement toward long-term supply chain partnerships reduces transaction costs associated with repeated tendering, coordination, and non-value-adding activities, resulting in a more economically viable and resilient value chain (Eriksson et al., 2014).

In this way, industrialisation offers the potential for a necessary productivity leap, enabling the sector to execute extensive renewal programmes within financial, temporal, and environmental constraints, while maintaining quality and safety standards. However, this conceptualisation implies that it cannot be operationalised through isolated methods, technologies, or best practices alone. Given the diversity of asset types, organisational settings, and institutional arrangements in the infrastructure sector, prescriptive solutions are unlikely to be transferable or scalable across contexts (Bletsis, 2020). Therefore, industrialisation requires a framework that articulates the fundamental conditions underpinning such a transition, while allowing for contextual interpretation and implementation.

In this study, these foundational conditions are expressed in the form of principles. Principles serve as high-level propositions that describe essential characteristics of industrialised asset management systems without prescribing specific solutions or technologies. As such, they provide a shared analytical lens for understanding industrialisation across different actors and contexts. They form the basis for systematically analysing how organisations enable or constrain the adoption of productivity-enhancing approaches.

Research Method

This study adopts a qualitative, exploratory research design aimed at defining foundational principles for the industrialisation of infrastructure asset management. The study uses thematic analysis as its primary analytical method to identify, synthesise, and abstract recurring values and patterns into a coherent set of industrialisation principles.

The research process began by formulating a working definition of industrialisation in the context of infrastructure asset management. Industrialisation was conceptualised as a systemic transformation that reduces the inherently project-based nature of infrastructure delivery with scalable, process-oriented approaches. Based on this definition, the purpose of the principles was defined. The principles were positioned as (1) fundamental propositions that provide an action-oriented perspective for stakeholders; (2) a conceptual foundation for defining and guiding industrialisation efforts and for informing policymakers; and (3) a basis for future maturity assessment models. This step established the analytical lens used throughout the study.

A targeted literature review was conducted to explore theoretical and empirical insights related to industrialisation. Search strings combined keywords such as industrialised construction, industrialised building systems, modular construction, prefabrication, and product platforms, together with related concepts including standardisation, DfMA, off-site manufacturing, process integration, supply chain integration, and construction productivity. The initial set of 84 identified publications were screened based on their relevance to the objectives of this study. The primary inclusion criterion concerned the extent to which a study provided insight into why industrialisation-related approaches were adopted and which organisational, institutional, or process conditions were associated with successful implementation and productivity improvement. Following this screening, 39 publications were retained for detailed analysis. Given the limited availability of systemic perspectives on industrialisation within infrastructure, many selected studies originated from the building sector.

Data from literature were analysed using thematic analysis. The analysis proceeded in four iterative steps. First, key concepts and terms related to industrialisation, productivity, and organisational change were identified across data sources. Then, related codes were grouped into broader themes representing recurring values and

patterns. The focus during this analysis was understanding what the characteristics, enabling conditions, and motivations behind various implementation of industrialisation technologies were. The identified themes were further refined and abstracted to capture their underlying fundamentals, resulting in a set of higher-order principles. Each principle represents a necessary condition for enabling industrialised asset management.

The derived principles were subjected to expert validation through a series of semi-structured interviews with domain experts. In total, experts included asset managers, policy specialists, and engineers representing four decentralised authorities, one national agency, and four contractors. In these sessions, the five principles and their preliminary definitions were presented to each organisation individually. Participants were asked to reflect on the extent to which the principles corresponded with their current productivity ambitions, strategic directions, and practical experiences.

The interviews examined the relevance, clarity, and completeness of the principles, as well as their recognisability in ongoing initiatives. Feedback from these validation interviews was used to refine the formulation of the principles, sharpen definitions, and ensure their applicability across both demand- and supply-side contexts.

Findings

The thematic analysis resulted in five principles that characterise industrialisation in infrastructure asset management. A detailed overview of the coding structure linking codes with relevant sources, themes, and principles is provided as supplementary material to this paper (TNO, 2026). Each principle is discussed in detail in the following sections.

Principle 1: Continuity and Repeatability

In any industry, the market operates most efficiently when there is a steady flow of demand (EIB, 2022). In construction, however, a fragmented, project-based approach forces organisations to constantly (re)adjust their resources and operations, leading to inefficiencies, increased costs, and slower delivery (Dubois and Gadde, 2002). A continuous flow of standardised demand allows for a stable and predictable environment where workflows can be optimised and scaled over time (EIB, 2022).

The principle of Continuity and Repeatability describes the extent to which infrastructure renewal activities are organised to enable stable production flows, and reuse across projects. The analysis highlights a transition from fragmented, one-off project delivery towards process-based approaches in which production logic is decoupled from individual project contexts (Eriksson et al., 2014). Central to this principle is the aggregation of demand through programmatic and portfolio-based planning to create predictable workloads that sustain industrial operations (Eriksson et al., 2014; EIB, 2022; van Groesen, 2022). Long-term supply chain integration also emerged as a key theme, reflecting the importance of stable partnerships, team continuity, and synchronised off-site and on-site processes in maintaining steady production flows (Vrijhoef and Koskela, 2005; Söderholm, 2010; Lessing, 2015; Pottachola, 2024).

Along these lines, we define Continuity and Repeatability as *the principle of ensuring continuous operations over time in a way that supports the development of repeatable products and processes.*

In essence, this principle enables scalable and predictable processes, optimises resource allocation, reduces costs and project durations, and fosters innovations and reuse of data, and modular solutions across projects.

Principle 2: Specialisation

Continuity in processes enables organisations to simplify workflows by reducing portfolio diversity and complexity. This, in turn, creates the opportunity to structure operations around a more focused and narrowed scope of products or services, allowing organisations to concentrate their resources and expertise on these defined areas (Vrijhoef and Koskela, 2005). Specialisation refers to the deliberate narrowing of organisational scope to increase efficiency and performance through focused capabilities.

The thematic analysis indicates a shift from generalist, project-oriented organisations towards product- and process-oriented structures. This includes strategic limitation of the solution space (Stout, 2016), market segmentation, and the development of specialised offerings aligned with repeatable production processes (Vrijhoef and Koskela, 2005). At the organisational level, specialisation is supported by permanent, dedicated teams and the distinction between core and non-core competencies (Vrijhoef and Koskela, 2005; Lessing, 2015). At the supply chain level, the analysis points to a transition from project-based subcontracting towards system suppliers and long-term strategic partnerships, enabling cumulative learning and early integration of specialised knowledge (van Ee, 2022; van Groesen, 2022; Pottachola, 2024).

Along these lines, we define Specialisation as *the principle of focusing resources and expertise on a specific, narrowed scope of assets or services by simplifying workflows and reducing portfolio complexity.*

Specialisation enhances the organisation's technical proficiency, simplifies portfolio management, and enables the market to deliver high-quality, tailored solutions for specific assets or types of interventions.

Principle 3: Knowledge Codification

Continuous improvement is necessary in an industrial system (Lessing, 2015). In the fragmented and project-based nature of the construction sector, valuable knowledge is often lost when teams disband after projects (Dubois and Gadde, 2002). Most of this knowledge remains tacit, leading to missed opportunities for improvement and a failure to learn from mistakes (Pottachola, 2024). Furthermore, this knowledge is frequently lost as individuals retire or move to organisations (Pottachola, 2024).

Knowledge codification captures the transformation of tacit, individual expertise into explicit, reusable organisational assets. The analysis reveals recurring themes related to formalising decision logics, and solutions in order to avoid repeated reinvention (Stout, 2016; Andersson and Lessing, 2017). Structuring information for interoperability and machine readability emerged as a critical theme, including the use of standardised data formats, taxonomies, and shared information structures such that knowledge and information from multiple individuals can be aggregated (van Ee, 2022; Pottachola, 2024). Feedback loops for continuous learning and the use of digital tools, such as semantic models, BIM, and design configurators support the retention, application, and evolution of codified knowledge across projects (Cao et al., 2021; van Ee, 2022; Pottachola, 2024).

Along these lines, we define Knowledge Codification as *the principle of formalising and embedding tacit knowledge into structured systems to ensure it is retained, reused, and enables continuous improvement across organisations, projects, and individuals.*

Knowledge codification thus enables organisations to systematically build on past knowledge, improving decision-making, execution, and long-term planning. This ensures the retention of expertise as individuals leave, enables building on experience for better decision-making, facilitates faster onboarding, and prevents repeated errors or rediscovery of solutions.

Principle 4: Pre-Engineering

In the construction industry, resources are often allocated to create bespoke designs and solutions for individual projects (Dubois and Gadde, 2002). While uniqueness is an inherent characteristic of construction projects, many projects share commonalities that are often overlooked, particularly in the infrastructure sector (Bletsis, 2020; EIB, 2022). These overlooked commonalities prevent the industry from utilising standardisation, thereby limiting scalability.

Pre-engineering refers to shifting engineering effort upstream by resolving complexity early and systematically. The analysis highlights the decomposition of complex systems into modular components (Stout, 2016; van Groesen, 2022) and the development of product platforms (Knippenberg et al., 2019; van Ee, 2022) or kits of parts (Cao et al., 2021) as central mechanisms. This enables configuration-based solutions while isolating variability to specific modules.

Front-loading design decisions, including early design freezes and early integration of suppliers (Wuni and Shen, 2020), is identified as a key theme to reduce downstream uncertainty. Further themes include the integration of design and production through Design for Manufacture and Assembly (DfMA) principles and the gradual shift of production logic from on-site construction towards manufacturing-oriented processes, including off-site and hybrid production models (Eriksson et al., 2014; Pottachola, 2024).

Along these lines, we define pre-engineering as *the principle of developing reusable products and processes through standardisation and pre-definition, enabling scalability and reducing the reliance on bespoke, project-specific efforts.*

Pre-engineering accelerates project delivery by reducing bespoke efforts and thus shorter design/ planning lead times, enhances market productivity through reusable and optimised designs and processes, and supports the development of sustainable and circular methods and processes.

Principle 5: Socio-Technical Alignment

The construction industry is inherently fragmented vertically (across project phases), horizontally (across expertise), and longitudinally (across projects) (Adriaanse, 2014). This fragmentation leads to misalignment between social systems (people, contracts, organisations) and technical systems (processes, technologies, tools) (Pottachola, 2024). Industrialisation requires a collective effort toward common goals, and achieving alignment between these systems is important for a full-fledged industrial system.

Sociotechnical alignment captures this need to align contractual, organisational, cultural, and digital dimensions of industrialisation. The analysis shows that industrial objectives are difficult to realise without contractual frameworks that support collaboration, shared risk, and early stakeholder involvement (Vrijhoef and Koskela, 2005; Bletsis, 2020). Traditional transactional and lowest-price contracting approaches frequently conflict with industrialised modes of operation (Eriksson et al., 2014; Bletsis, 2020). Beyond formal arrangements, the analysis highlights the importance of network-centric cultures based on trust, transparency (Stout, 2016), and shared situational awareness (Bletsis, 2020; Pottachola, 2024). Aligning digital systems with organisational workflows also emerges as a theme (Pottachola, 2024), indicating the required social and organisational transformation as a technical one.

Along these lines, we define Sociotechnical alignment as *the principle of achieving the alignment between social systems and technical systems, ensuring that resources are coordinated to function cohesively within a larger operational framework.*

Sociotechnical alignment ensures stakeholder priorities and resources are aligned for effective collaboration on large assignments, such as the infrastructure renewal assignment. Furthermore, this enables the full utilisation of product platforms' potential.

Expert Validation Results

To evaluate these principles, validation interviews were conducted with senior asset managers and project managers from asset owners, contractors and engineering firms. The principles and their definitions were well received, with practitioners confirming that they represent not merely theoretical constructs but active levers they consider for addressing the productivity gap. They were widely recognised, prompting reflection on how they are

already applied in practice while also revealing weaknesses in current approaches and opportunities for improvement.

Continuity & repeatability was consistently recognised as foundational to achieving industrialisation. Asset owners emphasised that creating continuity in demand is increasingly a strategic priority, as it enables more reliable collaboration with the market, lowers inherent variability in tender outcomes, and provides space for innovation. Contractors highlighted that continuity directly reduces transaction costs by allowing reuse of designs, processes, and supply-chain arrangements; several noted that repeatability enables significant learning effects that are currently lost in one-off projects.

Specialisation was seen as a means to allocate resources outside of the project scope and towards more continuous and repeatable operations. Specialisation is relevant at multiple scales within organisations and the sector. For example, on the team level specialisation was related to the ongoing shift of moving from project teams to expertise teams that works across multiple projects often resulting in higher productivity yields.

Knowledge codification was widely recognised by practitioners as essential, yet it remains a difficult principle to operationalise. While organisations acknowledge the need to retain and reuse knowledge, they struggle to translate tacit experience into structured, reusable assets. Challenges arise in transferring knowledge across projects. While lessons learned may be documented through evaluation at project closure, they are rarely converted into systematised and codified forms such as design rules, or configuration logics. In addition, underlying data is often fragmented, stored in inconsistent formats, or confined to individual projects. The experts linked this challenge back to specialisation, as a means to have coherent systems that enable knowledge capture across projects.

Practitioners mentioned a wide variety of activities in asset management where pre-engineering has benefits. Examples included pre-engineered parametric models for the reassessment of bridge typologies, development and use of IFD-standards to stimulate product-platforms for bridges, and detailed designs of specific modular bridge concepts that can be applied across projects. Across these applications, implementing this principle was seen to deliver clear added value.

Sociotechnical Alignment emerged as one of the most challenging and systemically important principles. Practitioners repeatedly noted that even when technical solutions exist (such as standards for IFD bridges) misalignment in contracts, governance structures, and organisational incentives prevents their adoption and potential. Examples included projects where standardisation was technically feasible but not contractually supported, resulting in bespoke solutions despite shared intentions to industrialise. Besides the variability in specifications across projects, current procurement practices often incentivise late-stage design changes thus hindering pre-engineering or the adoption of a pre-engineered concept.

Discussion

While extant literature has catalogued the barriers hindering industrialisation in construction a unified perspective explaining the foundational conditions required to enable this transition has remained largely absent, especially in the infrastructure sector. This study extends the existing body of knowledge by shifting the analytical focus away from individual enabling technologies toward the underlying conditions that shape industrialisation across the entire infrastructure value chain. The five principles identified through the thematic analysis collectively describe how industrialisation restructures the organisational, institutional, and production logic of infrastructure asset management. This supports the ongoing shift in the literature away from viewing industrialisation in construction as a production technique, toward understanding it as a broader organisational and system-level transformation of construction delivery (van Ee, 2022; Pottachola, 2024). The results help explain why the increasing maturity of individual enabling technologies has not translated into widespread adoption. The principles are not independent but forms an interdependent system of conditions. For example, Continuity and Repeatability create the essential market stability required for Specialisation. Without a predictable pipeline of aggregated demand, firms cannot justify the investments in specialised equipment or fixed process crews required for industrial efficiency (Vrijhoef and Koskela, 2005; EIB, 2022). Simultaneously, Knowledge Codification acts as the prerequisite for Pre-Engineering and configuration-based solutions. Shifting from tacit to explicit knowledge is critical for enabling digital configurators and product platforms that facilitate mass customisation (van Ee, 2022; Pottachola, 2024). Socio-Technical Alignment underpins the ability of organisations to sustain these industrialised practices over time by addressing the social gap where implementation fails due to a lack of cultural adaptation or workforce skills (Bletsis, 2020).

Partial implementation, such as adopting isolated technologies or methods without addressing their enabling conditions, is therefore unlikely to result in sustained productivity improvements. The interdependency of principles provides a plausible explanation for why many industrialisation initiatives remain confined to pilots rather than scaling across organisations and portfolios. By making these enabling conditions explicit, the principles offer a diagnostic lens for understanding where and why adoption stalls, and where targeted interventions are required.

These findings have important implications for infrastructure asset management organisations. Importantly, it challenges the implicit assumption that industrialisation is primarily a supply-side responsibility. Asset management activities can broadly be divided into demand-side led planning phases, and supply-side led realisation phases. In practice, industrialisation is

frequently associated with the realisation phases through technologies such as prefabricated systems, with the locus of responsibility placed largely on contractors and manufacturers (EIB, 2022). While these technologies represent concrete applications of industrialisation, they are insufficient in isolation to deliver the required productivity gains. The principles highlight that without the bundling of demand and the harmonisation of technical standards across projects, the market lacks the continuity needed to invest in standardised, repeatable, and scalable solutions. Thus, industrialisation must be reconceptualised not just as a downstream construction tactic, but also as an upstream asset management strategy.

To support the formulation of such upstream strategies, the principles developed in this study provide an actionable reference for both individual asset owners and for coordination across asset owners within the wider infrastructure governance system. At the level of individual asset management organisations, the principles offer a structured way to translate industrialisation ambitions into concrete strategic choices. In practice, this may manifest in portfolio and programme bundling strategies that prioritise repetition and continuity, or in the selection of procurement and contract arrangements that incentivise long-term collaboration, data sharing, and knowledge reuse.

Beyond individual organisations, achieving industrialisation at scale requires coordination across asset owners. In the context of the polycentric Dutch infrastructure sector (Bletsis, 2020), industrialisation cannot be realised through top-down control or isolated organisational change alone. The principles provide a shared coordination mechanism that can support alignment across organisational boundaries. By articulating common conditions for industrialised project delivery, the principles offer a common language through which multiple asset owners can coordinate strategies. In practice, this may manifest in joint project bundling to create market continuity, as well as in the alignment of specifications and contract frameworks to enable standardisation and repeatability. In this sense, the principles enable coordination without centralisation, allowing asset owners to retain autonomy while contributing to a shared industrialisation trajectory.

The principles also complement existing maturity models and transition frameworks by shifting the focus from organisational capability to system-level suitability. Existing maturity models for industrialised construction, such as the Industrialised Construction Maturity Model which evaluates organisational enablers and outcomes (Wang et al., 2020), primarily assess how well an organisation is equipped to develop and deliver industrialised solutions. Implicitly, these models assume that the broader system conditions in which organisations operate are conducive to industrialisation. The principles proposed help to assess whether the foundational conditions across the value chain are aligned to enable industrialisation in the first place. For example, a contractor may develop a technically mature modular bridge concept that scores highly on existing maturity models yet fails to scale due to misalignment with demand-side practices and needs, procurement frameworks, or other sociotechnical conditions. By explicitly accounting for such system-level alignment, particularly between asset owners, market actors, and governance arrangements, the principles enable an assessment of whether organisations are operating within an appropriate playing field for industrialised infrastructure renewal. This system-oriented perspective is largely absent from existing maturity frameworks in the literature.

Conclusions

This study examined why industrialisation, despite recognised potential and technological maturity, has struggled to scale within the Dutch infrastructure renewal context. Through a thematic analysis of literature, complemented by expert validation, the study identified five foundational principles that characterise industrialised infrastructure asset management: Continuity and Repeatability, Specialisation, Knowledge Codification, Pre-engineering, and Sociotechnical Alignment. The findings illustrate that industrialisation cannot be realised through partial or isolated interventions. The principles are inherently interdependent, and this interdependence helps explain why many industrialisation initiatives remain confined to pilots, despite technological maturity. Importantly, the study highlights the decisive role of asset management organisations in shaping the conditions for industrialisation through upstream decisions related to portfolio planning, requirement setting, procurement, and long-term demand aggregation.

Through the principles, this study contributes a missing system-level perspective to the literature on industrialised construction. The principles provide a shared language for aligning stakeholders, structuring decision-making, and creating the conditions necessary for sustained productivity improvements. In doing so, it supports the transition of industrialisation from an abstract ambition to a structured, strategic approach capable of addressing the scale, urgency, and complexity of infrastructure renewal.

This study has several limitations that open avenues for future research. First, the framework is grounded in the Dutch infrastructure renewal context; its applicability to other construction domains with different governance and market structures remains to be tested. Second, the principles are primarily derived from literature and supported through expert validation rather than extensive empirical observation. Future work could therefore enrich the framework through case-based studies that examine how industrialisation conditions emerge and interact in practice. Third, the principles are currently treated as equally important. While their interdependencies are recognised, their relative weight, sequencing, and dominance remain unexplored. Further research could investigate these dynamics and translate the principles into maturity models for transition support.

Abstract

While numerous built examples of free-form glulam structures demonstrate the complexities of creating glulam beams with out-of-plane curvature, the specifics of their modelling, rationalization, and realization have largely remained confined to specialist know-how and internal processes. We present a digital workflow that bridges unpredictable input design geometry and the reconstruction, rationalization, and preparation of free-form glulam beams for industrial production. This effort is part of an innovation project developing an automated press for serial production. It builds upon previous research into early-stage modelling and rationalization, extending it to real-world design contexts and industrial production constraints.

Introduction

While the complexity of timber structures has grown as their potential is discovered, the digital infrastructure required to translate free-form timber designs into robust, mass-produced industrial components remains sparse and fragmented. Techniques of rationalizing and modelling such geometrically complex structures are largely relegated to specialist experience and internal knowledge. The production of large-scale free-form glulam beams, for example, remains a labour-intensive and costly process, tailored to the specific delivery or project. The specifics of translating design geometry into feasible material specifications for such elements are often glossed over in favour of describing the wider design and production process (Stehling et al., 2017). As such, free-form glulam beams remain a largely craft-based product that resists automation and industrialization.

A number of wider efforts have spurred the tight intertwining of digital design and production in contemporary timber research and construction. New modes of relating timber properties and behaviours to architectural models or production environments (Svilans et al., 2019) have sought to imbue a sense of material agency in design and fabrication (Menges et al., 2016; Weinand, 2017). Considering this growing role of computation and automation within the timber manufacturing sector, we seek modelling and analysis methods for deriving production-ready data from coarse design models in an industrial production context, towards an industrialization of geometrically complex timber elements. A primary challenge in this process is the difference in fidelity between early-stage design models – often used for cost estimations and planning – and the necessary production data. Messy design geometry and poor interoperability necessitate interpretation and reconstruction of key manufacturing parameters and specifications. The use of coarse and ad-hoc models for early-stage design exchange often yields geometry that is unstructured and discretized. Further, free-form glulam beams present particular geometric and material constraints arising both from material properties as well as the nature of the pressing process. These must be respected, and the digital model must be validated against them to ensure that the production can be successful. Finally, considering the geometric constraints of bending timber lamellas, the discrepancy between the design geometry of the final beam and the geometry of the glulam blank must be recognized and integrated into the planning process.

We therefore develop a digital workflow for translating highly variable design inputs such as coarse and unstructured mesh objects into materially-responsive production data for pressing large-scale glulam beams under real-world constraints (Fig. 1). We draw from experience working with designers and architects on the delivery of complex timber buildings, and the observations made with respect to typical digital design models.

The presented work demonstrates a path towards the automation and industrialization of free-form glulam beam production from typical real-world design inputs.

Background and related work

Data exchange in free-form timber construction

The importance of robust digital workflows and good interoperability in AEC have been emphasized for a long time (Scheurer, 2012; Stehling et al., 2014), pointing at the wide variety of software used in the design, development, and production of a complex timber building and the lack of a “one size fits all” toolset. The prevalent use of Industry Foundation Classes (IFC) in AEC data exchange is beneficial for the general sharing of design information. However, in practice, the capabilities of the full specification are rarely utilized, especially when it comes to free-form surfaces. This means that the required input data is seldom authored in a

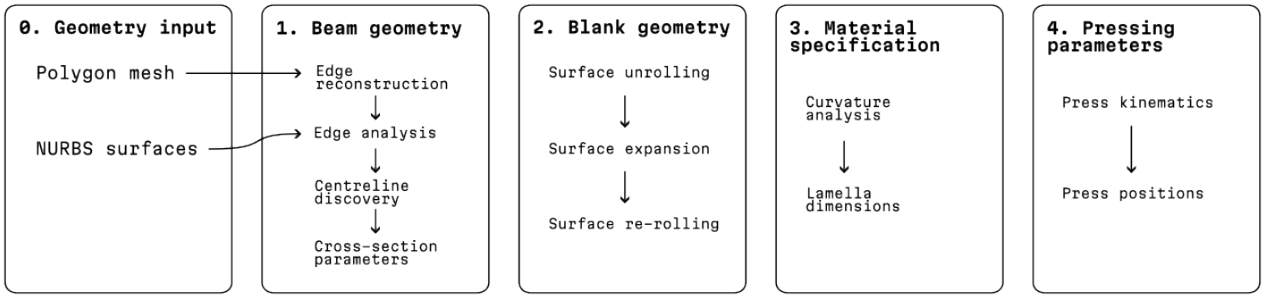

Figure 1 An outline of the digital workflow for automating the translation of coarse design data into production-ready information.

production-ready way. Specifically, the modelling of free-form beams is typically done through ad hoc or non-standardized ways and transferred as polygon meshes or overly detailed NURBS surfaces, creating hurdles for downstream processes. In the case of meshes, important features such as curvature and continuity must be inferred or interpolated. In the case of surfaces, fully detailed models can make it hard to extract precisely the necessary data for producing glulam beams since they might describe the final geometry of the fully detailed element rather than the glulam blank.

For evaluating material specifications and determining the correct press parameters, these geometric properties must be taken into account. Methods for reconstructing surfaces and edges that closely approximate the input design geometry are therefore required.

Single-curved glulam beams are relatively standardized in production, as both their geometry and production parameters are easier to derive. The planar curvature means that most considerations can be relegated to 2D analysis and rationalization. In this way, curvature calculations and lamella thicknesses are relatively straightforward.

For free-form glulam beams with out-of-plane curvature and torsion, previous work has developed modelling methods that result in appropriate material specifications and clean geometry for representing them (Svilans, 2021), however these rely on key data which is often absent in design models – such as a beam axis curve and related cross-sectional data and orientations. These must be introduced towards the beginning of the modelling process and are not always present in design models transferred from outside clients, partners, or collaborators. Additionally, these efforts do not include the translation of glulam blank geometry into specific press parameters for full-scale production.

Therefore, the transfer of information from design to the glulam press is shaky and unpredictable due to the large variance of inputs, necessitating techniques for stabilizing this translation into repeatable and automatable processes.

Industrial process and geometric constraints

Free-form glulam beams are typically fabricated using one of two methods:

- a two-step method where a single-curved blank is first fabricated out of individual *lamellas*, sliced into *layers* in the plane of its curvature, and then bent and laminated out of this plane; and
- a one-step process where approximately square lamellas are assembled in a grid and bent three-dimensionally at once.

We focus on the first method – the two-step lamination process – as it decouples the complex curvature into more manageable steps, albeit with some geometric caveats (Fig. 2).

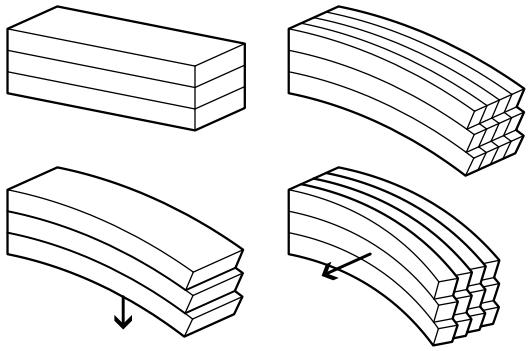

Figure 2 The two-step lamination process begins with straight lamellas (top left) which are bent into a single-curved blank (bottom left). This intermediate blank is resawn into layers (top right) and then bent and laminated in the out-of-plane direction (bottom right).

Double-curved glulam blanks present specific geometric constraints due to their production process. Given lamellas of equal length, as the blank is pressed into a curved shape, the lamellas will slide against one another, meaning that lamellas on the outside of the curvature will appear "drawn back" from the end of the beam and, conversely, lamellas on the interior of the curve will appear to be "pulled forward". While for single-curved glulam blanks this is simple to account for and the cross-section of the blank stays rectangular, out-of-plane curvature causes this slippage to manifest in geometrically complex ways, causing the cross-section to also slip into a trapezoidal shape (Fig. 3). Calculating the final geometry of the double-curved glulam blank therefore requires more advanced methods of analysis and modelling to more accurately reflect the true shape of the glulam blank.

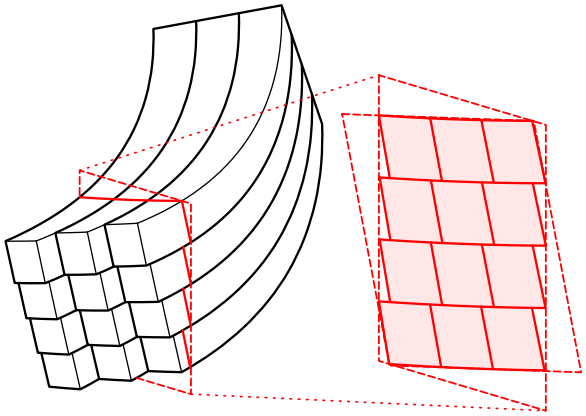

Figure 3 The out-of-plane bending causes the cross-section to become a trapezoid, depending on the degree of curvature.

Similarly, calculating the required lamella thickness for single-curved glulam blanks is straightforward: the lamella thickness is driven by the point of maximum curvature or the smallest radius of curvature in the plane of bending. The largest allowable thickness to avoid overstraining the lamella is defined by the ratio t/R, where t is the lamella thickness and R is the smallest radius of curvature. In Eurocode 5, this ratio must be less than 1/200 for softwoods. In double-curved glulam blanks, the curvature no longer lies in the plane of bending, therefore both the thickness and width of the lamella is affected. The assessment of curvature must therefore be broken down into components to arrive at the correct lamella thicknesses for both steps of the two-step process. To achieve this, the single-curved lamella thickness constraint must be reformulated to work with out-of-plane curvature.

Other challenges are similar for double-curved glulam blanks as for single-curved ones: as curvatures increase and lamella thicknesses get smaller, the spacing of the press pads must decrease to accommodate the sharper changes in geometry. Practically, this becomes an issue when the pressing infrastructure starts to get in its own way and inhibit the ideal distribution of lamination pressure.

Related research in this area has sought to avoid the difficulties of the double-curved lamination process in intriguing ways, such as through novel methods for sawing curved lamellas, thus reducing the bending required to achieve a particular 3d form

(Chai et al., 2021; Zhang et al., 2023). However, these prototypical approaches are not suitable for current industrial contexts that are based on the use of standardized lumber and straight timber lamellas.

Methodology

The project takes places in the factory of ZAZA Timber Production Ltd., a Latvian producer of large-scale timber building components (Fig. 4). An existing single-curved Ledinek press is used as a starting point to implement the two-step lamination process for double-curved glulam blanks. A separate modified press is used to perform the

Figure 4 The industrial production environment at ZAZA Timber Production Ltd.

second pressing step, with the objective to eventually automate both presses and digitize their operation.
The developed workflow is structured into three distinct phases:

- the conversion and reconstruction of design inputs,
- the analysis-driven validation of glulam blank geometry and decision support for material specifications,
- and the extraction of press parameters for production.

The aim is to robustly connect variable design inputs with a large-scale free-form glulam press towards an eventual automation of the preparation and pressing of free-form beams. The digital workflow makes extensive use of the IfcOpenShell (IfcOpenShell, 2025) and RhinoCommon (Baer, 2019) programming APIs.

Geometry reconstruction and rationalization

Early-stage geometry is often ad-hoc, non-standardized, and not appropriate for fabrication, due to uncertainty regarding the final outcome of the design process.

As such, design inputs for the planning and production preparation of glulam beams are usually coarse or otherwise unsuitable, requiring extensive remodelling before manufacturing. Free-form geometry is typically described either as NURBS surface patches or approximated mesh objects. While continuous surface data is ideal for transferring geometric features, limitations of popular exchange formats often hinder their usage, even when supposedly supported by the format. For example, the IFC specification – being related to the STEP format – fully supports structured geometric surface data, however this is rarely fully implemented in the interfaces with different software environments (Fig. 5).

To better understand the nature and variety of input geometry, small batches or individual beams were selected from recent projects. The majority of these were either coarsely modelled meshes with varying resolution – such as an increased density of polygons around details – or full-detailed surface models. Both types of input model benefited from the same approach to estimating the "blank of best fit": the difference chiefly being that the

surface models didn't require reconstructing continuous splines from discretized mesh edges.

To automatically reconstruct a suitable glulam beam model from variable input geometry, an edge-based heuristic method is developed for both mesh-based representations as well as NURBS surface models (Fig. 6). For mesh-based representations, the main additional step is the finding and reconstruction of longitudinal edges of the beam (Fig. 7). The subsequent steps are generally the same for both types of representations.
Reconstructing edges from a mesh model is done as follows:

- mesh edges are found based on their sharpness or angle between corresponding faces
- successive chains of edges within a certain continuity threshold are found
- splines are built through these chains to best approximate them in a curvature-continuous way

Subsequent steps are similar for both mesh and NURBS representations:

- the collection of splines or NURBS edges is evaluated to find the subset that is the most parallel over the longest length, suggesting a common "flow" or axis of movement
- a median curve is generated from this subset, spanning the longitudinal extents of the curve subset
- at regular intervals, a perpendicular plane is constructed on this median curve
- the intersection between the sample plane and the rest of the edge curves is found and the resultant points are used to generate a 2D convex polygon within the sample plane
- a bounding rectangle is fitted to the convex polygon, testing alignment with each edge to find the smallest enclosing boundary
- the resultant rectangle is taken as a cross-section candidate and compared to preceding and succeeding candidates, until the best candidate – i.e., the one that minimizes twist between preceding and succeeding sections – is found
- this step is iteratively refined until some defined threshold is reached
- the axis curve is fitted to the centre points of all resulting cross-sections

The process yields the equivalent of a solid sweep of a rectangle along the axis curve, with a constant cross-section. In similar terms, the resulting geometry creates an enclosing "beam coordinate system" around the input geometry, with one axis being the curved and elongated centreline of the beam. This also ensures that the faces of the resultant beam model are developable.

The resultant *glulam beam model* is an idealized rectangular sweep that must be further processed in order to arrive at the free-form glulam blank model – a more precise geometric representation of the form of the material after pressing, due to the aforementioned geometric constraints and deviations that occur during pressing.

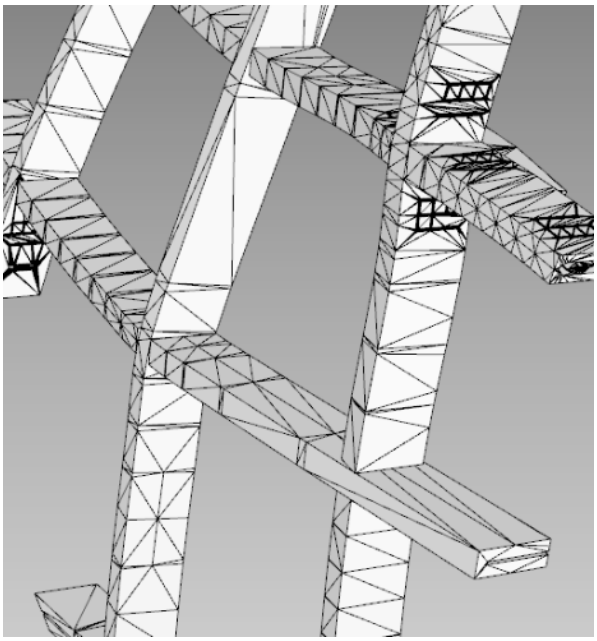

Figure 5 Example of a coarse mesh from an IFC model used for estimation and planning.

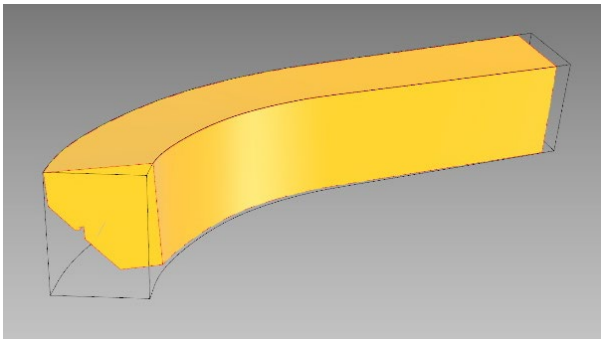

Figure 6 Example of a fitted beam model (black outline) over a detailed NURBS input model.

Once a feasible glulam beam model is acquired, it is decomposed into two phases that correspond to the two pressing steps and their respective constraints. To derive these two phases, the decomposition is done in reverse order of the production process.

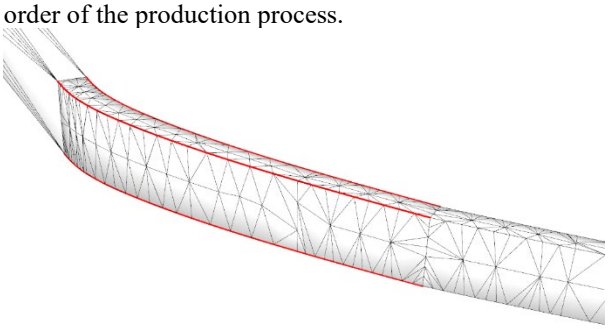

Figure 7 Reconstructed beam edges from a coarse mesh from an IFC model.

Firstly, the pair of beam faces that is least curved is taken as the second pressing step. This is due to the thickness limitations in the resawing of the first pressed form. A median surface between the two faces of the pair is extracted and serves as the neutral axis of the form. Both faces are geodesically unrolled with respect to this median

surface. Overlaying the unrolled faces shows how – due to the double curvature of the beam – achieving a rectangular cross-section is only possible if each layer of the second pressing is different (Fig. 8).

However, since each layer is the result of the same single-curved blank being resawn into layers, each layer is identical and therefore must be expanded so that it envelops both of the unrolled beam faces. This expansion is done by sampling both unrolled faces in relation to the centreline curve of the unrolled median surface to find the farthest point on either side, and offsetting it at the corresponding distance.

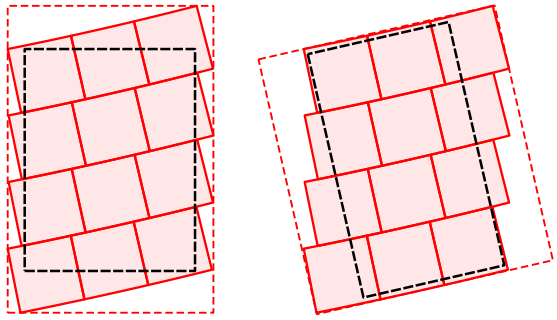

Figure 8 The skewed cross-section means that a rectangular cross-section (black) cannot fit neatly inside of the blank.

The resultant enlarged unrolled shape becomes the required form of the first pressing – in effect, the plan of the single-curved glulam that is to be resawn into layers for the second step (Fig. 9).

The resultant shape is then re-rolled onto the median surface of the glulam beam model, using the relative positions of the original faces. The edges of the resulting faces are connected, forming a closed solid. Depending on the degree of curvature from both pressings, the cross-section of the final glulam blank model becomes trapezoidal (Fig. 10).

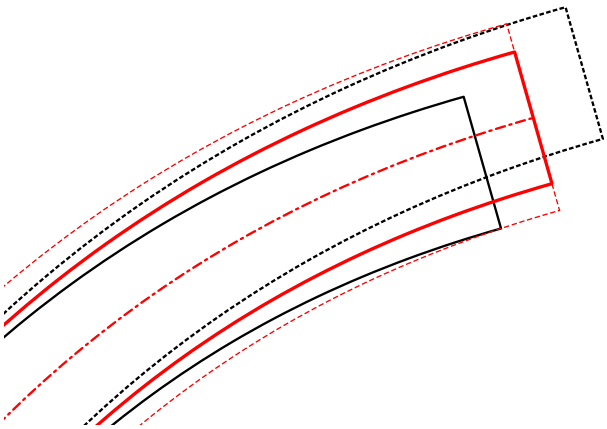

Figure 9 The difference in shape between the top (solid black), middle (solid red), and bottom (dashed black) surfaces when unrolled. A single, widened surface (red dashed) is needed so that the entire beam is encompassed by the re-rolled blank geometry.

Thus, the geometric and process constraints from the two-step pressing result in a particular geometric form that encompasses the original glulam beam model and a more accurate representation of the glulam blank model.

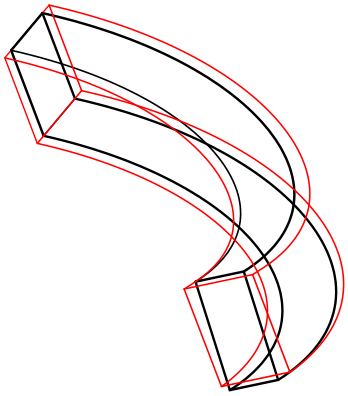

Figure 10 The difference between the beam geometry (black outline) and blank geometry (red outline).

Material parameters and production mechanics

Having arrived at the glulam blank geometry, the next step in the workflow is the selection of material specifications according to performance requirements and material limitations. The relationship between curvature in free-form beams and the lamella dimensions is developed from the typical method used for single-curved beams into a more broadly-applicable simulation-informed validation method. Mechanical tests done in a parallel effort transfer material properties from simpler glulam specimens into generalised design values.

For single-curved glulam beams, lamella thicknesses are related to the maximum curvature the beam, typically expressed as a simple linear ratio between the radius of curvature and the thickness of the lamella. While this provides a straightforward way of arriving at material specifications for planar glulam beams, double-curved – or free-form – beams require additional considerations.

Initially, in the two-step lamination process, curvature was also considered in two parts, leading to a lamella thickness specification for the first pressing and a different one for the second pressing out of plane. While this allows the curvature estimates to be done in a decoupled way, using only the planar curvature at each step, it does not capture the full strain induced on the lamella by the combination of both together, along with torsion.

To overcome this, the curvature limits from single-curved glulam specification are translated into strain coefficients which can then be used as limit values in more complex and three-dimensional scenarios. Bending strain in a beam can be defined by $\varepsilon = \kappa y$ where ϵ is the longitudinal strain, κ is the curvature of the beam (also defined as 1/R, where R is the radius of curvature), and y is the distance from the neutral axis. Since individual lamellas themselves behave like long and slender beams, we assume a Euler-Bernoulli model where bending strain dominates and shear caused by bending is negligible.

Considering the Eurocode ratio of 1:200 between the lamella thickness and the smallest allowable radius of curvature for softwoods (t/R, where t is the lamella thickness and R is the radius of curvature), the maximum induced bending strain for a curved lamella can be 0.0025. Transferring this principle to free-form glulam blanks therefore can be done through a projection of the curvature vector onto the cross-section and its decomposition into width and height values for the lamella dimensions, which is subsequently validated through simulation using the finite element method (FEM). The smallest 3d radius of curvature is found at the innermost lamella edge of the blank. The vector of curvature is decomposed into height and width components relative to the blank cross-section, giving the amount of bending in each direction. The thickness is then found using the established t/R ratio. To introduce a simulation-based validation step in our workflow, finite element analysis is used to simulate the bending of the critical lamella into its final shape in the glulam blank. The maximum longitudinal strain is compared to the strain limit to verify an appropriate dimensioning of the lamella. While this step is still at a preliminary stage in the project, further work will improve both the robustness of the FE model as well as compare the simulation with results of physical testing. This has implications for scenarios where the second pressing step induces substantial torsion on the layers, where shearing across the plane of the layer becomes a significant source of strain. The mechanical testing of lamellas and curved glulam prototypes is an on-going adjacent stream in the project. This parallel effort seeks to also experimentally arrive at generalizable strain limits for different lamella species such as spruce and pine to help with selecting the most appropriate material type and quality for a particular glulam blank.

As a decision-making tool, the lamella material and dimensioning are used to assess the feasibility of a producing a particular glulam blank, as the calculated optimal parameters must nevertheless be compared against process constraints along the glulam production chain. For example, board thickness at the material intake can dictate available lamella sizes, based on whether or not they can be resawn into thinner boards or the degree to which they should be planed. Similarly, the minimum resawing and planing thickness after the first pressing step constrains the possible curvature in the second pressing step, as the size of the first blank is much greater than the individual lamella, necessitating larger resawing and planing equipment. Finally, the spacing of the pressing heads on the glulam blank is strongly related to the thickness of the lamella – thinner lamellas require a closer and more consistent press spacing – however the geometry of the press and its kinematics dictates the possible head layout for a given glulam blank geometry. The ability to confidently identify these constraints and how an incoming glulam beam model stacks up against them is therefore a valuable tool for the assessing and planning of a project.

Production integration and prototyping

The final step in the workflow before production is the generation of positioning data for each of the pressing steps. In an automated workflow, this also includes the position of each linkage in the kinematic chain of the press and the motion planning of the entire assembly.

For the two-step lamination process, the pressing positions need to be generated for the first, single-curved step and then subsequently for the second, out-of-plane bending step. Future work will additionally investigate the feasibility of using the single-step process of bending a free-form glulam directly using smaller, more squarish lamellas.

For the first step, the intermediate or “unrolled” form of the glulam blank model is used. The resultant shape which encloses the unrolled top and bottom faces of the glulam beam model is effectively the 2d representation of the result of the first pressing. This is oriented so that it lies along the longitudinal axis of the single-curved press. For each press track, its linear axis is intersected with the inner – that is, the one closes to the resting position of the press – edge of this shape. The tangent vector of the inner edge at that intersection point yields the angle of the pressing head as well as its position along its track. This therefore gives the full press parameter description for the first step – the single-curved blank.

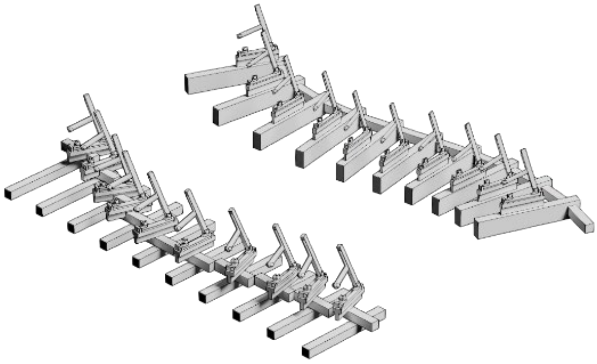

Figure 11 Visualization of the free-form press prototype, showing the modular and articulated pressing heads.

For the second step, a more complex route is required due to the additional degrees of freedom necessary to achieve the out-of-plane curvature. The design of the second press consists of a modified single-curved glulam press which introduces additional press heads that give additional axes of movement and rotation (Fig. 11). For this, a digital kinematic model is constructed consisting of the individual linkages in the press, their axes of rotation or displacement, and relative offsets. The simplicity of the linkage arrangement means that a direct numerical method can be used to solve the inverse kinematic problem instead of an iterative solver, greatly simplifying the computational complexity. For every target press position, the required linkage positions are determined by their offsets and relative rotations. The accuracy of the result is therefore dependent only on the quality of manufacture of the press linkages and the measurement of their true offsets and relative positions. The kinematic

solution is output as a structured dataset consisting of joint rotations and distance values for each press head. These are used to position the press into the required pose for pressing the target form.

The workflow is tested at a reduced scale using the full industrial infrastructure to evaluate the validity of the material specifications and the accuracy of the press data by producing 15 beam prototypes out of spruce lamellas (Fig. 12). Following the methodology, they are first formed as single-curved blanks in a Ledinek press, resawn and planed, and then pressed into the final 3d form with the second modified press. Lamellas thicknesses of 15mm are used for the first step – the minimum thickness driven by the resawing limitations for individual lamellas in the current production line – and 50mm for the second step – limited by the resawing and planing capacity in the current production.

Figure 12 Free-form glulam blank prototypes produced using the digital workflow.

Discussion and future work

The developed workflow demonstrates how inconsistent and coarse design geometry can be translated into a useful glulam blank model so that it can be evaluated against material and process constraints and further used to drive the generation of production data. This effort shows how a typically laborious and craft-based process can be augmented and streamlined through computational methods towards eventually becoming an automated and industrialized process for the construction of curvilinear timber structures. Key data for generating the glulam blank model is extracted or reconstructed from rough design models. Material limits from established standards are integrated into the specification and planning steps, with these being eventually supplemented with experimental data. Production data for the pressing of the glulam blank is derived from the model through geometric and kinematic analysis.

While the accuracy and implementation of the actual physical press infrastructure is outside of the scope of this paper, validation of the physical prototypes is nevertheless seen as a critical path forward in tuning and verifying the digital workflow. To this end, the prototypes have been 3d scanned and compared to their digital beam models to begin preliminary quality assessment of the pressing process (Fig. 13). As a feedback method, this is expected to identify areas of improvement and potentially additional geometric factors to test incoming models against. The result of this validation will primarily affect the generation of press parameters by determining how they must be compensated to better achieve the target form.

Preliminary analyses of the scans show mean deviations of point distance to model geometry between 0.32 and 3.84 mm with standard deviations between 3.42 and 8.14 mm. The mean deviation between beams is 1.29 mm with a standard deviation of 0.92 mm. A greater deviation was observed in the direction of the second pressing. Considering that there were fewer, yet thicker and therefore stiffer, layers in this direction, it is likely that this was caused by greater springback in the material after pressing. The analysis could be improved with more refined registration methods and by observing deviations separately for each step, instead of only for the final result. In 9 of the prototypes, over 90% of scan points were within 10 mm of the beam model, while in 4 prototypes, over 70% of the points were within 5 mm.

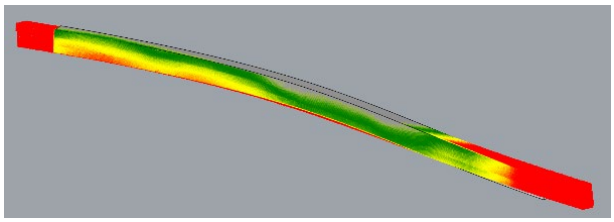

Figure 13 A preliminary comparison between the beam model and scan of a physical prototype, showing areas that lie within a 10mm tolerance (green and yellow) and areas that exceed this tolerance (red), especially at the longer ends.

Future work will also seek to include more nuanced material properties and strain limits based on the results of parallel material testing on both straight lamellas as well as free-form laminated prototypes, to arrive at a reliable material model that is tuned to the particular species and geometry type.

Alongside these plans for the digital workflow from model to press data, we plan for further automation of the press infrastructure itself and therefore using the results of the digital workflow directly in the actuation of motors to drive the press positions. The ability of the second press to achieve three-dimensional forms also shows potential in being used for the one-step lamination process with more squarish lamellas, bypassing the need for two pressing steps. The design and manufacture of free-form glulam elements using either method can therefore be achieved in a seamless manner, avoiding the need for laborious planning and manual work.

Regarding the wider positioning of this effort within the digital design chain, the sussing out of these material specifications and production parameters can serve as feedback mechanisms for evaluating designs at early stages. By relating geometric properties to specific

barriers in production, challenging beams could be identified and revised or else directed towards alternative fabrication methods. For example, pressing constraints – distances between the pressing heads, track sizes, and so on – imply that particular forms might exceed the capacity of a particular setup. This suggests a diversity of press configurations – some finer, some larger and heavier – to deal with a variety of input geometries as opposed to a "one size presses all" solution.

Along the same line of thinking, the issue of tolerances touched upon before also raises the idea of adaptive or performance-driven pressing, where tolerances are tightened around geometrically or structurally critical areas of the beam while relaxed elsewhere. This would enable a more efficient allocation of effort and energy, with implications not only for production time and cost but for material use and sustainability metrics.

Conclusion

We envision a fully automated and industrialized process for fabricating free-form glulam beams from coarse input data in typical architectural workflows.

The described work is positioned as a contribution to digital construction and industrialised timber fabrication, focusing on the design-to-production information workflow required to realise free-form glulam structures under real-world industrial constraints. The work demonstrates how computational modelling, automated rationalisation, and analysis-informed validation can be integrated into a robust, end-to-end digital pipeline that translates imperfect design input into production-ready manufacturing data. It foregrounds automation, data robustness, and scalability, addressing a key challenge in industrialized timber construction: the reliable manufacture of complex architectural intent in free-form structures. In doing so, it demonstrates how materially-aware computation in construction processes can lead to increased industrial efficiency, a greater flexibility and feasibility of manufacturing outcome, and new potentials in achievable architectural expression.

Acknowledgments

In accordance with the contract No. 1.2.1.2.i.2/1/24/A/CFLA/001 between "Forest Sector Competence Centre of Latvia" Ltd. and the Central Finance and Contracting Agency, the study is conducted by "ZAZA TIMBER Production" Ltd. With support from the European Regional Development Fund (ERDF) within the framework of the "Forest Sector Competency Centre" project ZP06 – "Development of bent glued timber manufacturing technology and prototype equipment enabling modelling and design of large-scale free-form timber structures".

TELEOPERATION INTERFACES FOR COMPACT DEMOLITION ROBOTS: RESULTS OF A PILOT STUDY WITH CONSTRUCTION WORKERS

Patrick Borges Rodrigues, Zihao Wang, Yiyang Fang, Gale Lucas, Shawn Roll, Burcin Becerik-Gerber, and Lucio Soibelman
University of Southern California, Los Angeles, United States of America

Abstract

As teleoperated robots become more common on construction sites, human-robot interfaces must better support operators' sensory needs. This paper presents results from a pilot study comparing a proposed sensory-enhanced teleoperation interface for compact demolition robots with a standard teleoperation interface. Recommendations from demolition stakeholders informed the design of the sensory-enhanced interface, while the standard interface was based on commercially available teleoperated construction equipment. The goal of this study was to refine the sensory-enhanced interface based on user feedback. Ten construction workers tested the interfaces, and we measured their perceived usability, telepresence, and trust in technology.

Introduction

Increasing numbers of robots with varying levels of autonomy are being deployed at construction sites (Liang et al., 2021). Among these, teleoperated systems are used extensively because they keep workers out of hazardous environments. These technologies fundamentally change construction site dynamics as workers adapt to these machines. However, despite their adoption, many teleoperated systems have created a mismatch between workers' needs and the control requirements of human-machine interfaces (Kim et al., 2026).

This mismatch can result in increased mental workload, decreased situation awareness, ergonomic issues, and compromised performance and safety (Kim et al., 2026). In teleoperated contexts, interfaces aligned with operators' preferences may reduce physical and mental loads, increase operator comfort, performance, and safety. Despite these benefits, teleoperation interfaces still face multiple issues that complicate their broader use (Rea & Seo, 2022), and better user-centered interfaces for construction robots are needed (Rasheed et al., 2024).

In this paper, we compare two teleoperation interfaces for compact demolition robots: a standard and a sensory-enhanced interface. The standard interface was designed based on construction robots' teleoperation interfaces (e.g., Caterpillar Inc. (2022)). The sensory-enhanced interface was designed based on recommendations from demolition stakeholders to extend the capabilities of traditional systems (Rodrigues, Lucas, et al., 2025).

We conducted a pilot study to test the two interfaces and ensure participants could safely complete various tasks in an obstacle course. We gathered participants' subjective feedback on perceived usability, telepresence, and trust in technology. We also conducted semi-structured interviews to collect their opinions and suggestions on interface designs. These results helped refine the interfaces, the obstacle course, and the experimental protocol before the full study with a larger sample.

Literature Review

Teleoperation is widely used in construction robotics (Liang et al., 2021). Applications include teleoperated drones for site inspection, safety surveillance, and surveying (Albeaino et al., 2022); teleoperated heavy equipment (e.g., excavators, bulldozers) for hazardous and remote sites (J. S. Lee et al., 2022); and teleoperated demolition (Rodrigues, Becerik-Gerber, et al., 2025), among others (Hu et al., 2025). This widespread adoption stems from the unstructured and dynamic conditions of most construction sites, which still limit fully autonomous operations and require human perception and decision-making to interpret site conditions, assess risks, and adjust operations in real time (Kim et al., 2026). As a result, the effectiveness of teleoperation in construction depends on the quality of the operator-interface interaction and the availability of adequate sensory feedback.

Commercial teleoperation interfaces in construction commonly replicate manned equipment interfaces (e.g., Caterpillar Inc. (2022)). Operators use seats, joysticks, and pedals modeled after those found on manned machines (e.g., excavators), with camera views replicating cabin perspectives. While this approach leverages operators' familiarity with traditional systems, directly transferring interfaces from manned to teleoperated machines is not straightforward, as physical separation between operators and the site in teleoperation affects the quality, quantity, and type of sensory information operators receive (J. S. Lee & Ham, 2022). For equipment not operated from a cabin, this approach is infeasible, requiring the redesign of the human-machine interfaces rather than transferring traditional control schemes (e.g., H. J. Lee & Brell-Cokcan (2023)).

Over time, however, these interfaces are often improved through trial and error. Advancements in artificial intelligence (AI) and hardware have enabled assistive teleoperation technologies that support higher levels of

robot autonomy, such as robots that adjust behavior to reduce operator workload (e.g., Liu et al. (2021)). AI has also enabled assistive features that fuse and simplify data, identify hazards, and support decision-making (Hong et al., 2020). Similarly, adaptive interfaces adjust the type, amount, and timing of the information operators receive, such as allowing manual or autonomous camera viewpoint switching (Xu et al., 2024). Many of these systems, however, are in early stages of development and have only been tested under laboratory conditions.

Introducing new robotic systems on construction sites has emphasized the need for user involvement in interface design. User Experience (UX) design has been instrumental in this process, supporting ideation, design, and refinement. By recognizing these needs, Rodrigues, Lucas, et al. (2025) proposed a framework to inform the design of sensory-enhanced teleoperation interfaces for construction machines through user engagement and testing. By engaging demolition professionals, the authors identified how operators in traditional demolition tasks use different sensory channels to monitor the robot, task, and environment, and gathered their suggestions for teleoperation interface designs. Drawing on these suggestions, we designed a sensory-enhanced teleoperation interface and tested it against a standard teleoperation interface typical in construction.

Methodology

Robot Description

This study employed a Brokk 120 DII demolition machine equipped with a Brokk BHB 155 hydraulic breaker (Figure 1). It is one of the most compact Brokk Inc. demolition machines, with dimensions of 2030 mm × 780 mm × 1250 mm and a maximum reach of up to 4300 mm.

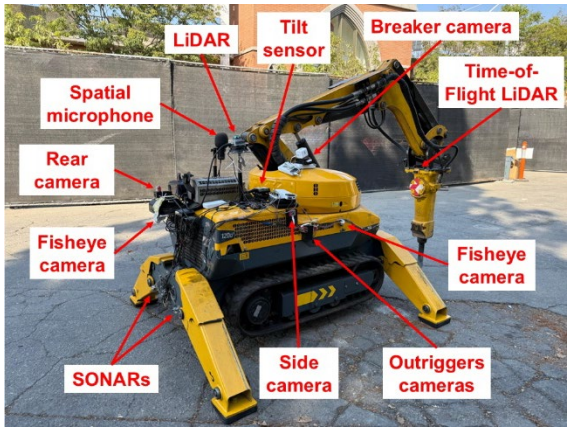

Figure 1. Brokk 120 DII sensor configuration.

Teleoperation System Architecture

Modularity

The teleoperation interfaces used modular designs to provide flexibility for testing and refinement. This approach allowed interface features to be added, removed, or adjusted based on user feedback. Various sensors connected to independent onboard computers and microcontrollers collected operational and site data, which was transmitted to a central computer that aggregated and relayed it via the user interfaces.

Communication Architecture

Communication between the robot and the teleoperation interfaces was enabled via a Wireless Local Area Network (WLAN) established with a single high-performance router in the obstacle course. The system combined the User Datagram Protocol (UDP) and the Web Real-Time Communication (WebRTC) protocol to ensure low-latency communication between the robot's onboard computers and the web-based interfaces.

The robot's onboard system included multiple Raspberry Pi 5 microcontrollers, wirelessly connected to a central minicomputer located inside the construction trailer, which aggregated data from the Raspberry Pi units and generated the web-based interfaces. A separate minicomputer installed on the robot, physically connected to a LiDAR sensor and a spatial microphone, provided real-time point clouds of the environment and environmental audio to the user interfaces. Finally, exocentric cameras installed throughout the obstacle course streamed external visual perspectives of the environment directly to the central minicomputer.

Control

The Brokk 120 DII demolition robot was controlled using the Brokk SmartRemote™ controller (Figure 2). This controller operates via radio communication and can control the robot at distances of up to 300 meters.

A deliberate design decision was made to maintain the robot's original hardware and software. Rather than modifying the robot's control system, an effort that would require an additional investigation, this study focused on augmenting operator situation awareness through external sensors and improved teleoperation interfaces.

Robot Sensors Configuration

Additional sensors were mounted on the robot and integrated with the teleoperation interface (Figure 1). Cameras were installed to provide egocentric views of the robot's front, rear, left, and right sides, its arm, and end-effector. Additionally, a bird's-eye view of the robot was provided using four fisheye cameras, offering operators an overhead perspective of its position and surroundings.

Several sensors were deployed to augment operators' spatial awareness. A tilt sensor measured the robot's pitch and roll. A LiDAR provided real-time point clouds of the environment, improving depth perception. Four robot-mounted sonar sensors measured distances to nearby objects as part of a proximity warning system for collision avoidance. A time-of-flight LiDAR measured distances from the breaker tip to demolition targets. Finally, a spatial microphone transmitted real-time environmental audio from the site to the teleoperation interfaces.

External sensors configuration

Several exocentric cameras were deployed throughout the obstacle course to provide external views of the robot to support localization and situation awareness. Two cameras were installed inside the trailer to capture the operators' postures and their usage of the interface.

User Interfaces

The user interface consisted of multiple TV screens, laptops, the Brokk SmartRemote™ controller, and a VR gaming chair equipped with vibration and rotation capabilities (Figure 2). The specific configuration of interfaces differed between the standard and sensory-enhanced interfaces. The user interface components were installed inside a construction trailer specifically adapted to accommodate the teleoperation interfaces and associated equipment. For the pilot study, this trailer was positioned adjacent to the obstacle course.

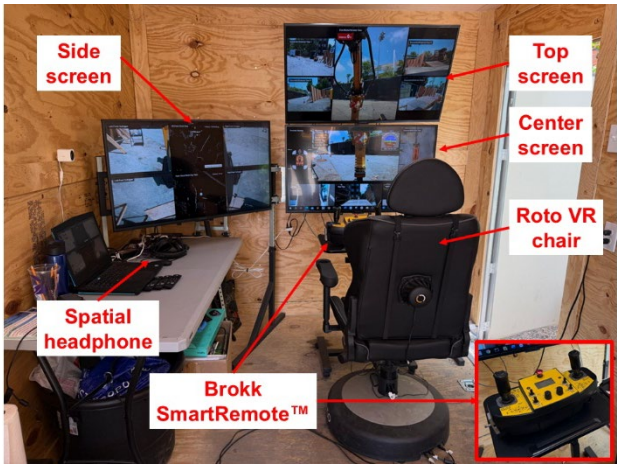

Figure 2. User interfaces inside the construction trailer. The inset shows a close-up of the Brokk SmartRemote™ controller.

Standard Teleoperation Interface

The standard teleoperation interface was designed based on the Caterpillar Cat® Command teleoperation interface (Caterpillar Inc., 2022), commonly used for heavy machinery such as excavators. This interface provided operators with multiple egocentric camera perspectives (i.e., front, rear, left, and right), exocentric camera perspectives, robot status information, environmental sound, and attitude data. In addition to the conventional design of the Caterpillar Cat Command interface, this implementation included a fixed camera to provide a continuous view of the robot's arm and end-effector.

Visual Feedback

Visual feedback (Figure 3) was presented on two vertically stacked 43-inch TVs. The center screen (Figure 3a) displayed four egocentric views: front, rear, left, and right. For the front and rear cameras, the interface also displayed grid lines to help operators estimate the robot's distance to objects. It also included an attitude indicator for the robot's roll and pitch, along with status information such as engine temperature, fuel levels, hydraulic system pressures, and maintenance indicators. The top screen (Figure 3b) presented four exocentric camera perspectives showing the obstacle course and an egocentric view of the robot's arm and breaker. All cameras used in the standard interface were fixed cameras with automatic focus.

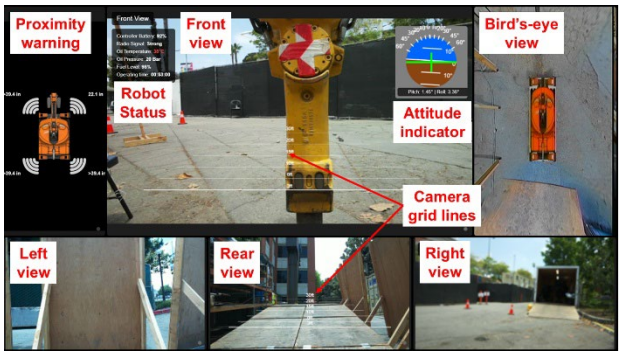
Sound Feedback

The sound feedback system consisted of a headset and TV speakers, through which sounds captured by a microphone mounted on the robot were transmitted.

(a)

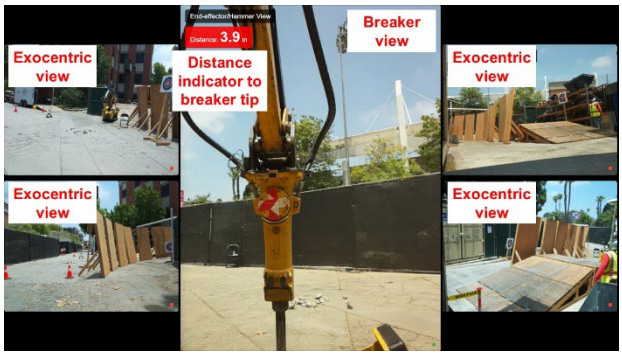
(b)

Figure 3. Standard teleoperation interface. (a) Center screen. (b) Top screen.



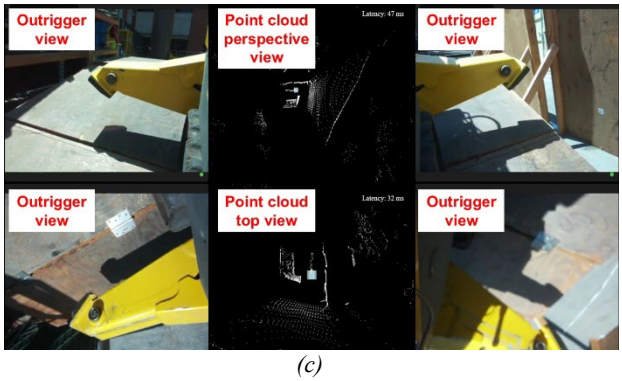
Sensory-Enhanced Teleoperation Interface

The sensory-enhanced teleoperation interface expanded on the standard interface by incorporating enhanced visual, auditory, and haptic feedback, alongside a proximity warning system to improve operator situational awareness. These inclusions were based on recommendations from demolition professionals during focus groups and preliminary testing of VR interfaces in a demolition tradeshow (Rodrigues, Lucas, et al., 2025).



Visual Feedback

The sensory-enhanced interface visual feedback (Figure 4) was presented through three 43-inch screens. The center screen (Figure 4a) displayed four egocentric robot views: front, rear, left, and right. The front and rear views included grid lines to help operators estimate distances. It also showed the robot with proximity warning arcs and distance indicators at each corner, providing real-time visual feedback from four sonar sensors. The screen also included a stitched bird's-eye view of the robot's surroundings from four fisheye cameras placed on the robot's sides, an attitude indicator for pitch and roll, and robot status information, including engine temperature, fuel levels, hydraulic pressures, and maintenance needs.



The top screen (Figure 4b) displayed four exocentric views of the obstacle course, an egocentric view of the robot's arm and breaker, and a distance indicator to the breaker tip. Finally, the side screen (Figure 4c) displayed four dedicated camera views, one for each robot outrigger. This screen also displayed two LiDAR point clouds (i.e., top and perspective views) to enhance operator depth perception and situation awareness. All cameras used in the sensory-enhanced teleoperation interface were fixed and equipped with automatic focus.

(a)

(b)

(c)

Figure 4. Sensory-enhanced teleoperation interface. (a) Center screen. (b) Top screen. (c) Side screen.

Sound Feedback

Sound feedback was delivered via a headset and the TV speakers, providing real-time environmental sound captured by a robot-mounted microphone. In addition, the sensory-enhanced teleoperation interface incorporated auditory alerts as part of the proximity warning system.

Haptic Feedback

The sensory-enhanced interface incorporated haptic feedback via a VR gaming chair (Roto VR chair) that vibrated (rumble) and rotated. Haptic feedback was used in the proximity warning system to provide vibratory alerts when the robot approached an obstacle.

Safety Mechanisms

The sensory-enhanced teleoperation interface included a proximity warning system using robot-mounted ultrasonic sensors to alert operators to potential collisions. Visual and auditory feedback were provided when obstacles were within 2 feet, while haptic feedback was activated at distances of 1 foot or less, with warning levels and frequencies increasing as distance decreased.

Additionally, the LiDAR point cloud highlighted moving objects such as people, vehicles, and equipment in red, thus enhancing operator awareness of dynamic elements.

Pilot Study

The objective of the pilot study was to identify opportunities for improvement before a full user study. The pilot also served to test the sequencing and timing of training and experimental tasks, verify the setup and functionality of the teleoperation systems, and ensure the safety of the obstacle course. By identifying potential challenges and opportunities before the user study, we aimed to minimize technical issues, enhance data validity, and avoid mid-study modifications that could introduce bias and compromise data comparability.

After providing informed consent, participants completed intake surveys that included demographics and baseline trust in technology and self-efficacy. We also recorded five-minute baselines for heart rate variability (HRV) and electrodermal activity (EDA) using an Empatica EmbracePlus smartwatch. Participants then underwent VR-based training in the Unity Game Engine, covering the robot's parts and controls, collision avoidance, worker safety, and safe operation on elevated and sloped surfaces. The VR training included three guided exercises focused on driving, arm positioning, and breaking concrete. Next, participants completed pre-experiment surveys assessing trust in technology, self-efficacy, state-trait anxiety, fatigue, musculoskeletal discomfort, and workload.

Next, participants received in-person training with the real robot, covering the Brokk SmartRemote™ controller, safe driving, arm operation, concrete breaking, and robot configuration for operations on ground and elevated surfaces. Then, participants went to the construction trailer to be introduced to their assigned teleoperation interface (standard or sensory-enhanced), with the researchers explaining its functions and features.

The experimental trial involved remotely operating the Brokk robot through a three-task obstacle course (Figure 5). The tasks included (1) driving in a flat open space while avoiding objects such as cones, construction tools, and concrete debris, and positioning the breaker on a target located above the robot, (2) driving in a constrained corridor while avoiding objects such as walls, utility pipes, and concrete beams, positioning the breaker on two targets located at the height of the robot, and demolishing part of a concrete beam, and (3) driving on sloped surfaces (ramps) and elevated surfaces (platform) while avoiding objects such as corridor walls, construction crane, and shelves, and positioning the breaker on a target located above the robot while the robot is on a sloped surface.

Throughout the trial, participants wore the Kexxu Eye eye-tracker to record gaze behavior and the Empatica EmbracePlus smartwatch to record HRV and EDA. After the trial, participants completed post-experiment surveys assessing trust in technology, self-efficacy, state-trait anxiety, fatigue, musculoskeletal discomfort, workload, situation awareness, telepresence, and system usability. Finally, they participated in a semi-structured exit interview to provide feedback on the interfaces.

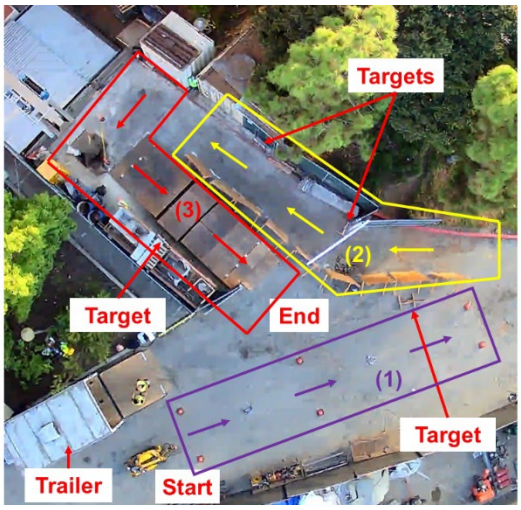


Figure 5. Obstacle course for the pilot study. (1) Open space. (2) Corridor. (3) Ramp.

Participants also completed a survey evaluating workstation features across different site conditions and tasks. Finally, participants assigned to the sensory-enhanced teleoperation interface completed a scenario-based evaluation, in which they read descriptions of demolition scenarios with varying site complexity levels and rated the importance of different sensory features under those conditions. The study protocol was approved by the Institutional Review Board (IRB) at the University of Southern California (USC) (Study ID: UP-24-01122).

Participants

We recruited 12 construction workers to test the two interfaces (*Table 1*). The first two participants were dismissed from the study due to technical issues with the WLAN and were not included in subsequent analysis. Participants were required to be construction workers fluent in either English or Spanish. Recruitment efforts included outreach to construction and demolition industry partners and site visits to construction projects at the USC University Park Campus (UPC). In addition, we employed snowball sampling by asking participants to refer the study to their colleagues.

Participants received compensation for their participation. Those who tested the standard interface completed a session that lasted up to 3.5 hours and received up to $380. Participants who tested the sensory-enhanced teleoperation interface completed a session that lasted up to 4.5 hours and received up to $450. The difference in duration and compensation was due to the scenario-based evaluation at the end of the experiment for the participants assigned to the sensory-enhanced teleoperation interface.

Pilot Study Results

Due to the small sample size of the pilot study, we did not perform formal statistical tests and group comparisons. Rather, we present descriptive statistics on the metrics for the effectiveness and usefulness of the interfaces. We also discuss our observations during the pilot study, the participant recommendations, and how they helped us refine the interfaces, the obstacle course, and the experimental procedures for subsequent studies.

Table 1. Demographic information of the participants (n=10) by experimental condition.

Characteristic	Category	Standard Interface	Sensory-Enhanced Interface
Gender	Male Female	5 0	4 1
Age	18-29 30-39 40-49	2 1 2	2 2 1
Preferred Language	English Spanish	4 1	5 0
Play Video Games	No Yes	4 1	1 4
Work Experience in Construction	None < 5 years 5-10 years	0 1 4	1 3 1
Demolition Experience	None < 5 years	3 2	4 1
Construction Machine Operation Experience	None < 5 years 5-10 years	2 2 1	4 1 0
Construction Machine Type	Excavator Crane Forklift Aerial lift	1 1 2 2	0 0 1 0
Teleoperation Experience	No Yes	5 0	5 0

Note: Totals may not equal 10 because participants could skip questions or select multiple choices.

Trust in Technology

Trust in technology was assessed at three time points: during the pre-VR training session, pre-experiment, and post-experiment. We used a modified version of the Trust Scale with 12 items (Jian et al., 2000), in which participants rated their trust, distrust, and familiarity with their assigned teleoperation interface. First, we reverse-coded the distrust items (items 1-5). Then, we used the average scores across the 12 items of the scale to determine each participant's trust in the teleoperated Brokk robot system. Final scores were in the range of 1 (not at all) through 7 (extremely). Figure 6 presents the means and standard deviations of the trust scores for each interface type and measurement time.

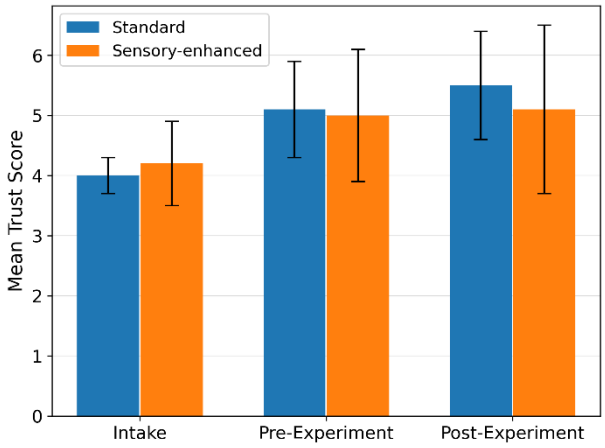

Figure 6. Mean trust scores by interface type and measurement time. Error bars represent ±1 standard deviation.

Usability of the Teleoperation Interfaces

The usability of the two interfaces was assessed using the System Usability Scale (SUS) (Brooke, 1996), a 10-item questionnaire in which participants subjectively rated each interface's usability, yielding final SUS scores ranging from 0 to 100. In usability testing, a commonly used threshold for SUS scores is 68 (Lewis & Sauro, 2018). Scores above 68 indicate above-average usability, while scores below 68 indicate below-average usability. Figure 7 presents the means and standard deviations of SUS scores for each interface type.

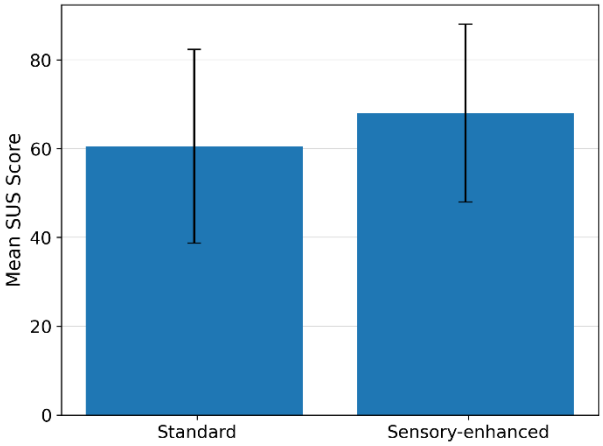

Figure 7. Mean SUS scores by interface type. Error bars represent ±1 standard deviation.

Telepresence

We used the 24-item Presence Questionnaire (PQ) modified by Robillard et al. (2002), based on the original instrument by Witmer & Singer (1998). Of the 24 items, we used 22, excluding the two optional haptic-sensation items, which were not applicable to our interfaces. We computed scores for overall presence (Total Presence) (items 1–19) and for the following presence subscales: Realism (items 3, 4, 5, 6, 7, 10, 13), Possibility to Act (items 1, 2, 8, 9), Quality of Interface (items 14, 17, 18), Possibility to Examine (items 11, 12, 19), Self-Evaluation of Performance (items 15, 16), and Sound (items 20–22). Items 14, 17, and 18 were reverse-coded before analysis. For each variable, scores were computed by summing the responses to the corresponding items and then normalizing by the number of items, so that all variables are in the 1-7 scale. Figure 8 presents the means and standard deviations of total presence scores and presence subscales scores for each interface type.

Refinements of the Interfaces

During the experiment and the exit interviews, participants provided feedback on the interfaces, training, and their experiences. Across both groups, users reported an initial learning curve to get accustomed to the controls. Sensory-enhanced interface users commonly reported improvements in usability over time, with one participant describing the interface as "very self-explanatory" and quick to learn. Conversely, standard interface users frequently reported persistent challenges with depth perception and camera-based navigation, particularly in narrow spaces or when approaching targets.

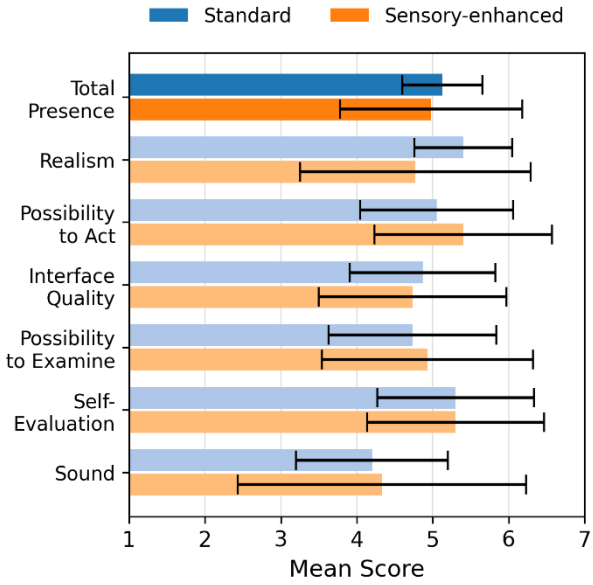

Figure 8. Mean total presence and presence subscale scores by interface type. Error bars represent ±1 standard deviation.

Both groups identified depth perception as a key limitation of the interfaces and suggested additional depth cues and visual overlays. Sensory-enhanced interface users reported positive reactions to the additional sensory feedback (e.g., extra views, sound, vibration), but some found it cognitively demanding to process information from multiple screens simultaneously. Similarly, standard interface users suggested additional visual representation of the arm's position to aid manipulation. Regarding training, participants from both groups valued the VR-based training, noting that it improved confidence during real robot operations.

When asked about interface features, some sensory-enhanced interface users reported ignoring or underutilizing certain features (e.g., point cloud and outrigger views), suggesting that these features require better integration or explanation. Several participants recommended adding automated tilt warnings, collision avoidance, and automated stops, especially for complex arm positioning tasks. While the interface's physical layout was generally well received, some participants from both groups noted that the number of screens could be overwhelming and suggested simplifying the interface to improve operational efficiency. In general, participants felt that the interface improved safety, but noted that its complexity and cognitive demands could reduce productivity and require extensive training due to the number of camera feeds and data streams presented.

Discussion

In this pilot study, we observed that participants' trust in the teleoperation systems increased over time, consistent with expectations as they gained familiarity through VR training and real-world robot operation, such as in Adami et al. (2022). Participants initially reported neutral trust levels prior to interface exposure (intake), which increased following VR-based training (Pre-Experiment) and further after operating the real robots (Post-Experiment). Importantly, this increase was observed for

both teleoperation interfaces. These findings suggest that trust development may be more strongly influenced by interaction time and user experience than by interface design alone, at least in early stages of system exposure.

Regarding SUS scores, both interfaces were relatively close to the industry average of 68 (Lewis & Sauro, 2018), suggesting room for improvement. Another aspect of the pilot study that supports the usability of both interfaces is that all ten participants, five per interface, completed all three obstacle course tasks.

The presence scores suggest that participants experienced moderate to high levels of presence across both interfaces, with mean total presence scores in the upper half of the possible range. The presence subscales showed a similar pattern, with realism and possibility to act having relatively high scores, suggesting that participants felt able to interact with and influence the system. Next, interface quality and possibility to examine were slightly lower, but still above the midpoint of their respective score ranges, suggesting some limitations in these areas. Finally, the sound subscale yielded average scores near the middle of the possible score range, suggesting a moderate contribution of auditory feedback to participants' overall sense of presence for both interfaces.

Participant feedback provided valuable insights that informed refinements to both the teleoperation interfaces and the experimental protocol. As documented in prior teleoperation research, depth perception has been recognized as a persistent challenge, underscoring the need for enhanced visual cues to support spatial awareness (Chen et al., 2007; Luo et al., 2021). The sensory-enhanced interface was generally perceived as more supportive of safety, but some participants also noted it might have induced higher cognitive load, particularly due to the greater number of screens and data streams compared to the standard interface.

Participants also provided valuable suggestions for improving the interface layouts. To better align with participants' needs, we moved the end-effector and exocentric views, which participants identified as more critical for task performance, from the side screen to the top screen for improved visibility. Consequently, the side screen in the sensory-enhanced interface displayed the point cloud and outrigger views. Additionally, the initial laptop screen showing robot status information (temperature, fuel levels, hydraulic pressures, maintenance indicators) and proximity warnings was eliminated, and this information was integrated into the center screen alongside the egocentric and bird's-eye views. These adjustments directly addressed participants' concerns about information overload and interface complexity while preserving situational awareness.

Along with these visual interface changes, we also modified the audio feedback system to improve safety. Originally, both interfaces provided sound feedback through spatial audio headphones. However, the headphones were later replaced with TV speakers because participants struggled to hear the researchers' instructions and safety alerts, which could lead to accidents.

This pilot study had several limitations. First, the sample size was small (N = 10), limiting statistical power to detect differences between interface types and increasing the risk of Type II errors. Second, although all participants were construction workers, their experience with construction machine operations varied widely, potentially influencing their perceptions of usability, trust, and presence, and their task performance. Third, participants used the interfaces for a limited time during the pilot test, and longer-term use may change their perceptions of usability, trust, and presence. Additionally, while eye-tracking data were collected during the study, intermittent internet connection issues caused communication failures between the cellphone app and the eye-tracker, leading to calibration and tracking losses and video corruption. These issues made eye-tracking data unreliable during analysis. However, the issue was resolved by stabilizing the data acquisition setup for subsequent studies. Finally, while this analysis focused on subjective self-reported measures of trust, usability, and presence, further analyses of objective task performance and gaze behavior are necessary to provide a more comprehensive evaluation of interface effectiveness.

To address these limitations, in subsequent full-scale studies, we will recruit more construction workers to robustly analyze how different interface designs affect operators' performance and safety, using both objective and subjective measures. We will also conduct moderation and mediation analyses of the data to examine how demographic characteristics (e.g., age, machine operating experience) and operator responses (e.g., workload) explain observed performance and safety outcomes.

Conclusions

This pilot study provided valuable preliminary insights into usability, trust development, and presence afforded by two teleoperation interfaces for compact demolition robots. Both the standard and sensory-enhanced interfaces supported increasing trust over time, and presence scores were consistent with established reference values in the teleoperation and VR literature. Similarly, SUS scores for the initial designs of both interfaces were rated similarly to those of interfaces in industry and academia.

Next, participants' feedback highlighted specific areas for interface refinement, including improved depth cues and interface layouts. Importantly, iterative adjustments to the interface configuration and experimental protocol were made based on this feedback, highlighting the value of the selected user-centered approach in designing teleoperation systems that better support operator needs.

While results should be interpreted with caution due to sample size and other limitations, this work represents an important first step toward developing teleoperation systems that enhance operator safety, usability, and situation awareness in demolition. Moving forward, integrating objective performance data and involving a broader range of experienced operators will be key to validating and extending these initial findings.

AUTOMIZED PLANNING & DATA EXCHANGE FOR PREFABRICATED FAÇADE RENOVATION PROCESSES

Julius Emig[1], Orjola Braholli[1], Dietmar Siegele[1] and Dominik T. Matt[1,2]
[1]Fraunhofer Italia Research, Italy

Abstract

Europe's renovation rate remains below what is needed for climate-neutrality targets; scaling façade refurbishment demands standardised, data-driven automation. Current practice relies on bespoke BIM modelling and file-based scan-to-BIM pipelines, which are labour-intensive, sensitive to as-built deviations, and fragmented across design, production, and logistics. We present an end-to-end workflow that ingests 3D point-cloud surveys and performs geometric panelisation to derive storey-scale and small prefabricated façade panels. The system outputs IFC-compliant panel objects with cut-outs and metadata, synchronised via a self-hosted, versioned Speckle hub. A residential case study demonstrates workflow feasibility and reliable handover.

Introduction

Europe's climate-neutrality ambitions, reinforced by energy crises, place immediate pressure on the renovation of the ageing building stock. In the European Union, buildings account for around 40% of total energy consumption and 36% of energy-related greenhouse-gas emissions (European Commission, 2020b). Despite this central role, the annual renovation rate remains persistently low: on average, less than 1% of the building stock is renovated each year (European Commission, 2020a). This is well below the level required to meet European climate targets, which call for at least a doubling of renovation rates by 2030 and the sustained acceleration of renovation activity thereafter to achieve climate neutrality by 2050 (European Commission, 2020b).

At the same time, renovation projects are frequently perceived as slow, costly, and highly disruptive, while the construction sector faces a structural shortage of skilled labour. Together, these factors create a compelling need for a step-change in productivity, predictability, and scalability in renovation processes, particularly for façade retrofits, which offer high energy-saving potential but are still largely executed through bespoke, labour-intensive on-site construction methods.

A widely discussed pathway to address these challenges is the industrialisation of façade refurbishment through prefabricated façade panels or modules. Compared with conventional, largely on-site insulation retrofits, off-site prefabricated façade approaches shift critical activities to factory-controlled environments, enabling shorter on-site phases, improved quality control, and reduced disturbance for occupants during installation (European Commission, 2024; Zimmermann, 2012). In addition, componentised prefabricated assemblies, especially when designed with demountable connections, offer favourable conditions for circular-economy strategies. When combined with digital material passports, such systems can support planned disassembly, higher-value material recovery, and improved material traceability across the building lifecycle (Akinade et al., 2015; ISO, 2020; Çetin et al., 2023).

However, industrialising façade renovation is not merely a matter of developing new construction products. It is fundamentally a process and information-management challenge. Even where technically mature prefabricated solutions exist, their large-scale deployment remains constrained by the high effort required for building surveying, as-is modelling, project-specific design adaptation, multi-stakeholder coordination, and fragmented data handovers across specialised tools and organisational boundaries.

Prefabricated façade renovation

Over the last decade, research and innovation initiatives have advanced prefabricated façade retrofit systems and serial renovation concepts. The TES Energy Façade project established a timber-based modular façade approach for energetic renovation and investigated a survey-to-installation data-flow concept to reduce time and cost (Larsen et al., 2011). EU projects such as SINFONIA implemented prefabricated façade modules in real contexts, albeit sometimes with conventional on-site execution for specific layers (e.g., cladding and sealing) (Andaloro et al., 2019). The iNSPiRe project developed "Industrialised Renovation Kits", including prefabricated timber-frame façade elements with integrated active components to reduce planning and installation effort (Ochs et al., 2015). 4RinEU similarly explored integrated façade modules with active components (e.g., PV, ventilation, shading) as part of deep renovation packages (Noris et al., 2017; Pernetti et al., 2019). On the market-facing side, Energiesprong (n.d.) is often cited as one of the most advanced examples of industrialised renovation combined with an enabling business model, though its roll-out still tends to focus on building typologies that are easier to standardise and replicate. Across these efforts, a

recurring observation is that although technical feasibility is demonstrated, planning and process overhead remain a major driver of cost and a barrier to scaling, particularly when each project requires substantial manual adaptation and coordination effort.

From a computing-in-construction perspective, these observations highlight the central role of digital workflows across the entire renovation process, spanning survey capture, scan-to-model transformation, modular design configuration, performance assessment, production planning, logistics, and installation. Multiple studies report that renovation productivity bottlenecks stem not only from tool-level limitations (e.g., the effort and uncertainty involved in converting survey data into reliable as-built BIM), but also from socio-technical factors such as multi-stakeholder coordination complexity, communication bottlenecks, and information losses/redundancies across phases and organisations (Volk et al., 2014; Prieto et al., 2024; Lupica Spagnolo et al., 2022; Chen & Luo, 2026). In this context, continuous end-to-end digital workflows, linking building survey/scan-to-BIM to downstream design, prefabrication/CAM, and on-site assembly, are increasingly highlighted as key enablers to reduce planning effort and rework, mitigate data loss at interfaces, and support scalable deployment of prefabricated façade renovation solutions (Lupica Spagnolo et al., 2022; Fichera et al., 2025; Iturralde et al., 2025).

Scan-to-BIM & as-is modelling

A reliable, planning-grade as-is description of façade planes and openings is a prerequisite for panelised renovation. Scan-to-BIM / as-built BIM creation is commonly decomposed into (i) reality capture and preprocessing (e.g., registration and cleaning), (ii) geometric and semantic interpretation (segmentation / object recognition), and (iii) generation of parametric BIM/IFC entities and their relationships (Tang et al., 2010; Pătrăucean et al., 2015). Recent work increasingly leverages learning-based segmentation to automate recognition and downstream model creation, as exemplified by SCAN2BIM and Cloud2BIM (Campagnolo et al., 2023; Zbirovský and Nežerka, 2025). However, façade openings remain a hard case: measurement quality deteriorates at edges and window glazing often returns few or no points, while occlusions and missing data still necessitate manual validation/correction in practice (Pu and Vosselman, 2007; Tang et al., 2010; Tang et al., 2009). Consequently, renovation-oriented pipelines often adopt hybrid automation with human-in-the-loop controls, targeting a fit-for-purpose envelope representation (e.g., alignment planes and opening extents) that supports panelisation and prefabricated-panel installation rather than a fully detailed as-built BIM (Fichera et al., 2025; Song et al., 2023).

Research gap & Contribution beyond the state of the art

Across the reviewed literature, a persistent gap can be identified: while numerous methods address individual stages of prefabricated façade renovation, such as reality capture, scan-to-BIM transformation, panelisation strategies, IFC-based exchange, or logistics optimisation, far fewer contributions demonstrate an operationally usable, end-to-end workflow that explicitly treats continuous data flow as a primary research concern. In practice, large-scale deployment is constrained by fragmented information exchange across specialised tools and stakeholders, frequent data loss due to file-based handovers, and the absence of workflow-oriented ecosystems capable of linking survey-derived geometry, planning artefacts, and downstream operational outputs through a shared, versioned backbone.

This paper addresses this gap by presenting an integrated, web-based planning workflow for prefabricated façade renovation that prioritises continuous, interoperable data flow from survey ingestion to panel planning and logistics preparation. Rather than optimising isolated algorithms, the work focuses on the ecosystem-level potential of a modular toolchain coordinated through a central workflow layer. Accordingly, the implemented computational components should be understood as research prototypes for validating end-to-end workflow continuity; in future implementations, individual modules may be replaced by mature third-party solutions where interoperable interfaces and data continuity can be maintained. The implemented workflow combines point cloud ingestion and geometric pre-processing, semi-automatic derivation of façade planes and openings, interactive yet automated panelisation with IFC-compliant outputs, and downstream logistics preparation through panel-to-package transformation and interactive container loading.

Methodology

We propose a structured, workflow-oriented system that prioritises continuous data flow from survey to planning and logistics. The system follows the three-block structure shown in Figure 1: site survey as the data source, a 3D renovation planning web interface as the interaction layer, and a backend that provides custom services and a persistent data layer. The interaction layer is a Three.js-based (three.js, n.d.) web application used for both façade panel planning and the logistics planning. The communication with the backend works through GraphQL- and REST-APIs. The backend stores all project artefacts as versioned objects in a self-hosted Speckle server (Speckle, n.d.).

Overall, the workflow proceeds in four stages. First, façade and window point clouds (see Detection of window opening dimensions) are uploaded through the web interface and validated. Second, façade planes are reconstructed from the point clouds and stored together with the cleaned survey data. Third, façade panelisation is generated and reviewed interactively in the Three.js-based web frontend, and the resulting panel objects are persisted via Speckle. Finally, the panel objects are converted into package objects and transferred to the Three.js-based logistics interface for 3D packing and container loading.

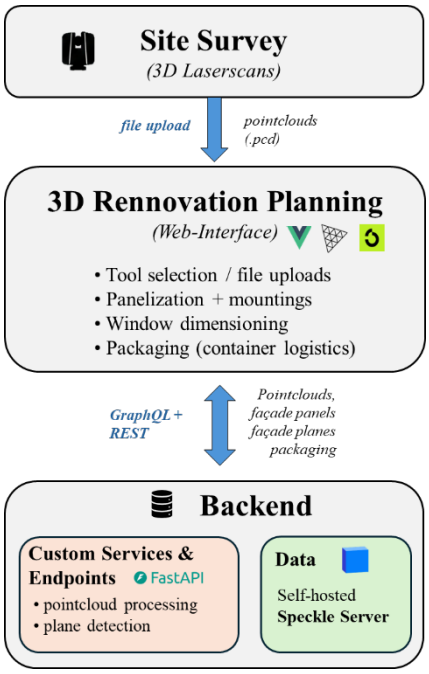

Figure 1 System architecture

Versioned Data Management

When point cloud data are uploaded via the web interface to the backend they get stored as Speckle point cloud. The backend uses the Open3D python library (Zhou et al., 2018) to read the scan data and creates a versioned object graph in the *pointcloud-facade* branch. This gives all downstream tools a consistent and queryable source of truth.

Speckle is used as a versioned common data environment with a deliberate branch/model structure. In Speckle, each project contains named models (branches) that hold a sequence of versions (commits) referencing object graphs. The workflow assigns one model per artefact type so that tools can query the latest version deterministically: *pointcloud-facade* and *pointcloud-windows* store survey data; *facade-planes* stores derived plane objects; and *facade-panels* stores panel layouts in IFC-compliant data format. This convention makes data handovers explicit, reduces ambiguity when multiple tools write to the same project, and enables reproducible retrieval of the latest artefact by model name.

Façade plane reconstruction

A critical process step is the reconstruction of the façade planes from the 3D point cloud data. As discussed already in sub-section Scan-to-BIM & as-is modelling there are existing scan-to-BIM tools. We found however that the results of that tools are not accurate enough to execute a detailed façade planning with prefabricated panels. That is why we implemented a semi-automated approach that lets users define the façade planes directly based on the 3D point cloud data. This ensures a maximum of accuracy and flexibility.

Façade panel generation

The reconstructed façade planes are the basis for the panel generation which follows a parametric grid-based process in the 2D façade plane. The panel system is defined by parameters (standard width & height, minimum width & height, depth, gap width, mounting position, weight) that are iteratively fitted to the façade while respecting openings and façade boundaries. To control where a panel must terminate, the user defines horizontal and vertical break edges (e.g., façade edges and opening boundaries). These break edges induce a rectilinear grid on the façade plane and thus a set of grid fields. Within each grid field, the algorithm first places panels at the standard width/height. If boundary panels would need to be cut, the remaining strip is evaluated against the minimum admissible panel dimension. Whenever the remaining width/height would violate this minimum, the algorithm avoids producing undersized edge pieces by uniformly resizing the panels along the affected direction within that grid field so that all resulting panels satisfy the minimum dimension constraint while maintaining the specified gap. This resizing is applied locally within the affected grid field; standard panel dimensions are preserved in unaffected fields, while only boundary-adjacent panels may deviate where necessary. The resulting panel layout in the 2D façade plane space gets extruded and transformed back to the global 3D coordinate system. The 3D panels are now represented as Three.js geometries with a stable identifier, a façade ID, and dimensional metadata (width, height, depth, gap).

A dedicated IFC writer transforms the generated Three.js panels into IFC-compliant objects (e.g., IfcPlate with swept-area geometry) and attaches property sets containing Width, Height, and Depth. The resulting IFC model is stored on the Speckle server. File-based exports were also implemented (.ifc model with 3D façade panels, .csv lists with panel dimensions and mounting points), but they are meant primarily as documentation features; the operational data for prefabrication and on-site mounting remains available as versioned Speckle objects that can be queried and reused across tools.

Detection of window opening dimensions

Window planning is supported as an optional, separate module. Detailed window design typically requires denser scans than façade-level surveys, so the workflow accepts dedicated window point clouds when they are available. In practice, these local scans are acquired from accessible interior or exterior positions using higher-density close-range measurements, depending on site access and required detail. They are registered to the building-level façade point cloud during survey preprocessing and then uploaded as already aligned window point clouds to the *pointcloud-windows* branch. Then they are processed by a light-weight plane detection routine that produces structured instances with fitted planes which represent the window opening (four reveals and one wall plane). Leveraging Open3D the backend performs a deterministic sequence: The window scan is down-sampled with a voxel size of 0.02, normals are estimated and oriented

consistently, and planar patches are detected using normal variance 60°, coplanarity 75°, outlier ratio 0.75, and a k-nearest-neighbour search of k=30. The largest detected plane is interpreted as wall and the remaining planes as window reveal candidates. Each candidate is converted to a rectangular plane using its oriented bounding box and stored alongside the raw point cloud for detailed window planning.

Container packaging

A logistics planning feature was developed and implemented to calculate the number and size of shipping containers required for transporting the planned façade panels. It consists of an interactive 3D environment based on Three.js and ThatOpen bim-components (ThatOpen, n.d.) with a packing solver that is based on 3D-bin-picking algorithm from (Aoulad Lahcene, 2023).

The backend resolves the latest *facade-panels* model through the GraphQL API, loads the referenced object graph, and traverses it to identify panel candidates. Dimensions are taken from attached property sets when available. The backend emits a package list with dimensions, quantity, priority, stacking capacity, and allowed rotations, which is consumed by the logistics tool for packing.

The packing solver uses a greedy heuristic with priorities and open-point placement. Packages are expanded by quantity, grouped by priority, and sorted by volume within each priority. Placement proceeds by testing rotations at available open points, checking container bounds and collision constraints, and honoring stacking limits. New open points are generated on the front, right, and top faces of each placed package, while invalid diagonal points are removed to stabilize the search. A manual drag-and-drop mode remains available for operational corrections that are not captured by the heuristic.

Results & Discussion

The workflow was validated on a representative residential building using terrestrial laser-scan (TLS) data captured with a FARO Focus M70. Figure 2 shows the façade point cloud used as survey input. To anchor the digital planning workflow in a manufacturable solution, a physical prototype of the prefabricated wood-fibre insulation panel was used as planning reference (Figure 3), confirming the feasibility of the intended panel geometry and joint concept for off-site fabrication and on-site installation.

Across the end-to-end validation, three main outcomes were observed. First, the semi-automated façade-plane reconstruction provided planning-grade reference geometry from real scan data, enabling downstream panelisation without relying on fully automatic scan-to-BIM outputs. Second, automated panelisation generated façade module layouts that are directly usable for downstream BIM and fabrication preparation through IFC-compliant objects and associated dimensional metadata. Third, the versioned Speckle-based data backbone enabled a consistent handover from survey-derived façade modules to logistics planning, avoiding repeated file exports/imports and reducing data fragmentation between tools. Given the single-case validation, these results should be interpreted as evidence of workflow feasibility and reduced data-fragmentation effort rather than as a benchmarked productivity gain.

Figure 2 Point cloud of residential building façade

Figure 3 Prototype of prefabricated wood-fiber insulation panels mounted on lab test wall

Based on the survey data, façade planes were reconstructed in a human-in-the-loop step by selecting a small number of corner points directly in the 3D point cloud. In practice, this interaction step acted as a controlled “alignment and interpretation” layer: it resolved ambiguities caused by occlusions and scan noise and ensured that the resulting planes represent the reference geometry required for fabrication-oriented planning. Human input is retained where survey ambiguity or design intent materially affects manufacturability, whereas steps governed by explicit geometric rules and machine-checkable constraints are automated and subsequently interactively reviewed.

Figure 4 exemplifies the resulting panel layout for a reconstructed façade plane. In this validation, user-defined break edges (e.g., storey lines, façade boundaries, opening extents) proved effective to enforce architecturally meaningful alignments while keeping the layout manufacturable. The panelisation outcome demonstrates that minimum-dimension constraints can be respected without producing impractically small boundary pieces; where the grid would otherwise create undersized edge panels, the layout adapts by distributing the residual dimension within the affected grid field. As output, the workflow produces an IFC-compliant façade panel model (IfcPlate entities with dimensional property sets) and a fabrication/installation part list containing panel dimensions and mounting positions.

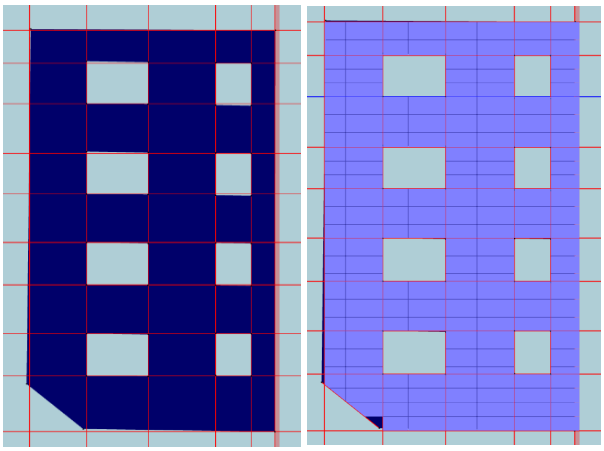

Figure 4 Façade plane (left) and generated panels (right) with grid pattern composed out of break edges (red)

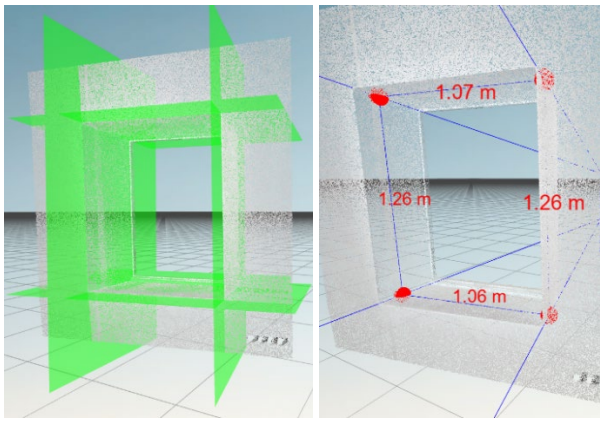

Figure 5 Detected window reveal planes (left) and dimensioning of window opening (right)

For optional window replacement, dedicated window scans were processed to detect planar patches corresponding to the wall plane and window reveals (Figure 5, left). The fitted planes enable robust opening dimensioning. In the shown example, the extracted opening measures approximately 1.26 m in height and 1.06–1.07 m in width (Figure 5, right). These dimensions can be re-used to parametrically define window objects and to validate panel cut-outs and tolerances at the interface between façade modules and window frames.

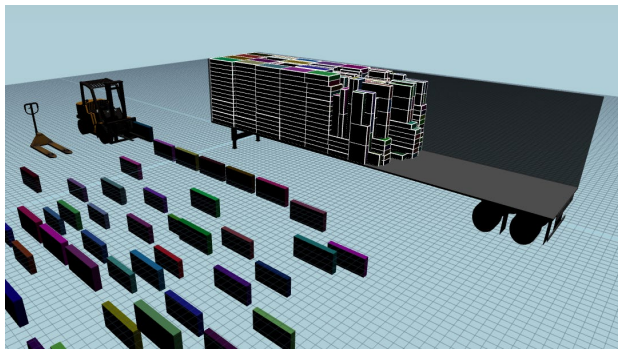

Figure 6 Logistics tool for container shipping with IFC and Speckle APIs

The generated panel objects were subsequently transferred to the logistics planning tool without file-based re-entry. By resolving the latest façade-panels version from Speckle and reading panel dimensions from their attached properties, the backend automatically emitted a package list that was consumed by the Three.js-based packing interface. Figure 6 shows the interactive container-loading environment, where a 3D bin-packing heuristic proposes an initial packing based on priority, rotations and stacking constraints. Planners can apply drag-and-drop corrections when operational considerations require it, i.e., the packing logic functions as decision support rather than a fully automatic optimiser. Overall, this end-to-end handover demonstrates that a versioned, interoperable data backbone can connect survey-derived planning artefacts to downstream logistics decisions in a consistent way.

Encountered limitations

- Operator input remains a dependency for "planning-grade" geometry. While the human-in-the-loop plane reconstruction improved robustness on real scan data, it introduces operator effort and potential variability (e.g., depending on how corner points are selected under occlusion/noise).
- Break-edge definition is a knowledge bottleneck. The quality of panel alignments and module boundaries strongly depends on correctly specified break edges. This provides necessary design control, but it also limits full automation and requires consistent modelling conventions.
- Standardisation vs. manufacturability trade-off. Avoiding undersized boundary panels through layout adaptation improves feasibility, but it can increase the number of non-standard panel dimensions near boundaries/openings and thus may reduce production economies unless size-variant limits are introduced. This effect is expected to become more pronounced for more geometrically complex façades with a higher density of break edges and local exceptions.
- Window dimensioning requires dedicated scan coverage. Reliable opening extraction benefits from denser, targeted scans. Where such data is unavailable or incomplete, window replacement support may be partial and cut-out validation less robust.

- Packing is not fully automatable in operational contexts. Even with a heuristic initial packing, manual adjustments were necessary to reflect practical constraints (handling preferences, sequencing, transport considerations), implying that packing quality should be assessed by "solution usefulness + edit effort" rather than by optimality alone.
- Limited external validity and limited quantitative evaluation. The validation was conducted on a single representative case; additional façade typologies (e.g., highly articulated/non-planar façades, heavier occlusion) and systematic metrics (time-on-task, number of panel variants, amount of manual correction, downstream IFC usability checks) are needed to quantify scalability and robustness.

Conclusions & Outlook

This paper presented an integrated, web-based planning workflow for prefabricated façade renovation that connects survey ingestion, façade and window geometry extraction, automated panel planning, and logistics preparation through a shared, versioned data backbone. In contrast to tool-isolated solutions, the contribution is workflow-oriented: a central object graph provides a consistent "source of truth" across planning stages, while IFC-compliant semantics expose façade modules in a form that is directly consumable by downstream BIM and production environments.

Validation on a residential façade scan demonstrated that a semi-automated, human-in-the-loop reconstruction of façade planes provides the accuracy required for fabrication-oriented module planning, motivated by the observed insufficiency of fully automatic scan-to-BIM outputs for detailed panel planning. On top of this reference geometry, grid-driven panelisation yields IFC-compliant panel objects and installation metadata suitable for fabrication documentation and on-site mounting preparation. Optional window opening dimensioning further supports coordinated window replacement when dedicated, denser window scans are available. Finally, the same panel objects can be transformed into logistics packages and transferred to an interactive container-loading environment without file-based re-entry, demonstrating continuous data flow from survey-derived planning artefacts to downstream logistics decisions.

The validation also highlights practical limitations that shape industrial applicability. First, "planning-grade" envelope geometry currently depends on operator input for plane definition, reflecting a deliberate accuracy–automation trade-off. Second, panel layout quality depends on consistently defined break edges (storey lines, façade boundaries, opening extents), which provide necessary design control but remain a manual knowledge bottleneck. Third, robust window dimensioning depends on scan coverage quality and the availability of dedicated window scans. Fourth, logistics packing relies on a heuristic with an explicit manual correction mode for operational constraints not captured algorithmically. Finally, results are currently based on a single representative case study, motivating broader evaluation across building typologies.

Future work will therefore focus on closing remaining process gaps, strengthening downstream integration, and quantifying robustness and productivity gains under realistic constraints, in particular:

- Socio-technical workflow integration and praxis adoption, including stakeholder roles, validation responsibilities, trust in semi-automated outputs, and acceptance in multi-actor renovation practice.
- Coupling to LCA/LCC assessment to provide early-stage environmental and cost feedback for alternative panel configurations.
- Integration of construction-site simulation and 4D time planning to link panel layouts and logistics decisions to installation sequences, crane operations, and site constraints.
- A production link to prefabrication/CAM systems (e.g., CNC cutting, drilling templates, labelling) to translate panel and mounting-point metadata into shop-floor instructions.
- Refinement of joint/gap modelling and tolerance handling, including explicit as-built deviation compensation strategies, to improve robustness for industrial roll-out.
- Further automation of façade feature extraction (openings, storey lines) and systematic evaluation on additional building typologies, including metrics such as time-on-task, number of panel variants, required manual corrections, and downstream interoperability performance, to quantify time savings and error reduction.

EVALUATION OF MOBILE PLATFORMS FOR AUTOMATION OF METRO TUNNEL INSPECTIONS

Timur Kuzu, Katharina Klemt-Albert
Chair and Institute of Construction Management, Digital Engineering and Robotics in Construction,
RWTH Aachen University, Aachen, Germany

Abstract

Metro tunnel inspections face growing demands from urbanization and tight maintenance windows, yet manual and time-consuming inspection methods remain. While rail-bound vehicles, wheeled and tracked robots, quadruped robots, and Unmanned Aerial Vehicles (UAVs) show promise for inspection tasks, no systematic evaluation addresses metro tunnel-specific constraints like track geometries, tunnel access and inspection windows for mobile platform choice. This paper reviews inspection platforms, derives evaluation criteria from literature, operator interviews, and observations, and quantitatively compares platforms across sensing, payload, speed, runtime, deployment, and locomotion. Results identify optimal use-cases for each system, guiding deployment strategies for automated metro tunnel inspections.

Introduction

Motivation

Tunnel infrastructure, including road tunnels, railway tunnels, utility corridors and metro systems, plays a crucial role in modern transportation networks, particularly in regions with complex topography or high population density. Urbanization and the resulting densification of cities are driving the need to maintain and expand this underground infrastructure. In the past 75 years, the urban population has increased from 20% of the global population (500 million people) in 1950 to 45% of the population in 2025 (3.69 billion people) (United Nations, 2025). During a similar period of time, from 1950 to 2015, the cumulative global length of metro systems has increased more than tenfold from 1250 km to 13000 km through a combination of extending old networks and the construction of new metro lines (Bono et al., 2022). As such, metro systems have established themselves as a substantial contributor to inner-city passenger transport with a total annual ridership count of 58 billion in 2023 (International Association of Public Transport, 2024), accounting for up to 33% of the modal share in major cities like Tokyo (Le et al., 2022).

Like other infrastructure buildings, tunnels inevitably deteriorate over time due to the influence of material aging, heavy loads, environmental conditions, and irregular events such as earthquakes. In combination with an increasing average service life of tunnels due to the demand for underground infrastructure, structural damage can occur in the form of cracks, leakages and cross-section deformations (Bao et al., 2026). From a safety perspective, defects in tunnel linings and surfaces, such as water ingress and spalling, pose a potential threat to passengers and workers within them. Regular building inspections are thus required to ensure the safe, fully-functional operation of tunnels. Currently, manual on-site inspections are performed by certified inspectors and structural engineers at regular inspection intervals (routine inspection) or after unforeseeable events (post-disaster inspection). These inspections are used to assess and predict future building conditions, plan investments and allocate maintenance and repair resources, however the manual inspection process is time-consuming and often suffers from poor visibility and subjective judgment, expressing the demand for more intelligent and automated approaches (Bao et al., 2026).

Metro tunnels impose particularly stringent operational constraints that further demonstrate the need for automated inspections. As metro services operate throughout the day, maintenance windows are timely restricted and typically limited to a maximum of 4-6 hours, including time required for safety checks, resulting in an effective inspection window of approximately 3 hours during nightly shutdowns (Chen et al., 2023). Moreover, the metro-specific environment, including central rails, ballast, crossties, and frequent stations create fundamentally different requirements for automated inspection systems compared to road tunnels. Given the unique combination of metro tunnel-specific inspection constraints, a comparative assessment of mobile inspection platforms is necessary to guide future developments of inspection systems and inform metro operators looking to automate their inspection processes.

Contributions and Outline

While previous work mainly focused on the design and development of individual inspection systems for tunnel environments, this work contributes by evaluating different mobile platforms for automated metro tunnel inspections, specifically focusing on the requirements and operating conditions therein. By doing so, this paper addresses the research gap of systematically evaluating mobile inspection platforms such as rail-bound vehicles, wheeled and tracked robots, quadruped robots and Unmanned Aerial Vehicles (UAVs) against metro tunnel-specific environments and operating constraints.

Including the Abstract and Introduction, the paper is structured into seven sections. Section 3 presents the methodology for deriving metro tunnel-specific evaluation criteria from literature, operator interviews, and in-tunnel observations. Section 4 reviews literature on developed mobile inspection systems for tunnel environments and identifies the main platform classes analyzed in this study. Section 5 provides the core contribution, an evaluation of mobile platforms including rail-bound vehicles, wheeled and tracked robots, quadruped robots, and UAVs. Sections 6 and 7 discuss the implications of the findings and present the conclusions, with recommendations for future work.

Methodology

The evaluation of mobile platforms presented in this paper is based on a mixed-method approach combining a literature review, semi-structured interviews with German metro tunnel operating companies, and qualitative in-tunnel observations. The following section explains how these three data sources were collected and analyzed, and how they informed metro tunnel-specific evaluation criteria.

First, a literature review was conducted to identify existing mobile inspection systems for tunnel environments and to extract key technical parameters. The review focused on robotic and automated inspection systems used in road tunnels, railway tunnels, and metro systems. Relevant publications were identified through the Scopus and Google Scholar databases using a keyword-based search approach, with combinations of terms related to automated tunnel and subway tunnel inspections. From the resulting set of publications, studies were selected based on their relevance to tunnel inspection tasks and the maturity of the described systems. For each platform class, typical performance ranges of key system characteristics were consolidated.

Semi-structured interviews were carried out with multiple representatives from German metro tunnel operating companies. In total, six participants from maintenance and infrastructure departments participated, covering a range of responsibilities from planning and scheduling to on-site inspection and asset management. The main focus of the interviews was on existing maintenance approaches for metro tunnels and the derivation of requirements for a digital, predictive maintenance system. The interview guideline addresses several thematic blocks, including the organizational processes of tunnel inspections from planning to execution, current maintenance strategies, handling of inspection data and reports, and operational constraints in the maintenance process.

The interviews were recorded and transcribed, and the textual data were analyzed using qualitative content analysis according to Mayring's approach. The analysis aimed to identify recurring themes and explicitly stated operational constraints relevant to metro tunnel inspections, such as the duration of night-time inspection windows, track-related access restrictions, and safety procedures. The main outcome for this paper was the extraction of key operational constraints that later served as core criteria in the platform evaluation.

Third, qualitative in-tunnel observations were conducted inside a German metro tunnel during regular inspection and maintenance windows. These observations focused on the physical environment and infrastructural conditions inside metro tunnels. The observations were documented through photos and videos, and the collected material was subsequently analyzed to identify requirements that were not explicitly mentioned in academic literature. The resulting insights were translated into additional evaluation criteria and integrated into the final comparison of mobile platforms.

Tunnel inspection systems

The following section presents existing mobile systems developed for tunnel infrastructure inspections. Since the focus of this work is on the mobile platform of inspection systems, they are categorized according to four main locomotion types: rail-bound vehicles, wheeled and tracked robots, quadruped robots and UAVs. These platforms were selected as they represent the largest share of used platforms for developed systems, including the most mature commercial technologies, balancing trade-offs in characteristics such as payload and terrain adaptability. Figure 1 shows an inspection system based on each locomotion type.

Rail-bound vehicles

Rail-bound inspection vehicles represent an established approach for railway and metro tunnel maintenance, leveraging existing rail infrastructure for stable, high-capacity operation. The Metro Tunnel Surface Inspection System (MTSIS) (Li et al., 2021) deploys a rail-mounted platform equipped with eight high-resolution line-scan cameras and linear lights, capturing tunnel lining images at speeds up to 15 km/h with 0.15 mm/pixel resolution during 3-hour nightly windows. Covering 280° of the tunnel circumference, MTSIS enables automated defect detection via deep learning, achieving 88.5% mean average precision while reducing inspection time by 40% compared to manual methods, which has been evaluated in a series of experiments within different metro tunnels (Li et al., 2021).

Similarly, Zhou et al.'s mobile laser scanning rail trolley (Zhou et al., 2021) uses a Z+F PROFILER 9012 laser scanner on a motorized rail cart, generating intensity/depth point clouds at 0.5 m/s (100 Hz scan rate) for 3D spalling quantification in railway tunnels. The SIDNet model segments defects with 92.5% mean intersection over union (MIoU), enabling volume calculation of spalling via depth analysis. The system was experimentally tested in several railway tunnels in China, proving the validity and feasibility (Zhou et al., 2021).

Specifically targeting crack detection, Liu et al. (Liu et al., 2022) present a system mounted on a Metro Intelligence Inspection Vehicle (MIIV) for subway tunnels. The MIIV

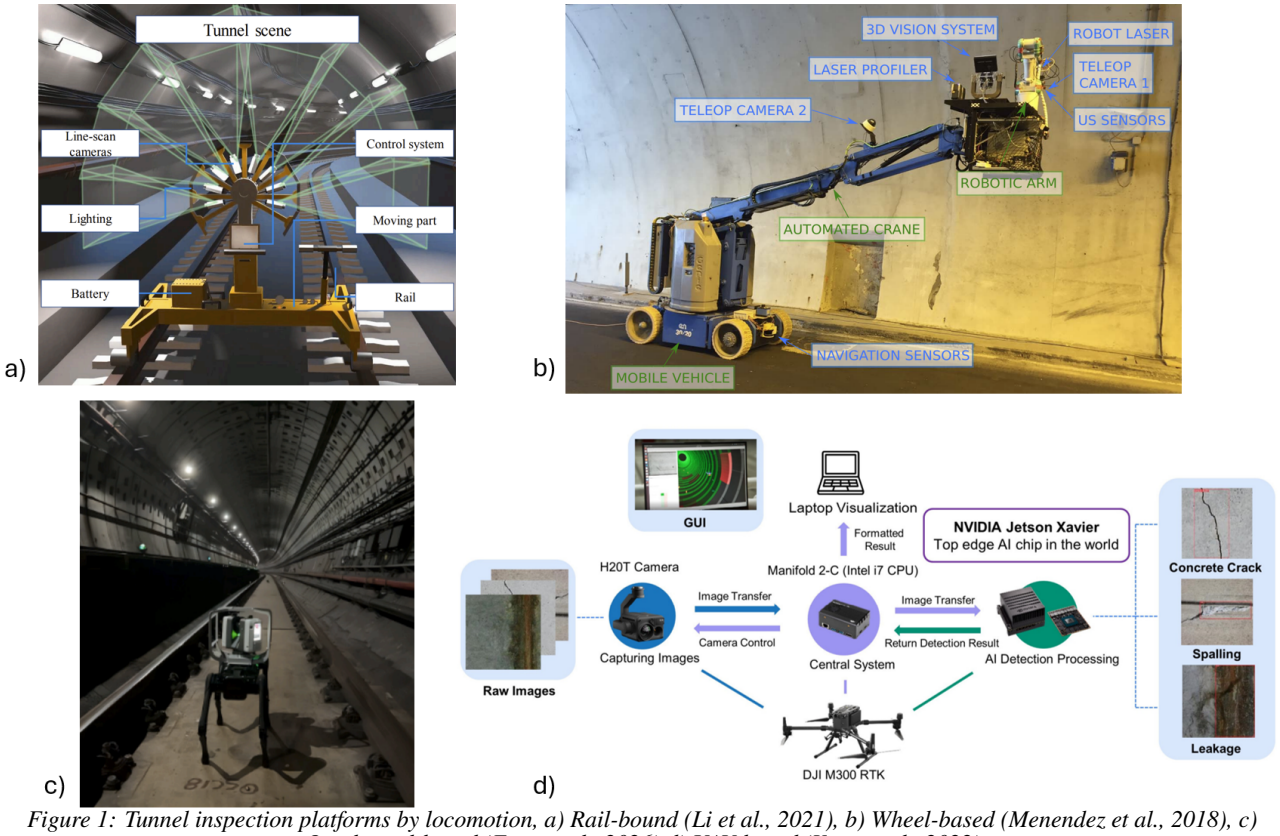

Figure 1: Tunnel inspection platforms by locomotion, a) Rail-bound (Li et al., 2021), b) Wheel-based (Menendez et al., 2018), c) Quadruped-based (Feng et al., 2026) d) UAV-based (Yang et al., 2022)

carries three high-speed cameras on a circular frame, synchronized to capture 150° of inspection range at an optimal inspection speed of 18 km/h. An improved image processing pipeline, including illumination correction, adaptive thresholding, structural noise removal and pixel-level crack width estimation, achieves a crack recognition rate of 91.15%, evaluated in railway tunnel environments (Liu et al., 2022).

Wheeled and tracked robots

The ROBO-SPECT project presents a highly integrated road-tunnel inspection robot composed of a self-navigating mobile vehicle, an automated crane, a 7-degree of freedom (DOF) robotic arm carrying an ultrasonic sensor, stereo cameras, and a 3D laser profiler. The wheeled platform autonomously follows the tunnel wall using laser-based navigation and Simultaneous Localization and Mapping (SLAM) with reflective beacons, performs visual inspection for cracks and other defects, and when a crack is detected, repositions the crane and arm to place the ultrasonic sensor on the lining for width and depth measurements, while the laser profiler captures 3D deformation with 2 mm accuracy. Field trials in motorway tunnels demonstrate the complete inspection workflow and show reduced inspection times compared to manual methods while delivering comparable inspection quality (Menendez et al., 2018).

Earlier work by Yu et al. in 2007 presents a mobile robot-based crack inspection system for concrete tunnels that combines a two-wheel differential-drive platform with a line-scan camera, high-power illumination, and an image-processing pipeline for semi-automatic crack detection and measurement. The robot maintains a constant distance to the tunnel wall, acquires line-scan imagery at up to 5 km/h with a spatial resolution of 0.3 mm/pixel, and applies contrast enhancement, edge detection, graph-based crack tracing, and feature extraction to estimate crack length, orientation, and width, yielding measurement errors below 10%. Although the system focuses on 2D vision rather than full 3D evaluation, it demonstrates the feasibility of wheel-based tunnel inspection with higher speed and more objective results than manual inspections (Yu et al., 2007).

Quadruped robots

Quadruped robots are emerging as a promising mobile platform for autonomous tunnel inspection because they decouple the inspection system from the rail infrastructure while maintaining high mobility on uneven terrain. Feng et al. integrate a laser scanner with a legged inspection robot to realize rail-independent deformation inspection of metro tunnels, enabling dense point cloud acquisition in sections where trolley-based mobile laser scanners are impractical due to track layout. In their system, the quadruped robot carries a laser scanner through the tunnel and, together with terrestrial laser scanners, provides a point cloud dataset containing more than 574 mil-

lion points to support segmentation of tunnel components and deformation analysis. The approach achieves submillimeter accuracy (average error 0.60 mm) comparable to total stations while overcoming the low efficiency of static terrestrial laser scanning and was tested in various metro tunnel sites in Shanghai, China. (Feng et al., 2026).

Beyond pure defect inspections, quadruped robots are also being used as carriers in heterogeneous inspection approaches that combine legged mobility with aerial close-up sensing. Chu et al. propose a collaborative system composed of a quadruped robot and a collision-resilient micro-UAV for crack inspection in road tunnels, explicitly addressing GPS-denied navigation, poor lighting, and wet, obstacle-rich road surfaces that challenge wheeled or tracked platforms. The quadruped robot is equipped with stereo and panoramic cameras plus a VLP-16 LiDAR scanner to autonomously follow a pre-planned path to perform global scanning and patch-based CNN crack localization, while serving as a mobile helipad and communication relay for the UAV. Once potential damage regions are detected, the caged UAV is launched to perform detailed crack segmentation, allowing tiny cracks to be identified with over 93% segmentation accuracy in field tests (Chu et al., 2023).

Unmanned Aerial Vehicles (UAVs)

UAV tunnel inspection is increasingly defined by full-stack, field-tested systems that tightly couple navigation, sensing, and defect analytics in Global Navigation Satellite System (GNSS)-denied, low-light environments. Zhang et al. propose a Proximity-Pause-Photo for Surface Defect Inspection (PMPP-SDI) method, which uses a DJI Mavic 2 Enterprise with onboard lighting and omnidirectional obstacle sensing to execute a reactive grid-scan of tunnel walls. Instead of relying on pre-built maps, the UAV regulates lateral position via vision, height via infrared ranging, and axial motion via front/back obstacle distances, moving in short steps (1 m - 1.5 m) and pausing to acquire high-overlap image strips that later feed a structure-from-motion photogrammetry pipeline. A field test in a railway tunnel demonstrates stable navigation in darkness, high-resolution 3D reconstruction, and accurate surface defect localization, while highlighting remaining needs in higher-level autonomy, data quality control and integrated computer-vision-based defect analysis (Zhang et al., 2024).

Yang et al. developed a real-time tunnel lining inspection system that embeds an edge-AI stack and a dual RGB/infrared payload on a DJI Matrice 300 RTK platform to detect cracks, spalling, and leakages in TBM-driven tunnels. Positioning and tunnel coverage are enforced by AprilTag-based relative pose estimation, with an automated routine that captures 12 RGB and 12 infrared images per tunnel segment. Subsequently, the on-board YOLOv3-inference evaluates the data and returns the defect results, achieving the highest precision when combining RGB and thermal channels during field tests (Yang et al., 2022).

Evaluation of Mobile Platforms

Metro tunnel operating constraints

While robotic tunnel inspection literature often assumes highway or generic underground conditions, metro tunnels present distinct operational challenges that fundamentally constrain mobile platform selection. The following aspects are derived from the three complementary data sources (literature, interviews, observations) and later serve as an underlying basis for the evaluation of different mobile platforms.

Literature-based constraints:

- **GNSS-denied environment:** Absence of GPS demands robust onboard localization, while tunnel feature scarcity and repetitive geometries challenge SLAM performance (Schichler et al., 2025).
- **Low illumination:** Low-light tunnel environment requires the addition of external light sources for sufficient illumination and high quality data acquisition (Liao et al., 2022).
- **Dust pollution:** Metro tunnels show increased particulate matter concentrations (Smith et al., 2020), demanding sealed electronics, filtered intakes and protective covers for reliable sensor operation.

For the low illumination and dust pollution constraints, while they are derived from literature, in-tunnel observations confirmed the presence and operational impacts of these conditions.

Interview-based constraints:

- **Limited inspection time:** Interviewed metro operators in Germany reported that daily inspection windows during nighttime shutdowns are limited to approximately 3 hours of effective inspection time.
- **Railway track maintenance:** Major maintenance and repairs of railway tracks require temporary track closures, resulting in sections periodically unavailable for continuous track access (Dao et al., 2018). Interviewed metro operators confirmed that individual track sections are regularly unavailable for maintenance.

Observation-based constraints:

- **Railway track geometry:** Tracks, ballast and crossties require obstacle-straddling capability for non rail-bound platforms, ensuring reliable navigation and freedom of movement.
- **Metro tunnel access:** Entry and exit to metro tunnels can involve overcoming elevation changes such as stairs.

Platform Evaluation

Building on the general constraints of tunnel environments and the metro-specific constraints outlined previously, Table 1 evaluates four mobile platforms against criteria including payload capacity, speed, system runtime, deployment time, locomotion, and general considerations, de-

rived from inspection requirements.

Payload Capacity

Payload capacity directly determines sensor quality and availability in metro tunnel inspection. Rail-bound platforms excel with high possible payloads, supporting extensive sensor suites for data collection. Depending on the system size, wheeled and tracked platforms can achieve around 20 - 100 kg of payload capacity, offering potential for comprehensive multi-sensor setups, while quadruped robots are usually limited to around 10 - 40 kg. UAVs remain with the lowest payload capabilities of up to 2.7 kg for commercial drone systems, usually restricting them to camera setups.

Inspection Speed

Inspection speed reflects the traversal efficiency across tunnel geometries. Rail-bound platforms can achieve fast inspection speeds of up to 4.2 m/s due to their ease of locomotion in subway environments, while wheeled and tracked platforms reach a velocity of 2 m/s in non-track areas, further limiting the resulting inspection speed due to track-crossing and ballast navigation. Quadruped systems can maintain a speed of 0.75 - 1.6 m/s in non-track environments, however they are able to maintain more of that speed due to their obstacle avoidance capabilities. UAVs attain up to 20 - 23 m/s in ideal outdoor conditions, but tunnel constraints reduce practical speeds significantly.

System Runtime

System runtime depends on energy capacity and operational demands in tunnel conditions. Since inspection windows are usually limited to around 3 hours per day, this reflects the target system runtime for inspection operations without battery changes. As such, rail-bound platforms, wheeled and tracked systems and quadruped robots can reach system runtimes of up to 4 - 8 hours depending on the installed sensor systems, resulting in sufficient operation time for metro tunnel inspection windows. UAVs are usually limited to a shorter runtime due to limited battery-to-weight ratios, leading to required battery changes and inspection stops.

Deployment Time

Deployment time critically impacts the 3-hour inspection window. Developed rail-bound platforms require 3 - 5 minutes for assembly and disassembly tasks on tracks. Wheeled and tracked systems are estimated for around 10 - 15 minutes for deployment due to their bulky nature and difficult tunnel access. Quadruped robots, usually lighter and more flexible in motion capabilities, are estimated to require around 5 - 10 minutes, while UAVs excel with the fastest deployment due to their low size and weight.

Locomotion

Locomotion determines the access to diverse tunnel locations, while considering the complexity of system control. Rail-bound platforms use available rail systems with no possible deviation from the track layout, however they require very simple control to move along the tunnel. Wheeled and tracked platforms feature medium control complexity, while being able to navigate floors effectively but struggling with track straddling and poor object avoidance. Quadruped robots depend on complex system control, but reward high flexibility, being able to efficiently navigate around obstacles and provide large tunnel access including side tunnels not connected by tracks. UAVs require complex control due to aerial collision avoidance, but benefit by being able to inspect hard-to-reach locations that would be inaccessible by other systems.

General Considerations

General considerations highlight platform-specific limitations for metro tunnel operations. Rail-bound systems depend entirely on available tracks, excluding any areas currently under track maintenance. Wheeled and tracked systems suffer from poor obstacle avoidance and track-straddling features in complex metro environments. Quadruped robots benefit from stair-walking capabilities, while large UAVs face the risk of propeller-induced dust swirling, reducing visibility and damage detection potential.

Discussion

The comparative evaluation of mobile platforms reveals distinct strengths and weaknesses emerging from metro tunnel-specific inspection conditions, guiding deployment decision based on environment, access, data requirements and mission duration. Each platform benefits in particular aspects, which promotes scenario-specific deployment strategies rather than generic platform recommendations.

Rail-bound platforms excel in linear inspection with substantial payload capacity for comprehensive sensor suites, achieving fast traversal and extended runtime on established rails. They therefore perform well in long, straight sections with uninterrupted track access and limited track maintenance activity. Thus, their ideal use case involves track-maintenance free tunnels with uninterrupted track access, where large amounts of the tunnel surface can be inspected rapidly once the system is established.

Wheeled and tracked platforms offer balanced performance across payload, speed, and runtime, with robust sensor integration but limitations in obstacle avoidance and reliable track straddling. They perform best in relatively flat metro tunnel areas, where the ground surface is continuous and track-crossing poses minimal issues. In such scenarios, their locomotion simplicity supports efficient coverage of extensive tunnel sections, prioritizing horizontal mapping and data acquisition over vertical or complex geometries. However, they lag in environments with frequent ballast sections, crossties, and stations, where their limited obstacle-navigation reduces inspection capability.

Quadruped robots provide versatile and flexible locomotion with good stair-climbing and obstacle avoidance.

Table 1: Comparison of mobile platforms for automated metro tunnel inspection.

Criteria	**Rail-bound** (Huang et al., 2017) (Zhou et al., 2021) (Li et al., 2021)	**Wheeled and tracked** (Clearpath Robotics, 2020) (Clearpath Robotics, 2024)	**Quadruped** (ANYbotics AG, 2022) (Boston Dynamics, 2024) (Unitree Robotics, 2023)	**UAV** (DJI, 2021) (DJI, 2024)
Payload Capacity	high (total system weight 65 - 140 kg)	20 - 100 kg	10 - 40 kg	<0.2 - 2.7 kg
Speed	0.5 - 4.2 m/s	~ 2.0 m/s, in non-track environment	0.75 - 1.6 m/s, in non-track environment	20 - 23 m/s, outdoor and no-wind conditions
System Runtime	3 - 4 hours	2 - 8 hours	1.5 - 4 hours	30 - 55 min
Deployment Time	3 - 5 min, for each assembly and disassembly	10 - 15 min, bulky and difficult tunnel access	5 - 10 min, fast tunnel access and mid-range weight	<3 min, fast setup due to small size and weight
Locomotion	simple, no deviation from track possible	medium complexity, struggles with crossing tracks	complex, high flexibility	complex, able to inspect hard-to-reach locations
General Considerations	dependent on available tracks	poor 3D obstacle avoidance	stair-walking capability	risk of dust swirling from large drone propellers

They support comprehensive sensor configurations with sufficient system runtime for typical inspection windows available for metro tunnels, while excelling in complex-geometry environments such as station-adjacent tunnels, cross-passages, and elevated areas reachable by stairs. Their main drawbacks are slower inspection speeds compared with rail-bound platforms and higher control complexity. Nevertheless, they benefit in complex-geometry environments such as direct track proximity and inspection routes that require climbing stairs or navigating uneven terrain.

UAVs deliver fast deployment and unique aerial reach for otherwise inaccessible locations such as overhead and ceiling inspections, despite short runtime and payload constraints that are mostly limited to camera setups. They are therefore superior in confined, vertical, or hard-to-reach areas where ground-based access is limited. As such, they pose most valuable for quick vertical scans in confined areas or for temporary assessments and spot checks in areas not reachable by other platforms.

Conclusions and Outlook

This work evaluates mobile platforms for metro tunnel inspections, demonstrating how rail-bound, wheeled and tracked, quadruped, and UAV systems address distinct operational constraints through tailored strengths in system payload, mobility and deployment. The analysis identifies optimal deployment strategies matching platform capabilities to tunnel geometries, access challenges and time windows, advancing automated inspection and monitoring of metro tunnel infrastructure. In summary, the evaluation confirms rail-bound platforms suit long linear rail surveys, aiming to cover large portions of the tunnel surface, while wheeled and tracked systems excel in flat-floor mapping due to their balanced performance and ease of control. Additionally, quadruped robots enable access to complex areas with their high locomotive flexibility and stair-climbing ability, while UAVs offer quick system deployment, targeting short overhead inspections in hard-to-reach areas.

Future research can be conducted into hybrid inspection fleets combining multiple platforms for entire metro tunnel coverage under efficient system usage. Thus, the benefits and drawbacks of single systems can be compensated to allow for comprehensive metro tunnel inspections under varying conditions. Additional emerging research fields include multi-platform sensor fusion, enabling the data of different platforms and sensors to merge into single

evaluation models, which could leverage complementary strengths such as UAV overhead imagery with quadruped ground-level LiDAR for advanced defect mapping.

Acknowledgments

The authors would like to thank the German Federal Ministry of Transport (BMV) for funding this research within the mFUND initiative as part of the RoboTUNN project (funding code 01F2280A), as well as the associated project partners for their valuable collaboration and support throughout the research.

Abstract

Large-scale linear construction projects involve complex interdependencies, extended sites, and numerous execution variants, while existing approaches lack personalized recommendation systems for trenching applications. This paper presents a simulation-based framework conceptually enabling AI-driven optimization methods to support data-informed planning under limited historical data availability. A bottom-up simulation model captures process-specific dynamics and enables synthetic data generation, forming the basis for proposing focused parameter ranges with promising execution variants. Parametric validation across 3,200 simulation runs confirms realistic system behavior. The results indicate that AI-integrated simulation frameworks represent a viable and transferable approach for optimization in data-scarce linear construction environments.

Introduction

The European Union has established comprehensive guidelines for trans-European energy infrastructure to achieve climate neutrality by 2050 while ensuring energy security and market integration across Member States (European Parliament and Council, 2022). Priority electricity transmission corridors have been defined, particularly North–South interconnections in Central and South Eastern Europe, to support renewable energy integration into the internal market. To support this European objective, the Federal Requirements Plan Act has promoted 35 projects totaling approximately 14,000 km since 2013, yet by 2023 only about 4,000 km had been approved or completed (enercity, 2025). This discrepancy reflects persistent challenges in the planning, approval, and execution of large-scale linear infrastructure projects.

The scale and complexity of these projects limit the availability of robust empirical reference data and standardized methods for performance assessment and optimization. Construction processes are highly dependent on site-specific conditions such as geology, logistics, and resource availability, complicating systematic evaluation of alternative construction strategies. Simulation-based methods provide a promising means to address these challenges. By representing construction processes as parameterized models, simulation enables systematic analysis of construction sequences, resource interactions, and logistical dependencies. When combined with optimization methods, such approaches can support informed decision-making and contribute to the timely implementation of projects critical to achieving national and European climate and energy objectives.

Given the complexity of large-scale construction sites operated by numerous crews simultaneously, the integration of Artificial Intelligence (AI) for decision support represents a promising extension of simulation-based planning. Recent surveys indicate growing industry interest in AI applications for optimization tasks. While German construction companies increasingly employ data analysis and predictive modeling, personalized recommendation systems remain largely unimplemented despite planned investments by over one-third of surveyed firms with more than 250 employees (Engels et al., 2025). This indicates substantial development potential and demand for AI-supported optimization tools. Consequently, this work investigates whether AI-integrated simulation can effectively address the variant generation and optimization challenges inherent in large-scale linear construction projects.

State of the Art

In order to contextualize this paper within the existing body of research, relevant literature on simulation-based decision support and AI-integrated optimization methods is reviewed. Particular emphasis is placed on applications in industrial manufacturing and their transferability to construction domains. While construction projects present distinct challenges due to site-specific variability and data scarcity, methodologies proven in manufacturing environments provide valuable foundations for developing simulation-based planning approaches in linear infrastructure construction.

Relevant Related Work

In industrial manufacturing, the discrete event simulation (DES) is a well-established tool for decision support, system analysis, and performance evaluation. Negahban and Smith (2014) identify three primary areas of application:

- Manufacturing system design
- Manufacturing system operations
- Simulation language/package development

These categories can also be applied in the construction industry, as relevant construction literature subsumed under

these categories can be found. With respect to manufacturing system design, simulation-based approaches have been adopted to address construction site layout planning. This aspect is particularly critical for linear construction projects, where site layouts continuously evolve along the project corridor and material transportation distances represent a major cost and performance driver. Petroutsatou et al. (2021) proposed an algorithm for optimizing construction site layouts by dynamically relocating site facilities and storage areas, demonstrating reductions in transportation effort and overall operating costs. Similarly, RazaviAlavi and AbouRizk (2021) developed a simulation-based decision-support tool to evaluate alternative site layouts based on on-site transportation, construction logistics, and safety considerations.

Analogous to manufacturing system operations, simulation has also been applied to the analysis and optimization of construction processes themselves. Typical approaches vary equipment capacities, crew sizes, or task sequences and analyze resulting impacts on process performance through repeated simulation runs. König et al. (2007) applied this principle to drywall construction by simulating processes to analyze the impact of resource constraints and scheduling on efficiency.

More recent work extends this paradigm by systematically exploring large sets of feasible construction schedules instead of isolated scenarios. Morkos (2014) presents an approach that automatically generates schedules while enforcing precedence, resource, and spatial constraints. Rather than identifying a single optimal solution, the method enables the exploration of the feasible solution space and the analysis of trade-offs across multiple alternatives.

Within the category of simulation language and package development, a trend toward hybrid simulation frameworks can be observed, combining generic models, comprehensive system architectures, and integrated optimization methods. A similar development can be observed in construction-related research. Early work by Weber (2007) focused on the evaluation of logistics and site layout strategies for material flow in building construction. The developed tool, *SIMUBAU*, utilized CAD models to derive geometric and semantic model components and integrated these with databases and external programs for logistics and planning data. Within the research project *ForBAU*, a further framework was developed for earthworks in road construction. This approach employed CAD-based tools to generate voxel-based earthwork models and linked them with external databases providing simulation parameters, thereby improving both visualization and result analysis capabilities (Günthner et al., 2013).

More recent research extends these frameworks toward data-driven and continuously updated simulation environments. Jungmann (2025) proposes a digital twin-based approach in which real-time data collected on construction sites are processed to extract activity durations, calibrate stochastic simulation models, and generate key performance indicators (KPIs) for decision support. The approach further integrates machine learning-based activity recognition, stochastic productivity modeling, and DES to enable continuous model calibration and more accurate forecasting of construction processes.

While such approaches significantly enhance the realism and timeliness of simulation models, they primarily focus on improving model accuracy and enabling data-driven evaluation of predefined decision alternatives. Although multi-criteria optimization techniques are applied to identify promising solutions, these approaches do not inherently generate or adapt decision alternatives through learning-based mechanisms.

Addressing this gap as well as the third area of application, research has increasingly focused on integrating optimization methods with simulation frameworks. In construction, hybrid approaches combining simulation with genetic algorithms have been applied particularly for site layout planning, jointly addressing cost efficiency, safety, and productivity objectives (Said and El-Rayes, 2013; Papadaki and Chassiakos, 2016). However, these approaches remain largely static and do not adapt to changing site conditions. Evidence from related fields suggests that a more dynamic integration is feasible. In industrial manufacturing, Choi et al. (2024) and Klar et al. (2024) demonstrate that combining simulation with learning-based optimization enables continuous performance improvement. Kandemir et al. (2025) on the other hand, integrates DES with AI methods to optimize job scheduling under uncertainty. These results highlight the broader potential of adaptive, data-driven optimization, which remains largely untapped in construction site management.

Despite considerable progress in simulation-based decision support, the reviewed literature reveals limitations that need further investigation. Particularly in the construction domain, the integration of optimization methods with simulation frameworks remains underexplored compared to manufacturing applications. Moreover, recent advances in AI-driven optimization show promising results, yet their practical application in construction site management, particularly for personalized recommendation systems, remains limited.

Limitations and Open Directions in the Current State of the Art

A review of existing approaches indicates limitations concerning practical applicability, integration challenges, and data availability.

While numerous simulation frameworks have been developed for construction site management, their practical deployment remains limited. The *ForBAU* project's demonstrator exemplifies this challenge: despite representing a powerful approach, Wimmer et al. (2010) explicitly stated that expert knowledge is necessary to utilize the tool effectively. Most existing systems are developed primarily in research environments rather than for practical use by site managers, who would benefit most from them in daily

operations. Future research should therefore emphasize user-friendly interfaces and intuitive workflows that enable construction professionals without extensive expertise to apply these tools effectively for decision-making.

Despite significant advances in AI-driven optimization and their successful application in industrial manufacturing, the integration of these methods with construction site simulation frameworks appears to be an emerging area of research. While several studies have explored AI-based optimization using parametric BIM models (Hoeng et al., 2025; Wiederer et al., 2025), these primarily focus on optimizing building geometry, site layout, or isolated aspects such as resource allocation and scheduling. To the best of the authors' knowledge, comprehensive frameworks systematically integrating AI-based optimization with construction execution processes within a simulation environment are scarce in the current literature. Such frameworks would need to simultaneously consider dynamic scheduling, task allocation, resource constraints, logistical dependencies, and overall project costs while accounting for the strong interdependencies between site layout, transportation processes, and resource utilization.

A key barrier to AI adoption in construction is the lack of structured historical data for training machine learning models. Unlike manufacturing, where data is consistently captured in standardized environments, construction projects involve heterogeneous processes, site-specific conditions, and high contextual variability. This challenge is especially pronounced in linear infrastructure projects due to long durations, spatially distributed work fronts, and continuously changing site conditions.

Simulation-based approaches provide a way to potentially overcome this challenge through synthetic data generation. By simulating diverse construction scenarios with varying parameters and constraints, researchers can create comprehensive training datasets that capture complex interdependencies (Chan et al., 2022). Future research should investigate methodologies for generating high-quality synthetic construction data based on simulations that accurately reflect real-world variability, including validation frameworks and transfer learning approaches that effectively leverage synthetic data alongside limited real-world observations.

Within the specific domain of resource allocation optimization for linear construction sites using simulation-based approaches, several research opportunities emerge: (i) development of user-friendly simulation tools tailored to construction practitioners; (ii) integration of AI-based optimization methods with comprehensive construction process simulation; (iii) systematic approaches to synthetic data generation and validation; (iv) holistic frameworks capturing interdependencies across planning, scheduling, and execution; and (v) real-time adaptive optimization capabilities for dynamic construction environments.

In addressing the aforementioned opportunities, this work presents a framework that enables the concept of AI-based optimization in conjunction with construction site simulation by generating synthetic training data.

Methodology: Integrated Simulation Framework for Process Optimization

The methodology presented in the following is built upon a modular, process-oriented simulation framework specifically designed for open-cut trench construction in energy transmission projects. It provides the foundation for an AI-supported decision-making approach aimed at improving the allocation and coordination of earthwork resources. Figure 1 illustrates the overall structure and workflow of the proposed framework. The process begins with the collection and preprocessing of project-specific input data provided by the user.

The framework follows a hierarchical modeling strategy in which individual subprocesses are initially represented in a structured and modular form. These representations are used to derive simplified performance estimates that capture the essential behavior of each process step. The resulting information is then aggregated to form an abstracted representation of the overall construction workflow, linking the subprocesses in a sequential manner. Based on this abstraction, an AI-based component defines a constrained parameter space that focuses on promising execution strategies. Instead of evaluating isolated process steps, the simulation is applied at the level of the integrated system, allowing interactions between subprocesses to be considered. Within this reduced solution space, parametric simulations are conducted to assess different resource allocation strategies and their system-wide effects, from which KPIs are derived.

Finally, an iterative validation and refinement loop involving the user ensures the resulting scenarios are realistic, comparable, and optimized.

Input Information and Preprocessing

The proposed framework requires a set of project-specific input information provided by the user, which is accessible through an intuitive graphical user interface. The project's geometric and spatial characteristics must be specified, including segment cross-sections, lengths, radii, and gradients, as well as the intermediate storage location. Project-specific construction alternatives may also be considered, such as whether to improve existing soil in place or replace it entirely. Additional restrictions, such as the availability of machinery and labor, can likewise be incorporated. The user is further able to specify overarching project goals, for example maximum allowable cost or target construction duration. On the basis of these inputs, the simulation model as well as the appropriate parameter ranges for an optimized execution are subsequently generated.

Generation of the Parameter Space

Large scale linear construction projects are characterized by a high number of interdependent decisions. Even individual construction steps provide numerous configuration

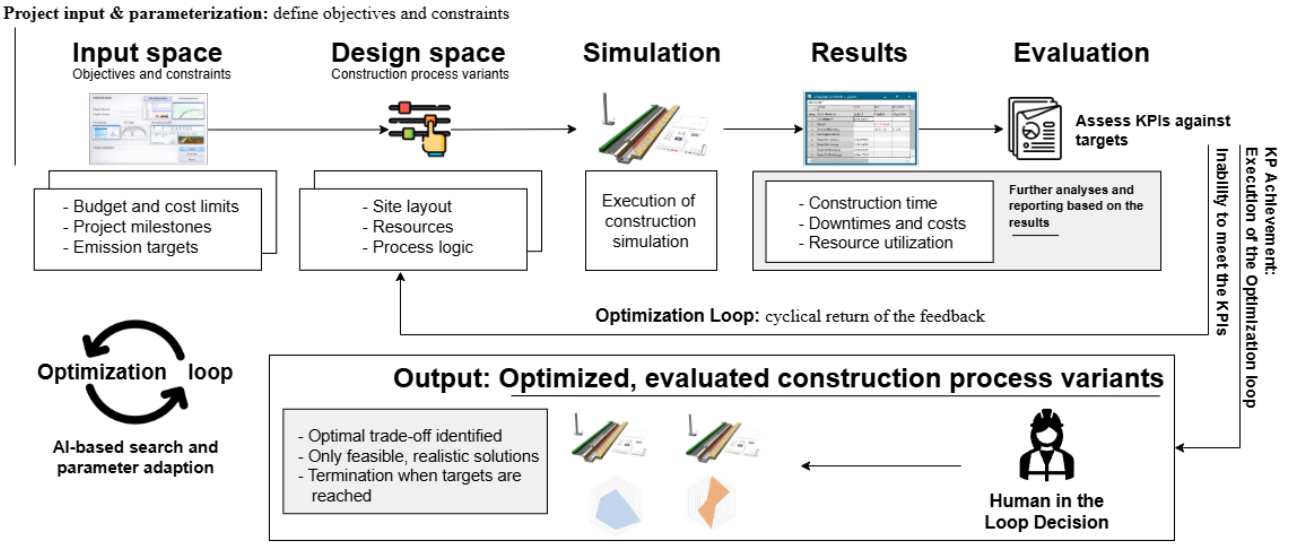

Figure 1: Holistic framework for AI-based parameter space generation and parametric simulation

options depending on equipment selection and logistical setup. When multiple crews operate simultaneously, identifying efficient task allocation and coordination strategies becomes increasingly difficult, making a comprehensive exploration of all possible configurations impractical.

To address this challenge, the proposed approach combines data-driven prediction with hierarchical aggregation to reduce the solution space. At its core, the method follows a bottom-up principle, first evaluating individual process steps independently. For each subprocess, a regression-based model is trained to predict the duration and cost based on the given input parameters. Processes that do not require logistical coordination can be evaluated through direct performance predictions. In contrast, logistics-dependent processes are further refined by optimizing relevant parameters using a differential evolution algorithm. This enables the identification of efficient equipment configurations and transport strategies.

This step provides KPIs for each individual process, including estimated duration and cost factors. Where applicable, it also provides optimized logistical configurations, all without requiring simulation at the subprocess level.

A higher-level learning component then aggregates these subprocess KPIs to derive system-level predictions, including overall project duration, cost development, task allocation, machinery utilization, and process synchronization. Although subprocess characteristics such as duration may initially serve as input variables, the model is also intended to capture inverse relationships. This indicates that adjustments at the subprocess level, such as longer execution times, may improve overall system performance. One example of this would be stabilizing process synchronization. In such cases, sub-processes can be re-evaluated in light of these updated objectives. This results in an abstract yet consistent representation of the overall construction workflow and defines a constrained parameter space that is likely to contain promising execution variants. Based on this reduced solution space, the simulation model is applied exclusively at the level of the integrated system to evaluate and compare these variants in detail.

In order to enable this predictive capability, the AI system must learn the complex interdependencies inherent to large-scale linear construction processes, which require sufficient high-quality training data. However, as previously mentioned, adequate volumes of such data are not available in a structured form. Therefore, synthetic training data is generated by systematically varying project and execution parameters in order to capture the underlying process interactions. This enables the AI models to generalize from limited empirical data and supports robust and optimized decision making.

Parametric Simulation for Energy Transmission Lines

To evaluate the parameter space proposed by the AI system and derive KPIs for execution variants, a parametric simulation model for energy transmission line construction is employed. The simulation follows a bottom-up approach and comprises three main components: a parametric representation of the working corridor, detailed models of individual process steps, and a holistic model of the entire open-cut construction process.

The working corridor model forms the foundation of the simulation and includes the trench cross-section, construction road, and soil storage areas. Key parameters such as trench depth, width, slope angles, layer heights, and number of pipes can be adjusted, ensuring broad applicability across different scenarios and projects.

This geometric representation provides the basis for calculating earthwork volumes and material quantities. Rather than deriving soil conditions from continuously updated 3D models, as demonstrated by Ji et al. (2009), they are provided directly by the user as input parameters. To ensure practical applicability, subsoil categories have been developed in collaboration with domain experts based

on the traditional German classification system for earthworks (DIN 18300, 2019). The categories are designed for rapid and reliable field assessment by construction personnel. Based on user-specified soil class percentages, stochastic models simulate the spatial distribution and behavior of different soil types within the trench.

Based on the project-specific working corridor, individual processes of open-cut construction are modeled separately. Five main processes have been identified: (1) topsoil removal, (2) trench excavation, (3) pipe zone construction, (4) trench backfilling, and (5) topsoil replacement. Each process model centers on an excavator that traverses the trench and moves material to its designated location. During (2) trench excavation and (3) pipe zone construction, additional transport vehicles are required to remove or deliver materials, as exemplarily shown for process (3) in Figure 2. Various logistic parameters can be adjusted within these individual process simulations. To ensure realistic representation, machinery does not operate at full capacity continuously. Instead, randomly distributed disruptions are integrated to reflect actual field conditions. Each process is simulated independently, allowing process duration and downtime to be determined individually based on the input parameters of each section.

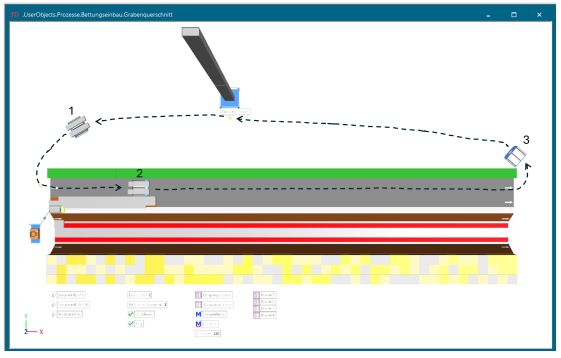

Figure 2: Parametric simulation of the pipe zone construction

These detailed process simulations provide the foundation for a holistic model that analyzes the interdependencies between different execution steps. This higher-level model is intentionally kept at a greater level of abstraction, using effort values and average durations derived from the process simulations as input parameters rather than replicating their logistical detail. At this level, tasks can be distributed across varying numbers of excavators and scheduled with different timing patterns, enabling identification of the fastest and least disruption-prone construction sequence. This combination of detailed process-level and abstract system-level simulation has proven effective for optimizing earthwork processes, as Ji et al. (2011) have similarly shown.

Simulation-Based Performance Metric Derivation

Each simulation yields performance metrics related to time, economics, and sustainability. Following the framework's bottom-up structure, these metrics are first determined for each process step based on the deployed equipment and project parameters. Then, they are aggregated at the system level. The calculations are based on a comprehensive database of effort values, cost factors, and machinery emission data provided by industry partners. This allows for the systematic comparison and evaluation of different execution variants.

Human Validation, Refinement and Final Output

The derived KPIs are evaluated based on predefined project goals by combining quantitative criteria with qualitative user judgment about the plausibility of each variant. If the resulting variants do not satisfy the specified criteria, the relevant parameters are adjusted iteratively, and a new optimization loop is initiated. This process continues until either a sufficient number of viable execution variants have been generated or the predefined termination criteria have been met. The result is a set of feasible, optimized construction scenarios that align with project-specific requirements.

Verification of the Simulation

The simulation model was developed using *Tecnomatix Plant Simulation*, with most methods implemented in the platform's native programming language, *SimTalk*. Technical verification was conducted iteratively throughout the development process using integrated debugging tools. This iterative verification process ensured that the model implementation accurately reflected the intended conceptual design.

Structured historical performance data for linear construction processes is scarce, and existing documentation is influenced by numerous confounding factors, such as weather conditions, regulatory delays, and crew-specific practices. This makes it difficult to isolate baseline process performance. Consequently, traditional validation approaches relying on historical performance data were not fully applicable. To address these limitations, the simulation model was developed in close collaboration with construction personnel, ensuring alignment with practical experience. Performance factors were verified through spot checks on active sites, and experienced professionals confirmed that the simulation produces plausible results, including realistic daily work targets.

Table 1: Simulation parameters and their value ranges

Logistic Parameter	Lower Limit	Upper Limit	Steps
Vehicle Count	1	10	1
Cycle Time [min]	15	120	15
Distance to Storage [km]	5	40	5

To further validate the realism of the simulation, systematic experiments were conducted by varying key input parameters. At this stage, only the temporal output is fully implemented, therefore, the experiments focus exclusively on construction time as the performance metric. The input parameters including vehicle count, cycle time, and distance to the intermediate storage facility were varied across the ranges shown in Table 1. These were defined by experienced site personnel to represent realistic conditions. Each parameter combination was simulated with five different random seed values to account for stochastic variability in simulation outcomes. This yielded a total of 3,200 simulation runs, covering a comprehensive and structured parameter space. The resulting simulation outputs were subjected to comparative sensitivity analyses to verify whether parameter variations produced effects on construction time and resource utilization consistent with empirical expectations and practical construction experience.

Due to their independence from logistic parameters, the processes of (1) topsoil removal, (4) trench backfilling, and (5) topsoil replacement displayed only limited temporal variability, driven primarily by randomly distributed disruptions. The resulting standard deviation was approximately 20 minutes for trench backfilling and about 9 minutes for topsoil removal and replacement. In contrast, (2) trench excavation and (3) pipe zone construction exhibited substantially higher temporal variability due to multiple logistical influences, with a standard deviation of approximately 3.5 hours for pipe zone construction and around 21 hours for trench excavation. Consequently, trench excavation emerges as the process with the greatest influence on overall schedule variability.

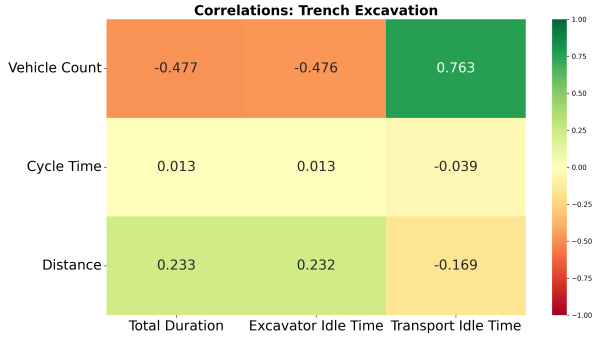

Figure 3: Heatmap of the trench excavation parameter space

To reveal the influence of different logistic parameters more clearly, a correlation analysis was conducted. The results are presented in Figure 3 and Figure 4.

The vehicle count shows a strong negative correlation with total duration (r = -0.477 for trench excavation, r = -0.464 for pipe zone) and excavator idle time (r = -0.476 and r = -0.464), and a strong positive correlation with transport idle time (r = 0.763 and r = 0.751). The parameter cycle time demonstrates minimal correlation with all output metrics in trench excavation (|r| < 0.04). In the pipe zone process, correlations are slightly higher (r ~ 0.09 for duration and excavator idle time, r = -0.312 for transport idle time). Distance to storage location shows moderate positive correlations with total duration and excavator idle time (r = 0.23 for trench excavation and r = 0.454 for pipe zone), and negative correlations with transport idle time (r = -0.169 and r = -0.179).

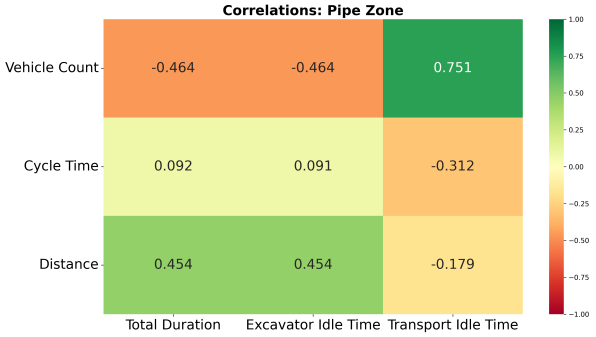

Figure 4: Heatmap of the pipe zone parameter space

Discussion and Result Analysis

The parametric validation confirmed that the modeled relationships between parameters and system behavior are plausible and aligned with observed construction practices. Increasing vehicle count effectively reduces construction time and excavator idle time by ensuring continuous excavator operation. However, beyond a certain threshold, adding more vehicles results in smaller reductions in duration while substantially increasing idle time for the vehicles. This reflects a fundamental trade-off between excavator utilization and transport fleet efficiency.

The analysis of cycle time and distance to storage reveals distinct operational characteristics between trench excavation and pipe zone construction. In trench excavation, transport vehicles travel alongside the excavator during continuous loading, making the excavator's digging speed the limiting factor regardless of vehicle timing or transport distance. In contrast, pipe zone construction involves rapid unloading where vehicles simply discharge embedment material next to the trench and depart, operating independently of the excavator. Poorly synchronized cycle times in relation to storage distance can cause multiple vehicles to arrive simultaneously, creating bottlenecks and increased idle time. Nevertheless, the influence of the cycle time remains largely negligible except for its impact on transport vehicle idle time. This is particularly favorable from a practical standpoint, as cycle time is difficult to control in real construction scenarios due to synchronized work schedules and operational constraints.

The reliance on expert judgment and parametric validation does highlight limitations imposed by the absence of comprehensive historical performance data. Ongoing efforts focus on establishing structured documentation protocols for future construction phases, enabling more rigorous quantitative validation and supporting continuous model refinement.

Table 2: Comparison with existing tools

Criterion	proposed tool	ForBAU	Jungmann
Framework type	AI-integrated simulation-based optimization	3D simulation and decision support	Digital twin-based decision support
Domain focus	Linear construction sites (trenching)	Earthwork (road construction)	Repetitive construction site processes
Primary objective	automated generation, evaluation and optimization of resource- and schedule-related execution variants	integrated data management, simulation-based process optimization, dynamic 4D construction site information modeling	real-time data-driven simulation, KPI generation and decision support through continuous model calibration
Key innovation	Automated AI-supported variant generation and optimization	Resistance coefficient-based process modeling, holistic machine fleet interaction simulation	ML-based activity recognition and real-time model calibration
Spatial resolution	process - / segment-based	voxel-based	process-based

Conclusions and Scientific Contribution

This work introduces a framework combining parametric simulation with AI-enhanced parameter optimization to support decision-making in large-scale linear trenching projects. By enabling the automated generation and evaluation of execution variants, the framework addresses a key limitation of existing decision support tools, which typically rely on manually defined scenarios.

Compared to existing approaches such as ForBAU and the digital twin-based framework of Jungmann (2025), the proposed framework is specifically tailored to linear construction sites. While ForBAU applies voxel-based terrain models for road earthworks and Jungmann focuses on continuous model calibration from real-time sensor data, the proposed approach adopts a process- and segment-based spatial resolution aligned with the characteristics of trenching projects. This reduces data requirements and model complexity while maintaining practical relevance for construction planning.

A central contribution of the framework is the generation of synthetic training data through systematic simulation of diverse construction scenarios, addressing the lack of structured historical data. This potentially enables the AI component to learn process interdependencies and identify promising parameter ranges. Parametric analyzes show that the simplified simulation captures essential dynamics, while a user-oriented design based on familiar soil classifications ensures practical applicability without requiring detailed geotechnical input.

Despite promising results, several limitations remain. Cost and sustainability indicators are only partially integrated, and validation relies primarily on expert assessment and sensitivity analysis due to limited empirical data availability. Rather than adopting a sensor-based approach as proposed by Jungmann (2025), this work relies solely on simulated synthetic data, for which initial tests deliver encouraging results. Terrain and soil modeling remains simplified, restricting the representation of spatial heterogeneity, and the framework currently covers only the open-cut construction phase.

Two directions for future work deserve particular attention. First, the AI models must be trained across a sufficiently diverse set of cross-sections and project configurations to ensure robust generalization. Should the underlying construction processes or project characteristics change significantly, retraining may be required. Ongoing efforts therefore focus on making the data generation and training workflow as reproducible as possible to minimize the overhead of future retraining cycles. Second, the current workflow depends on licensed simulation software, which may limit accessibility. Once AI models are sufficiently trained, bypassing the simulation for routine optimization tasks represents a promising step toward broader practical applicability.

Overall, the results indicate that AI-integrated methods based on simulation frameworks offer a viable path toward data-driven optimization in linear construction, even under significant data scarcity. The proposed methodology for simulation-based synthetic data generation is transferable to other construction or production processes with similarly definable constraints, providing a solid foundation for more informed planning of large-scale linear infrastructure projects.

Abstract

Industrialized Construction (IC) is an approach to address ongoing challenges in the construction industry. Barriers affecting IC adoption include manufacturing inefficiencies caused by inaccurate production monitoring on shop floors. This paper presents the integrated use of machine learning and sensor data collected from IMUs and load cells installed on manufacturing platforms to monitor work progress. The research method includes the development of data collection, processing, and data analysis methods in a controlled laboratory, followed by validation on a real-world shop floor. Results present an accurate model robust against stochastic noise, achieving 77% F1-score monitoring through temporal windows and weighted deltas.

Introduction

The construction industry faces several challenges related to low productivity on-site (Kauppinen et al., 2024). The traditional approaches to monitoring production in on-site construction rely on error-prone and time-consuming manual operations, which lead to ineffective resource allocation, quality failures, high volumes of waste, rework, delays, and budget overruns (Hasan and Sacks, 2023).

Considering this context, Industrialized Construction (IC) has been pointed out as a viable alternative to address these gaps, adapting traditional construction methods through the integration of manufacturing-oriented design and optimization tools (Qi et al., 2021). IC involves performing activities and producing construction components in a controlled shop floor environment before assembling on-site (Melgar et al., 2025).

Despite its potential, current obstacles affecting IC performance include the difficulty in monitoring the production and identifying bottlenecks on the shop floor in a timely manner, thus requiring a change from manual methods (e.g., stopwatches, visual observation, or analysis of pre-recorded video footage) to automated methods (Rashid and Louis, 2020). Indeed, manual methods lack accuracy in representing actual working conditions (Chen et al., 2024). Besides, Barkokebas et al. (2023) argue that current strategies and decision-making processes in IC shop floors are largely based on workers' personal experience rather than on empirical and real-time data, which hinders process improvement. Moreover, Qi et al. (2021) argue that the adoption of emerging digital technologies can address current obstacles and thereby unlock the full potential of IC.

A step toward increasing productivity in IC is the implementation of automated work monitoring and tracking techniques, enabling managers to determine what and when work is being performed on the shop floor. Despite recent advances, existing techniques exhibit significant room for improvement. Authors such as Panahi et al. (2022), Chen et al. (2024), and Martinez et al. (2021) have applied computer vision (CV) in IC for progress monitoring and productivity measurement. However, this technique presents limitations due to general occlusions, illumination issues, and limited field of view (Alsakka et al., 2023). Although static cameras can provide an adequate viewing angle during the fabrication of linear or 2D components (i.e., wall and floor panels), it is challenging to follow the manufacturing of volumetric modules, considering that the components closer to the camera can occlude those positioned behind them (Rashid and Louis, 2020; Alsakka et al., 2023), resulting in a "black box" effect.

Other authors, such as Demiralp et al. (2012), Altaf et al. (2018), and Li et al. (2017), have proposed the use of tracking solutions based on radio frequency identification (RFID) and real-time location systems (RTLS). However, despite the capability of tracking the location of different elements, these techniques have limitations in interpreting the context and identifying the activities performed. In light of this, Rashid and Louis (2020) proposed a method based on machine learning (ML) that analyzes the sound of the shop floor environment to automatically identify activities, such as hammering and nailing. The main limitation is the difficulty in isolating and classifying only the sounds of interest in real-world conditions. Rashid and Louis (2020) also highlighted the advantages of inertial measurement unit (IMU) techniques, which can identify activities through parameters, such as motion and vibration. However, they argue that in previous applications, each sensor is attached individually to each element of interest, causing practical difficulties due to the multiple components and elevated costs.

Rashid and Louis (2021) proposed a framework for modular construction to automatically measure active and idle times at workstations using IMU vibration data and a

deep learning network. However, the framework limitations include issues related to data resolution, sampling frequencies, ground-truth labeling, and the lack of clearly defined methodological steps.

Considering the gaps and limitations highlighted in the literature, this paper proposes a novel system combining ML models with data acquired from sensors to monitor manufacturing activities of volumetric modules on IC shop floors. Real time data is collected from IMUs and load cells installed beneath the monitored IC workstations to identify whether work is being actively performed at workstations and therefore determine work progress. This paper's contribution is bi-fold: (1) it proposes ML-based methods to monitor manufacturing IC activities in real-time, and (2) it demonstrates their application.

Research methods

This paper presents the development of a system in a laboratory setting, followed by its final testing and validation on a shop floor in a bathroom pod in the Los Lagos Region, Chile. By applying both experiments, this research aims to validate the following hypothesis: "*The integrated use of sensors, such as IMUs and load cells, coupled with ML models, enables activity classification and work progress monitoring for manufacturing operations of volumetric modules on IC shop floors.*" Additionally, this research aims for the proposed system to achieve a technology readiness level (TRL) 5, in which the system is validated in a relevant environment (Kimmel et al., 2020).

As illustrated in Figure 1, the research steps and its workflow are divided into Laboratory and Shop Floor phases. Following its initial development in the Laboratory, the proposed method is then adapted and validated on the Shop Floor. The Laboratory phase follows a controlled experiment design as per the steps below:

- **Data acquisition:** Design of the experimental setup and data acquisition.
- **Data processing and algorithm development:** Conducting an exploratory data analysis (EDA) for ML model development and refinement.
- **Internal validation:** Checkpoint to assess performance within Laboratory experiments.

If the internal validation criteria are not met, the workflow loops back to the algorithm development stage for further refinement. Conversely, successful validation allows for further development of the proposed system. Following a quasi-experiment research design, the Shop Floor phase consists of the following stages:

- **System's adaptation:** Adapting the proposed system to shop floor conditions, including data acquisition procedures and the ML model.
- **External Validation:** Assessment of the proposed system in real-world operating conditions.

To verify the presented hypothesis, the proposed system relies on the monitored workstation being transformed into an instrumented platform (i.e., physical platform with sensors placed under it) so the manufacturing operations can be monitored as per Figure 2.

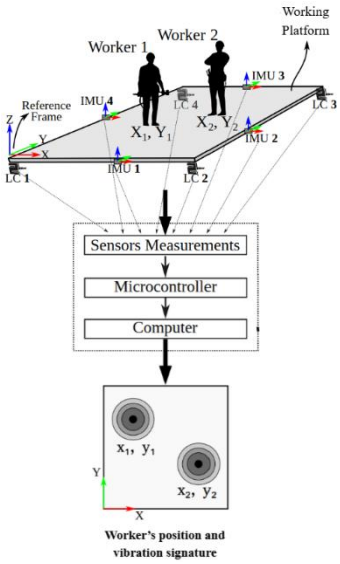

Figure 2: Graphical representation of the experimental setup.

The specific technical details of each environment are elaborated upon in the following subsections.

Laboratory experiment

A timber frame platform was built in the laboratory to replicate conditions in the shop floor and install sensors underneath it. The platform built measured $2{,}40 \times 2{,}40\ m$ and was designed to maintain structural stability during experiments.

The primary objective of this phase was to generate a high-fidelity dataset that captures the distinct kinematic and weight patterns of typical production activities as demonstrated in Figure 3a. This controlled environment allowed for the development and refinement of the machine learning pipeline, which was executed using the RapidMiner platform to evaluate model performance before industrial deployment.

Data acquisition

The data acquisition (DAQ) network comprised the following components:

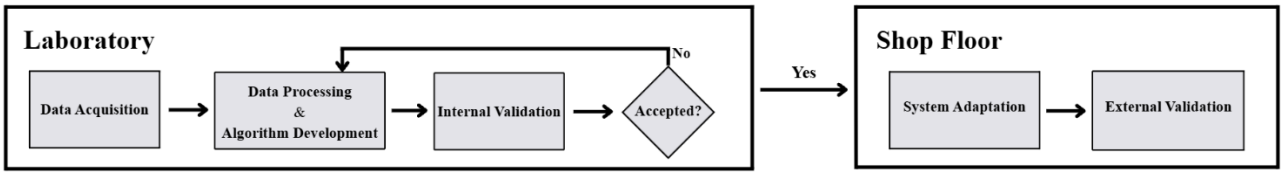

Figure 1: Research Methodology for the 2-Phase System Development and Testing.

- **Load cells:** Four industrial TRB load cells (15-ton capacity, 2.85 mV/V rated output) were installed under the platform at each corner. The weight signal (in kg) was acquired using HX711 ADC modules.
- **IMUs:** Four MPU-6050 3-axis IMUs were equidistantly mounted at the center of each lateral side of the base. The data was recorded in m/s^2.
- **Data management:** The hardware architecture was governed by an ESP32 microcontroller for each load cell and IMU pair, which facilitated data sampling at a constant Hz. Raw data transmission was executed via MQTT protocol and consolidated into temporal blocks for subsequent analysis, with each block being transmitted every second.

To replicate conditions typical of IC shop floors, several activities, such as "None", "Walking", "Hammering", and "Drilling" were executed in the laboratory. These were all recorded by the proposed system and video cameras. Furthermore, composite activities (i.e., two activities performed at the same time) were also performed and recorded. Recording manufacturing operations from both the proposed system and video cameras allows researchers to train and validate ML models to classify whether work is being performed or not under the platform, as demonstrated in Figure 3b.

Figure 3A Figure 3B

Figure 3: Images of the laboratory's experimental setup.

Data from the proposed system was acquired via the load cells and IMUs, transmitted by the ESP32 controllers and subsequently concatenated using Python scripts. The final data structure was exported as a comma-separated values (CSV) file containing nine primary features: a timestamp, four independent weight readings (w_1, w_2, w_3, w_4), and four IMU sensor streams (s_1, s_2, s_3, s_4). Tri-axial IMU measurements within each stream were combined using a semicolon (;) as the delimiter. Recordings from the video cameras were also stored locally and later processed to train the ML classification models.

Data processing and Algorithm Development

The raw CSV dataset was processed through a Python pipeline to enhance feature compatibility for the ML model. In that spirit, each rotational velocity column was decomposed into its tri-axial components (x, y, z), generating a total of 12 inertial features. This decomposition provides a higher dimensional representation of the kinematic signatures inherent to each activity.

To handle temporal resolution, a temporal alignment procedure was implemented. Given the 10 Hz sampling rate, 10 discrete rows were generated for every second of data, ensuring each IMU measurement was mapped to its specific time slot.

Final synchronization of the temporally aligned data relied on a multi-modal verification process. The documented activities timestamps were validated against the video recordings to guarantee ground-truth accuracy. This processed dataset was then organized into a matrix comprising seventeen variables, including: four weight readings, twelve inertial axes, and the target label, as detailed in Table 1.

Table 1: Initial Dataset: first three observations

Obs.	Weights (kg)	Acc. (m/s^2)	Target Variable
1	$w_{1,(1:4)}$	$a_{1,(1:4)}$	1_{st} value
2	$w_{2,(1:4)}$	$a_{2,(1:4)}$	2_{nd} value
3	$w_{3,(1:4)}$	$a_{3,(1:4)}$	3_{rd} value

An exploratory data analysis was then conducted on it to evaluate data quality and distribution before modelling. The primary objectives of this phase included:

- Analyzing the class distribution and balance across the dataset.
- Implementation of noise reduction and data cleansing protocols.

Internal Validation

The target variable was defined as a multiclass Activity feature. In instances of concurrent activities, a hierarchical labeling priority was implemented ("Walking" > "Hammering" > "Drilling") to maintain a mutually exclusive, single-label-per-timestamp structure.

To evaluate the contribution of each sensor modality, the models were subjected to an ablation study involving three distinct configurations: (1) load cells and IMU data, (2) load cells data exclusively, and (3) IMU data exclusively. The macro-averaged F1-score performance metric for each configuration was recorded and compared to assess the relative predictive power of each sensor type.

This metric was selected to mitigate the risk of an "Accuracy Paradox", "Walking" and "None" activities were more present in the dataset than others. This allowed that the high frequency of "None" and "Walking" couldn't mask poor model performance on shorter, more high-intensity tasks like "Hammering" or "Drilling".

The development of this phase successfully places the system in a TRL 4. By validating the technical integration of the hardware components and the initial classification models, this phase demonstrates that the basic technological elements can function together as a cohesive system in a laboratory environment, establishing a solid proof-of-concept before subjecting the system to the complexities of a real-world IC shop floor environment.

Shop floor experiment

System's adaptation

The experiment was conducted at an active bathroom module production facility using a $2{,}40 \times 1{,}80\ m$ mobile industrial platform. The platform featured a wooden deck integrated into a steel frame and, while equipped with casters for transit between production stages, it was secured in a stationary position for the duration of all data acquisition sessions, which were also recorded for ground-truth synchronization.

The experimental protocol mirrored the laboratory phase, with the only difference being that the sampling frequency was increased from 10 Hz to 90 Hz.

However, the dataset itself was processed through three extra stages to transition from the raw data-driven approach used in the Internal Validation to a robust supervised learning architecture. This progression was designed to better interpret the more complex physical signatures within the high-noise environment of industrial production facilities.

External validation

To isolate the sensing system from environmental noise, the platform was elevated by the load cells themselves, effectively bypassing the casters. This "floating", configuration visible in Figure 4**,** ensured that all vertical loads and mechanical vibrations were transmitted exclusively through the load cells and the DAQ system, replicating the controlled environment of the IMA laboratory.

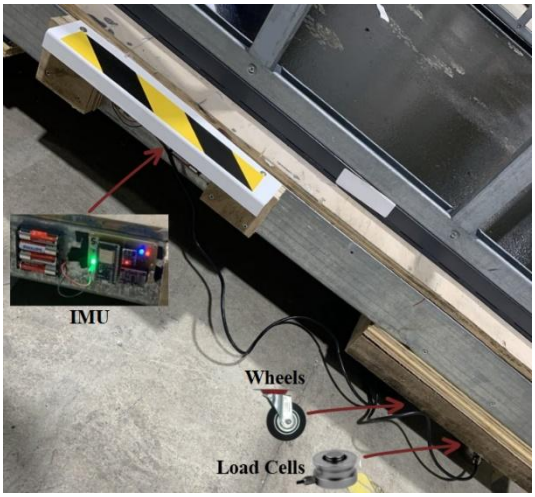

Figure 4: Shop Floor's experimental setup.

Operational activities (categorized as Working) were defined based on the assembly protocols established in the manufacturer's technical manuals, which were comprised of sub-activities like the "Walking", "Hammering", and "Drilling" activities tested in the laboratory. This label was assigned to any Value-Added (VA) construction task performed on the module structure, regardless of whether the operator was positioned on the platform or the factory floor.

Conversely, non-contributing activities were classified as Not Working. This category encompasses Non-Value-Added (NVA) tasks such as platform cleaning, the handling of secondary materials (e.g., relocating toolboxes), or worker random movement across the platform.

The development of this phase represents an advancement beyond laboratory experiments by exposing the system to the operational constraints inherent to an active IC shop floor. It marks the beginning of the transition towards TRL 5, allowing for verification of whether the ML model architecture and the system in general maintain their predictive capacity and robustness in a relevant environment.

Results and discussion

The performance of the proposed classification architecture was evaluated through a two-stage validation process. First, the laboratory dataset was used to develop and benchmark the algorithm performance and select a lead architecture. Second, the model was subjected to an external validation phase using the 90 Hz industrial shop floor dataset, where the impact of feature engineering and temporal windows was analyzed. This dual approach ensures that the final model is not only statistically accurate but also robust against stochastic noise, inherent to IC environments.

Laboratory experiment results

The Temporal Alignment procedure for the IMA dataset resulted in 28,120 observations, representing approximately 52 minutes of operational data. The class distribution was intentionally balanced across seven recorded activities to ensure the model could distinguish between similar kinematic signatures.

Five machine learning algorithms were implemented in RapidMiner to establish a performance baseline. As demonstrated in Table 3, the Random Forest (RF) ensemble emerged as the superior model with 86.77% accuracy. This performance is attributed to the RF's inherent bagging approach, which offered significant robustness against the inherent sensor noise and local outliers' data. Finally, the RF's built-in feature importance provided a layer of interpretability, allowing for an internal validation of which specific inertial signals were most indicative of the activities monitored.

Table 3: RapidMiner ML models average accuracy of the ablation study.

Model	Parameters	Accuracy
Random Forest	100 trees, max depth 15	86,77%
Gradient Boosted Tree	50 trees, max depth 7	83,81%
k-NN	k = 5	78,92%
SVM	RBF kernel	75,61%
Naive Bayes	10 Kernels	73,3%

Table 2: Random Forest's ablation study results

Activity	IMU and Load Cells		Load Cells Only		IMUs Only	
	Precision	Recall	Precision	Recall	Precision	Recall
Walking	89.56%	96.47%	97.95%	96.29%	71.34%	94.01%
Hammering	94.53%	72.49%	78.03%	98.24%	97.31%	50.70%
Drilling	91.06%	87.45%	91.38%	98.54%	91.32%	61.77%
None	91.89%	91.07%	97.23%	93.03%	86.47%	79.87%
F1-Score	88.91%		93.50%		76.13%	

Ablation Study

To further understand the contribution of each data source (IMU and load cells), an ablation study was conducted using the RF algorithm. The results, visible in Table 2, reveal a significant disparity between sensor modalities.

The Load Cells Only configuration achieved the highest overall performance with an F1-score of 93.50%. Specifically, the Recall for "Hammering" (98.24%) and "Drilling" (98.54%) indicate that the kinetic energy and vibration patterns transferred to the platform are highly distinct. This suggests that force-based sensing captures the "mechanical signature" of industrial tasks more reliably than human kinematics.

Conversely, the IMUs Only model yielded the lowest F1-score (76.13%), struggling particularly with "Hammering" (Recall 50.70%). This suggests that while inertial sensors capture the worker's gross motor movements, the high-frequency vibrations of manual tools are likely aliased or obscured at lower sampling rates. This implies that capturing such work signatures via kinematics would require a higher sampling frequency (Hz) to move beyond the noise floor.

Shop Floor Experiment Results

To capture higher-frequency mechanical transients, the sampling frequency in this experiment increased from 10 Hz to 90 Hz. Thus, the temporal alignment process done on the Shop Floor dataset yielded an initial 491,760 observations (61 minutes) with 58.6% of it labeled as Working and 42.4% as Not Working.

Model adaptation and Feature Engineering

Stage I (Baseline Configuration and Bias Identification): An initial Random Forest model was established using a standard 80/20 random split and optimized via *RandomizedSearchCV*. While this model achieved an F1-score of 0.97, a subsequent feature importance analysis revealed a structural flaw: static weight features accounted for 86% of the decision-making weight. This indicated that the model was functioning as a "digital scale" (identifying that a worker or object was on the platform), rather than recognizing the assembly processes.

Stage II (Feature Sensitivity, Class Balancing, and Temporal Integrity): To transition from presence detection to activity recognition, the raw weight columns were temporarily excluded. The goal was to evaluate the predictive power of the IMU data independently. This analysis yielded two critical architectural adjustments:

- A Signal Magnitude Vector (SMV) was calculated to ensure the model's robustness against sensor mounting variations. By transforming tri-axial data into a rotation-invariant magnitude, the model is prevented from overfitting to specific hardware orientations, mitigating the risk of memorizing axial-specific patterns.
- The standard random split was found to induce data leakage. The high-frequency (90 Hz) sampling rate caused adjacent samples to be highly similar, meaning that random shuffling placed temporally correlated fragments into both training and testing sets, resulting in inflated performance metrics. To rectify this, the protocol transitioned to a 73/27 Chronological Split (*TimeSeriesSplit*).

The 73/27 split was used to maintain a consistent class distribution across the Training and Test subsets, since the Working state was mostly concentrated in the initial portion of the dataset, while Non-working intervals were more prevalent in the latter half. This partitioning strategy ensured a more balanced representation in both the training and validation sets.

Stage III (Feature Aggregation and Temporal Context): Rolling Windows (RW) of one and three seconds were implemented, providing the model with a "short-term memory". This allowed the algorithm to filter transient noise and prioritize the sustained vibration signatures from Working activities. Finally, the raw weight data was replaced with a single 3-second Weight Delta (ΔW) feature. By calculating the change in weight across the platform, this feature emphasizes loading transitions and dynamic events, rather than static mass. The final dataset variables are summarized in Table 4.

Table 4: Final dataset: First three observations

Obs.	1s RW	3s RW	ΔWeight	Target
1	$w_{1,(1:4)}$	$a_{1,(1:4)}$	Δw_1	1_{st} value
2	$w_{2,(1:4)}$	$a_{2,(1:4)}$	Δw_2	2_{nd} value
3	$w_{3,(1:4)}$	$a_{3,(1:4)}$	Δw_3	3_{rd} value

This final model's *RandomizedSearchCV* reached an optimized configuration of 100 estimators, a maximum depth of 8, and a minimum sample split of 5.

Table 5: Final model Classification Report

	Precision	Recall	F1-Score
Not Working	0.71	0.73	0.72
Working	0.81	0.79	0.80
Weighted Average	0.77	0.77	**0.77**

As detailed in Table 5, this configuration achieved a Weighted F1-score of 0.77. Notably, the model demonstrates a sensitivity (Recall) of 0.79 for the Working class. Given the stochastic nature of the shop floor, this result suggests that the feature engineering process successfully filtered out ambient mechanical noise, typical of industrial settings.

Analyzing feature importance analysis, illustrated in Figure 5 identifies the 3-second vibration windows as the primary predictor for the final classifier. This confirms that temporal signal stability offers superior predictive power compared to instantaneous, high-frequency movement. Notably, weight variables were successfully attenuated to secondary support features. This shift transitioned the system from a presence detector to an activity monitor, capable of identifying true production cycles.

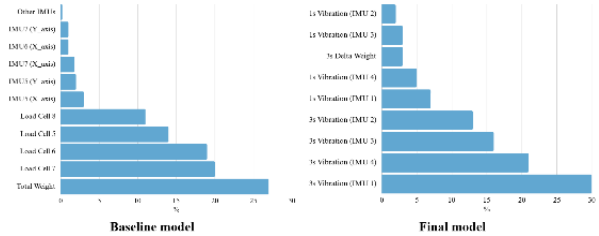

Figure 5: Baseline and Final models' most important features

The final normalized confusion matrix (Figure 6) identifies two primary error types: 12.37% (11,039) false negatives, where active work was classified as Not Working, and 11.15% (9,650) false positives, where NVA tasks (mostly walking on the platform) were misidentified as Working.

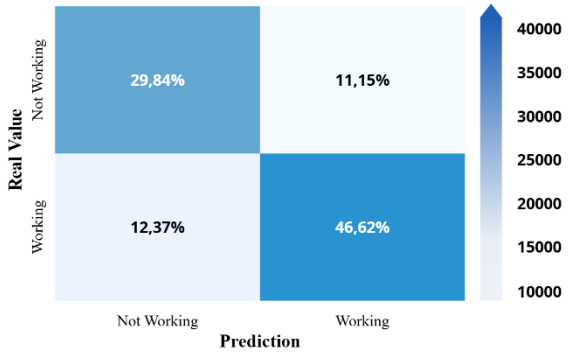

Figure 6: Final model's normalized confusion matrix

Key Differences Between Laboratory and Shop Floor Results

This section discusses the key differences between the laboratory and shop floor experiments, including variations in environmental conditions, data acquisition, and operational constraints that influenced the model performance.

In the laboratory, the Load Cells Only configuration achieved the superior F1-score, by capturing the isolated mechanical signatures of "Hammering" and "Drilling". However, it was later revealed that the model had become a "digital scale", meaning that, while load cells are excellent at detecting high-energy impulses in controlled settings, they can overshadow kinematic data in complex environments if not properly regulated. By replacing raw weight with the ΔW, the bias was mitigated, effectively forcing the model to prioritize dynamic events over static mass.

Another notable difference was observed in the classification of "Walking". In the laboratory, "Walking" was identified with high precision (only 3,05% false positives), but in the shop floor model there were 11,15% False Positives. This error is attributed to the environmental constraints of the active production site, since, unlike the spacious and relatively unobstructed laboratory platform, the shop floor required workers to perform short, irregular steps and weight shifts while reaching for tools or standing still during inspections.

On the other hand, the implementation of 1-second and 3-second temporal windows (Stage III) represented a shift towards a more human-centric monitoring logic. Just as a supervisor does not judge productivity based on a single millisecond of movement, the rolling windows allowed the model to account for "micro-rests" (i.e., the brief pauses when a worker catches their breath or adjusts a tool), which the Laboratory model could not do with its millisecond-scaled observations.

Ultimately, the integrated use of SMV and ΔW successfully enabled activity classification validating the hypothesis. However, the integration revealed a "weighted partnership" where the ΔW contributed only 3% to the model's predictive power. While this confirms the system is a functional activity monitor, it suggests that the weight sensors' primary value may lie in secondary applications.

Conclusions

The proposed approach integrated weight sensor data with IMU data, introduced a Random Forest model, and detailed the complete data flow and feature engineering process from raw data to the final model. By capturing weight shifts and mechanical vibrations, the system can infer internal activities, identifying internal assembly tasks without the need for line-of-sight or invasive wearable sensors on the workers. Since the system captures data directly through the volumetric module platform, it is not affected by the 'black-box' effect caused by occlusions, which commonly occurs in camera-based data capture. In addition, general technical advances include a more accurate distinction between working and idle states, higher data resolution, and customized ground-truth labeling based on exact activity execution times rather than fixed windows.

Building on these technical foundations, this research validates the system's effectiveness within the specific context of volumetric module production (IC) shop floors. During experimental testing in a bathroom pod facility, the methodology achieved a 77% Weighted F1-score, effectively elevating the technology to TRL 5. This successful deployment under real-world operating conditions confirms the system's feasibility as a monitoring solution for relevant complex industrial environments.

While initial laboratory results suggested that load cells alone could achieve a 93.50% F1-score, the shop floor validation revealed that such models are prone to structural bias toward simple presence detection. The implementation of feature engineering, specifically the use of Temporal Rolling Windows, allowed transitioning from a "digital scale" to a true activity recognition system.

Nevertheless, this paper also identifies different limitations such as the need for experiments to make ML models more robust, improvements in hardware to guarantee the integrity of sensors in the instrumented platform, and the difficulty in distinguishing between the high-frequency mechanical transients of manual tools and the erratic movements or weight shifts of workers in confined spaces. Furthermore, the current reliance on fixed platform locations suggests that future iterations should explore configurations that adapt to more complex, mobile, or dynamic shop floor layouts.

Several avenues for future research also arise from the experimental findings. First, the impact of extending the temporal windows to better capture the context needed to distinguish between active work and brief pauses should be studied. In addition to that, the ΔW feature's low contribution to the classification model suggests its utility may lie elsewhere. In that sense, future studies could leverage weight sensor data to detect the placement of heavy components on the platforms, providing a more robust mechanism for tracking production progress by creating an automated validation process of assembly sequences. In practice, a rule-based system could be developed to connect, in real time, the measured weight of heavy components to their corresponding positions on the platform according to the module plans. Thus, the final position of each component, as confirmed by sensor data, could indicate in real time the progress of module completion.

Finally, the study concludes that while human movement on confined IC platforms is inherently random and interwoven with production, it can be mathematically distinguished through the integrated use of IMUs and load cells, coupled with ML models. Ultimately, this system empowers IC managers with empirical data to identify bottlenecks and optimize shop floor workflows, unlocking the productivity potential inherent in industrialized methods.

Acknowledgments

The authors would like to express their gratitude to CIPYCS (Centro Interdisciplinario para la Productividad y Construcción Sustentable) and Axis Desarrollos Constructivos for providing laboratory and shop floor space, respectively. Moreover, the authors would also like to express their gratitude to Enrique Loeser, Claudio Inostroza, and Ignacio Peña for their continuous support. Also, the authors acknowledge the support of ANID Fondecyt Iniciación 11241027.

DESIGNING HUMAN–ROBOT COLLABORATION AS A JOINT COGNITIVE SYSTEM: A SOCIOTECHNICAL FRAMEWORK FOR MEANINGFUL WORK

Angelina Kozhevnikova and Daniel M. Hall
Delft University of Technology, Delft, Netherlands

Abstract

Despite decades of research, construction robotics adoption remains limited due to unstructured environments, task complexity, and misaligned automation models adapted from manufacturing. Integrating insights from Joint Cognitive Systems (JCS), Meaningful Work research and Human-Robot Collaboration in construction studies, we propose an alternative, sociotechnical framework for robotic system design structured around three interdependent dimensions: (1) Task and Agent Design, which supports dynamic structuring, agent configuration, and time-based collaboration; (2) Coordination and Communication, which facilitates communication, coordination, shared mental models and situational awareness; (3) Worker Well-Being, which embeds physical and psychological safety, relatedness, competence and autonomy considerations.

Introduction

Research in construction robotics dates back to the 1980s and earlier, yet adoption still remains limited. This may suggest a mismatch between dominant automation models, largely derived from manufacturing, and key characteristics of construction work, including unstructured environments, high variability in tasks and materials, and reliance on situational judgment and embodied skill (Ardiny, Witwicki & Mondada 2015; Cai et al. 2019; Liu & Jebelli 2022; Saidi, Bock & Georgoulas 2016). As a result, models developed for standardised and predictable settings are difficult to transfer to construction contexts, that are difficult to formalise and therefore automate with the dominant model (Liu et al. 2024; Ardiny, Witwicki & Mondada 2015; Cai et al. 2019; Saidi, Bock & Georgoulas 2016).At the same time, labour shortages, safety risks, and an ageing workforce increase pressure for automation while complicating its implementation (Ranasinghe et al. 2023; Schwatka, Butler & Rosecrance 2012; Yamani Bin Yahya et al. n.d.).

Human–Robot Collaboration (HRC) has recently gained attention as a way to enable robotic systems to operate in dynamic conditions through maintaining human involvement (Ma, Mao & Liu 2022; Onososen, Musonda & Ramabodu 2022; Zhang et al. 2023). However, many current frameworks still reproduce manufacturing-based models, such as levels of automation (LoA) taxonomies and function allocation schemes derived from Fitts' List (Yang et al. 2024; Liang et al. 2021). This approach shows limited adequacy for the adoption in the industry (Du et al. 2025; Hancock & Scallen 1996) and has been linked to broader negative implications on societal well-being (Constantinides & Quercia 2025; Hancock 2014; Kaur, Gautam & Verma 2025). In other words, our current technology-centric mindset restricts the full potential of HRC and risks repeating earlier failures of construction robotics.

In this paper, we offer a way to reframe human-robot collaboration in the context of construction. We suggest the need to define HRC more broadly as "*humans working jointly with robots or together in a specific construction task, and each role must be capable of making contributions to the overall system.*" (Zhang et al. 2023) and shift towards a sociotechnical framework that acknowledges the complexity of the process and supports safe, meaningful work integrated into the realities of the industry.

To do this, our paper proceeds as follows. First, the background section introduces two key theoretical foundations: the Impact of Automation on Work Design and the Joint Cognitive System as a design unit. Second, the methods section introduces Critical Interpretive Synthesis, a methodology used. The results section presents this framework, structured around three interrelated HRC system design dimensions: task and agent design, coordination and communication, and worker well-being, and identifies key considerations for each based on Joint Cognitive Systems theory, meaningful work literature, and current HRC practices. Finally, the discussion and conclusion outline the framework, and discuss how it can be further developed and translated into practical tools for research and application.

Background

Impact of automation on work design

Understanding how automation reshapes work is key to designing human–robot collaboration. Each new technology redefines work processes yet many approaches still rest on the *Substitution Myth*, the belief that machines can take over human tasks without broader consequences for the system (Hollnagel & Woods 2005).

This view treats automation as a neutral replacement rather than a transformation of work. It appears mainly in two forms: the *Left-Over Principle* and the *Compensatory Principle*.

Left-Over Principle. The focus is on automating as much as possible, leaving humans with tasks that are either too trivial or too complex, rare, and irregular, often leading to cognitive overload (Woods & Hollnagel 2006). Since it's mainly developed without users in mind, it can also compromise safety, as workers develop workarounds that introduce new physical or organisational risks (Goštautaitė et al. 2024).

Compensatory Principle. This principle is based on juxtaposition; it is often referred to as *"Men-Are-Better-At, Machines-Are-Better-At"* or *MABA–MABA*, also known as *Fitts' List* (Fitts 1951; Woods & Hollnagel 2006). It compares human and machine capabilities across fixed dimensions a-priori, assuming minimal variability and treating both as predictable systems. This approach also has safety implications. It often reduces human autonomy (Sadeghian & Hassenzahl 2022) and blurs responsibility, creating accountability gaps (Sadeghian, Uhde & Hassenzahl 2024). It also typically confines workers to supervisory or advisory roles with limited control, leading to alienation and difficulties in justifying the value of their work (Staaby, Hansen & Grønli 2021).

The question of meaningful human work design has become increasingly important with the growing automation of work. Organisational research on meaningfulness has developed two main perspectives: realisation and justification (Lepisto & Pratt 2017; Goštautaitė et al. 2024).

Realisation Perspective. The main focus is on fulfilling psychological needs such as autonomy, competence, and belonging. Meaningful work arises when individuals can express themselves through job design or job crafting, as described in Self-Determination Theory (Ryan & Deci 2000; Peters & Calvo 2023; Goštautaitė et al. 2024).

Justification Perspective. Here, meaningfulness is emerging through sense-making and reaffirming the significance of human contribution. It suggests that meaningfulness arises when people confront uncertainty about the value of their work, prompting sense-making processes shaped by leadership, organizational practices, and how performance is evaluated (Goštautaitė et al. 2024; Lepisto 2022; Beer, Micheli & Besharov 2022; Grant 2012). It draws on Honneth's recognition theory (Honneth 1996), where recognition at work means acknowledging individuals as skilled contributors in cooperative activity, fostering self-confidence, self-respect, and self-esteem (Hirvonen & Breen 2020; Mardosas 2024).

Complementarity Principle. These psychological perspectives resonate with a third view on automation called the *Complementarity Principle*, introduced in the 1990s (Grote et al. 1995; Wafler et al. 2003). This principle examines work as a dynamic system that develops over time and aims to enhance human performance and learning instead of replacing it. Often described as function congruence or function matching (Hollnagel 2018), it emphasises how work routines adapt to situational changes and seeks to maintain system performance across varying conditions (Woods & Hollnagel 2006). This principle becomes very useful for safety-critical industries like construction, which heavily rely on craft-based practice with workers at the center of decision-making.

Joint Cognitive System as a Design Unit

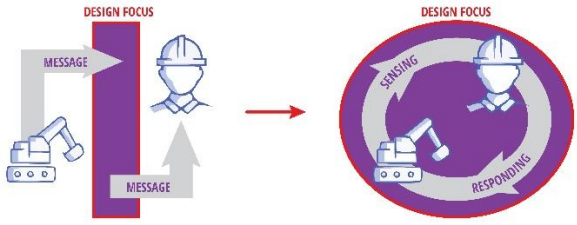

Figure 1: A figure contrasts the classical human–robot interaction view with the co-agency view across system boundary, temporal structure of action, and design focus

Joint Cognitive Systems (JCS) build on the complementarity approach and adopt a sociotechnical perspective, treating the practitioner as an integral part of the system. Developed in safety-critical domains such as aviation, nuclear power, and healthcare, JCS address the limitations of information-processing models by focusing on how systems maintain performance under changing conditions (Woods & Hollnagel 2006; Hollnagel & Woods 2005).

Classical Human-Robot Interaction (HRI) View. In the classical human–robot interaction view, humans and machines are treated as separate components connected through an interface. Interaction is defined as the exchange of inputs and outputs, as illustrated on the left side of Figure 1, where communication occurs through a bounded interface layer. Cognition is modeled as a response to discrete stimuli, and action is understood as a sequence of stepwise reactions. The analytical focus remains structural, describing system components and their interactions rather than how the system performs as a whole.

Limitations of the Classical View. This representation abstracts away key characteristics of real-world work. It treats action as discrete rather than continuous, and behavior as reactive rather than anticipatory. Context is reduced to inputs, rather than directly shaping action, and cognition is effectively placed outside of its situated environment. It also assumes isolated actors, while in practice human activity is embedded in broader systems of coordination. As a result, the design focus remains on interfaces and components rather than system-level performance.

Co-Agency View (JCS). JCS shifts the focus from interaction to co-agency, understood as joint agency within a single system. As shown on the right side of Figure 1, humans and machines are physically separate, but physical separateness does not imply functional

separateness. The unit of analysis becomes the joint system, engaged in continuous cycles of sensing and responding. The focus moves to what the system achieves as a whole, and how it adapts under changing conditions. Behavior is continuous and context-dependent, and agency is distributed across human and machine.

Critical interpretive synthesis (CIS)

This study employs Critical Interpretive Synthesis (CIS), a method first developed in medical research (Dixon-Woods et al. 2006) and later adapted for the built environment and construction automation (Bucher et al. 2024; Pan et al. 2018). CIS combines review and interpretation, using induction and critical reflection to identify conceptual patterns, making it suitable for developing theoretical frameworks that connect diverse perspectives.

After preliminary scoping, we conducted three targeted Scopus searches: (1) human–robot collaboration (HRC) in construction (272 records), (2) Joint Cognitive Systems (JCS) (144 records), and (3) meaningful work (MW) in automation contexts (45 records). After screening, studies without a human-in-the-loop or not related to construction were excluded from the HRC set, overly technical papers from the JCS set, and superficial human factors studies from the MW set. This resulted in 74 HRC, 39 JCS, and 21 MW papers, further reduced through full-text review to 38 HRC, 22 JCS, and 14 MW studies. Two foundational JCS books were also included (Hollnagel & Woods 2005; Woods & Hollnagel 2006).

The synthesis proceeded iteratively in three steps. First, the HRC literature was analysed inductively to identify recurring patterns in how collaboration is studied in construction. The review revealed a fragmented, largely technology-centric field dominated by experimental studies and demonstrators, with limited attention to real-world adoption and an underdeveloped account of the human role. This lack of implementation-oriented research motivated the search for a stronger theoretical foundation.

Second, these limitations led to the selection of Joint Cognitive Systems (JCS) as the primary theoretical foundation, as it provides a systems perspective grounded in safety-critical domains with established real-world use.

Third, meaningful work research was incorporated to extend this foundation with a more direct account of the human dimension, particularly longer-term work design and its impact on workers.

The framework was then defined by adapting JCS to the context of human–robot collaboration in construction, with meaningful work as a complementary perspective. The construction HRC literature was used to ground this adaptation, guiding the selection and alignment of concepts based on current developments, observed gaps, and practical constraints in the field.

Dimensions of human-robot collaboration (HRC) system design

This framework is a conceptual, high-level structure for human–robot collaboration system design in construction, intended for system designers, engineers, and researchers working at the level of system configuration and integration. It structures how work, coordination, and human factors are addressed together when designing joint human–robot work systems at the level of sociotechnical system architecture.

The framework is organised around the core components of human–robot collaboration: humans, robots, and their collaboration. Task and Agent Design focuses on work, addressing task structure and role configuration. Coordination and Communication focuses on the robotic system and its role in enabling joint activity, addressing sensing, interaction, and control. Worker Well-Being focuses on the human, addressing longer-term work conditions and their impact.

The dimensions are tightly interconnected and operate as system-level design lenses. Figure 2 shows their cyclical relationship: they are not ontologically separate components, but purpose-driven perspectives used to guide system design. Coordination and Communication is positioned centrally because the robotic system acts as the mediating and coordinating layer through which joint activity is organised, linking work processes and worker conditions.

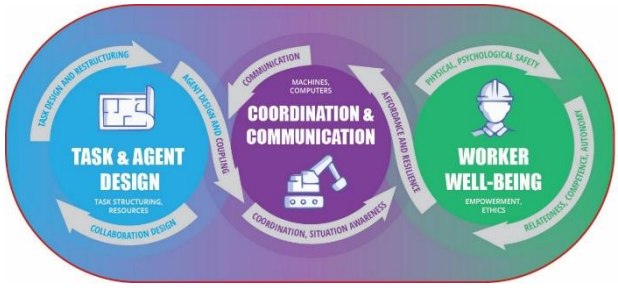

Figure 2: *Three main interrelated human-robot collaboration (HRC) system design dimensions.*

Task and agent design

Task design. To design a system, its boundaries must first be defined by distinguishing between the system and its environment. Since control, both in goals and variability, occurs at multiple levels, several joint cognitive systems can coexist (Hollnagel & Woods 2005). In construction, task design concerns what needs to be built and how it is divided into levels or subtasks based on granularity and scope. For example, scaffolding construction can be broken down into subtasks, steps, activities, and fine-grained task primitives (Pan & Yu n.d.). Integrating these task hierarchies into management workflows and related cognitive systems is essential. It is also important to consider not only direct but also indirect and off-task work (Van Diggelen & Johnson 2019), which often increases with automation, and to allow for dynamic adaptation when conditions change.

Dynamic task restructuring. Adaptation in a successful HRC system goes beyond allocating tasks based on human and robotic skills (Amtsberg et al. 2021). It also involves restructuring tasks and goals. Shifting objectives, refining standards, and enabling workers to shape tasks are central to meaningful work. This approach fosters ownership, responsibility, and helps prevent accountability gaps and alienation (Parmer 2024; Sadeghian, Uhde & Hassenzahl 2024; Staaby, Hansen & Grønli 2021; Mardosas 2024; Bielskis 2024; Smids, Nyholm & Berkers 2020; Celentano 2024). JCS studies highlight the importance of directability, the ability to assess and modify the actions of others in a joint activity as conditions evolve (Klein et al. 2004). In construction, this remains underdeveloped. One study addressed human control through a digital twin that visualises both the work object and the robot's motion plan (Amtsberg et al. 2021). The craftsman in the study can take over a task at any time in case of material inconsistencies, path collisions, or other unforeseen issues. Bidirectional communication and real-time visualisation support informed decision-making for timber handling.

Time-based collaboration design. Human–robot collaboration is inherently time-based, and construction management traditionally depends on distinct phases and scheduling. HRC design should acknowledge this temporality and the continuously shifting relationships between human and robotic actors. Instead of fixed roles, collaboration can be viewed as a sequence of shifting team patterns depending on task, state, and context. Common team patterns between humans and intelligent systems (Van Diggelen & Johnson 2019) include synchronous joint work, synchronous asymmetric work such as monitoring or teleoperation, and mixed modes that combine synchronous pre-planning with asynchronous execution. These patterns involve transitions and handoffs as activities progress and are interdependent with neighbouring ones. In practice, even highly autonomous modes remain embedded within broader human oversight and system interdependencies. The highly autonomous pattern is one among several interconnected patterns, implying a human backup role that requires continuous monitoring and readiness to intervene. In construction, this aspect remains underdeveloped as well. Most HRC studies prototype only one activity type, usually synchronous, focusing on physical interaction or teleoperation.

Agent design. In order to stay purpose-driven and goal-oriented, robotic agents should be seen as functionally integrated extensions of human capabilities rather than separate tools (Hollnagel & Woods 2005). From a JCS perspective, all work is cognitive, but for practical design, it is helpful to view the robotic agent as combining a machine and a computer, which are tightly coupled. This corresponds to the dual nature of construction work, where physical activity involves manipulating tangible materials and cognitive activity involves perception and information processing. In timber prefabrication, human and robotic skills can be grouped into manipulation and mobility, with humans contributing dexterity and robots providing precision and strength (Yang et al. 2024). Cognitive skills include situation awareness, decision-making, motion planning, and adaptation. In masonry, robots can take over repetitive lifting and bricklaying, allowing workers to focus on detailed finishing tasks (Baek et al. 2024). These examples show that agent selection must always be grounded in the specific capabilities required by each construction activity and seen as evolving over time.

Coordination and communication

Communication channels. An important part of human–robot collaborative co-agency is communication. Instead of viewing the interface as a piece of technology, the system can be understood through coordination and the flow of information between agents as the basis for effective collaboration. Human-to-robot communication can rely on gesture, voice, gaze, bio-signal, and vision-based commands or manual controllers, including haptic master devices, AR, and multiple sensors such as EEG (Liu & Jebelli 2022; Zhang et al. 2023). For other communication channels, the technology should be chosen or designed accordingly. For example, in on-site construction scenarios, robot-to-human communication can be embedded in wearables such as wrist-mounted displays or helmet indicators, and robot-to-environment communication can use simple machine-based indicators (Frank et al. 2019). These channels together provide essential infrastructure for coordination, but do not replace coordination design itself.

Multi-modal coordination. Support for effective coordination is one of the generic requirements for designing a joint cognitive HRC system. It involves synchronising agents in changing conditions, creating and updating a shared mental model, balancing goals, and ensuring observability (Woods & Hollnagel 2006). In practice, coordination should provide not only feedback, which is common, but also feedforward and feednow. In the Extended Control Model (ECOM), these correspond to control layers such as tracking, regulating, monitoring, and targeting (Hollnagel & Woods 2005). Integration with Building Information Modelling (BIM), the Internet of Things (IoT), digital twins, and other advanced technologies provides an additional coordination and data-processing layer within the joint cognitive system. (Amtsberg et al. 2021; Zhang et al. 2023).

Effective coupling. In HRC new qualities emerge through human-robot coupling or their interrelations (Hollnagel & Woods 2005). Human-robot coupling is crucial since inadequate cognitive coupling results in poor user acceptance (Woods 1985). Effective coupling and systems that remain viable over time require involving construction workers early in system design, well before implementation (Fraboni, Brendel & Pietrantoni 2023; Staaby, Hansen & Grønli 2021; Celentano 2024). This can be achieved through prototyped VR-based environments that provide low-cost, safe tools integrating simulation, ergonomic analysis, and embodied feedback to refine interaction, coordination, and workflow design

(Onososen & Dzuwa n.d.; Saffert et al. 2024; Onososen et al. 2023). These tools also act as methodological environments for exploring team dynamics with continuous human feedback.

Shared mental models and situation awareness. Effective coupling can be further improved through shared mental models, system transparency, and mutual observability. System transparency enhances explainability and helps prevent accountability gaps (Sadeghian, Uhde & Hassenzahl 2024). Maintaining shared mental models and situational awareness requires integrating multiple communication and processing threads. For dynamic environments such as on-site construction, integrating multi-sensory channels has shown promising results for human–robot collaboration (Zhang et al. 2023). This reflects real construction situations where workers routinely use multiple modes of communication, such as eye contact, gestural confirmation, and verbal exchange, especially before entering potentially hazardous areas near equipment (Frank et al. 2019).

Affordance and resilience. Beyond coordination and miscoordination, affordance and resilience are two main patterns that emerge at the intersection of people, technology, and work (Woods & Hollnagel 2006), and therefore should be explicitly addressed in HRC system design. In a study from Switzerland, construction and mining workers expressed similar views on what future automation should provide. They emphasised adaptation to changing situations and the facilitation of collaboration in all work contexts as fundamental requirements (Frank et al. 2019).

Worker well-being

Physical and psychological safety. Worker well-being is treated not as an external ethical constraint but as a constitutive condition and affordance for joint system performance. This includes strategic choices such as using teleoperation in high-risk scenarios (Zhang et al. 2023) or adjusting robot speed and working parts based on a worker's cognitive load (Liu & Jebelli 2022). Good practices include demonstrating safety and reliability, involving workers in hazard analysis, and applying explainable mechanisms that clarify system goals and reasoning (Fraboni, Brendel & Pietrantoni 2023; Sadeghian, Uhde & Hassenzahl 2024). Avoiding unrealistic expectations about communication or capability is equally important, as unmet expectations can harm team dynamics (Sadeghian & Hassenzahl 2022).

Relatedness and team composition. The question of socio-cognitive misalignment also arises when designing human-robot collaboration in relation to the need for human connection. Robots can successfully cooperate to achieve shared goals, yet they are not equivalent to human colleagues due to differences in social interaction, informal communication, and behaviour in safety-critical situations (Nyholm & Smids 2020). Social relationships remain fundamental for meaningful work and self-development (Sadeghian & Hassenzahl 2022; Staaby, Hansen & Grønli 2021; Smids, Nyholm & Berkers 2020; Nikolova, Cnossen & Nikolaev 2024). Interviews with timber construction workers consistently highlighted three key motivators: the joy of building, task variety, and teamwork (Yang et al. 2024). In the HRC system design, social connection must be explicitly supported.

Competence and expertise creation. A further human-centered goal in HRC system design is continuous learning for both human and robotic agents. This includes the refinement of standards, open-ended rather than predefined automation loops, and the active development of skills and self-growth (Parmer 2024; Sadeghian & Hassenzahl 2022; Staaby, Hansen & Grønli 2021; Smids, Nyholm & Berkers 2020; Celentano 2024; Graham & Jones n.d.). The system itself can learn and adapt through methods such as Robot Learning by Demonstration, Imitation Learning, or programming by demonstration, which enable robots to acquire complex construction skills (Liang et al. 2021). At the same time, embedded training modules and interactive systems can help workers strengthen their expertise and develop new interaction skills (Onososen & Dzuwa n.d.; Saffert et al. 2024; Shayesteh et al. 2023). This fluid, adaptive approach to expertise creation within co-agency can address workforce challenges in the construction industry.

Autonomy and job crafting. Continuous learning and adaptation also strengthen personal autonomy and its recognition in work design. Limiting human roles to supervision or advisory functions can fragment ownership, reinforce alienation (Staaby, Hansen & Grønli 2021), and create authority–responsibility double binds, where workers are accountable but unable to exercise real autonomy (Sadeghian, Uhde & Hassenzahl 2024; Woods & Hollnagel 2006). HRC systems should enable agency, feedback, and flexibility, fostering a sense of ownership and purpose (Parmer 2024; Sadeghian, Uhde & Hassenzahl 2024; Sadeghian & Hassenzahl 2022; Staaby, Hansen & Grønli 2021; Mardosas 2024; Bielskis 2024; Smids, Nyholm & Berkers 2020; Nikolova, Cnossen & Nikolaev 2024; Graham & Jones n.d.). This aligns with ethical design principles that emphasise privacy, autonomy, dignity, reliability, inclusion, and the right to choose one's own way of working (Kaasinen et al. 2022). HRC systems need to maintain open-ended structures that allow roles and tasks to be shaped dynamically. Job crafting should be treated as an active process of person–job fit, with explicit goals to support meaningful work and to avoid the Psychologist's Fallacy, which is the mistake of confusing the designer's or observer's vision of work with the lived experience of those who actually perform it (Staaby, Hansen & Grønli 2021; Woods & Hollnagel 2006).

Discussion

Prior human-robot collaboration (HRC) frameworks in construction (Yang et al. 2024; Liang et al. 2021) build on concepts from manufacturing and industrial automation, particularly Levels of Automation, function allocation, and Human–Robot Interaction (HRI) taxonomies, providing a structured basis for describing roles,

interactions, and system configurations under relatively stable, fixed, a priori conditions. This paper reframes HRC as a sociotechnical and temporal process in which human and robotic capabilities, fragmented organisational structures, shifting teams, and evolving site conditions co-adapt. It considers how responsibility shifts, how expertise is negotiated, and how coordination can be maintained under changing conditions.

It does so by redefining the unit of design from interfaces or separate human and robot agents to a joint cognitive system. This shifts the focus from task allocation to coordination of work, from static levels of autonomy to continuous co-adaptation, from isolated interaction variables to system-level performance, from describing and classifying parts or configurations to designing purpose-driven systems oriented to performance, adoption, and meaningful work.

From this perspective, construction robotics can move from being "robot-ready", organised around machine capabilities, to "system-ready", where task structures, communication flows, and organisational roles support joint performance.

Future research should further develop this framework into more explicit design-oriented structures that can guide system design. The current considerations define key domains and relationships but remain conceptual. They need to be translated into forms that inform task decomposition, role configuration, coordination, and system design. Empirical work in real construction settings is required to examine how these considerations support implementation, adaptation, and adoption in practice.

Conclusions

This paper synthesises insights from Human–Robot Collaboration (HRC) in construction, Joint Cognitive Systems (JCS), and Meaningful Work (MW) research to propose an integrated framework for HRC system design. The framework is structured around three interdependent dimensions: (1) Task and Agent Design, which addresses multilevel task design, dynamic task restructuring, agent design, and time-based collaboration design; (2) Coordination and Communication, which focuses on communication channels, multi-modal coordination, effective coupling, shared mental models, situational awareness, affordance, and resilience; and (3) Worker Well-Being, which emphasises physical and psychological safety, relatedness and team composition, competence and expertise creation, autonomy, and job crafting.

Grounded in Joint Cognitive Systems (JCS) theoretical framework with added perspective from Meaningful work (MW) scholarship, the proposed conceptual framework reframes construction Human-Robot Collaboration (HRC) as a joint cognitive system in which performance, safety, learning, and accountability emerge from the quality of coupling across people, robots, and work over time. The paper shifts the design problem from "who does which task" to "how joint work is structured, coordinated, and sustained without degrading human work." Future research will extend the framework into HRC system design and engineering tools for construction robotics projects.

A THREE-LAYER TAXONOMY AND PREDICTIVE DIGITAL TWIN FOR ROLE-AWARE HUMAN–ROBOT COLLABORATION IN 3D CONCRETE PRINTING

Ibrahim Chahbaz[1], Reina Chmayssany[1], Jiany Samara[1], Noha Ramadan[1], and Hiam Khoury[1]
[1]American University of Beirut, Beirut, Lebanon

Abstract

3D concrete printing (3DCP) has reached early industrial deployment, yet current standards exclude environmental, health, and safety aspects of robotic operation, and existing collaborative-robot frameworks do not address process-coupled hazards or multi-role construction environments. This paper proposes a three-layer Human-Robot-Site taxonomy and a site-wide predictive digital twin with five-second update cadence and short-horizon forecasting. The framework is operationalized through seven role-aware interaction patterns aligned with ISO 10218. A scenario-based evaluation of the Human-layer physiological pipeline using a proxy dataset demonstrates the feasibility of stress classification and calibration. The work provides a reference architecture for human–robot–site integration in 3DCP.

Introduction

3D concrete printing (3DCP) has crossed an inflection point. Recently, Harcourt Technologies completed the first social-housing project compliant with ISO/ASTM 52939:2023, the new qualification standard for additive construction, using a gantry printer to deliver three terraced units in 132 working days; a 35% reduction relative to conventional methods (COBOD International, 2024). The platform is no longer experimental.

What has not crossed that inflection point is the safety framework around it. For instance, Section 1 of ISO/ASTM 52939:2023 is unambiguous: the standard *"does not cover environmental, health* and *safety aspects that apply to printing facility setup, material handling, operating of robotic equipment, and packing of equipment and/or elements for shipping"* (ISO/ASTM, 2023). The standard governing print quality says nothing about how to keep workers safe alongside the machine that produces it. The companion standards available to fill this gap (ISO 10218-1:2025 and ISO 10218-2:2025) integrate the former ISO/TS 15066 collaborative requirement and were written for stationary articulated industrial robots in fixed cells (ISO, 2025). They define collaborative applications around four operational types (e.g. monitored standstill, hand guiding, speed and separation monitoring, and power and force limiting) but presuppose a workspace topology and hazard model that 3DCP does not match.

3DCP differs from cell-based collaborative robotics in four ways that matter for human–robot collaboration (HRC). First, the dominant on-site platform is a gantry: large, slow, with high inertia, traversing an open construction site rather than operating within a guarded cell. Second, the robot is tightly coupled to a continuous material process (e.g. pump pressure, nozzle flow, fresh concrete rheology) whose state cannot be paused without quality consequences such as cold joints, where bond strength reduces substantially with delay (Panda et al., 2018). Third, multiple worker roles operate concurrently in or near the work envelope. In other words, print operators monitor the system from a console, rebar placers physically intervene between layers, material handlers tend the pump and supply, and supervisors and other construction personnel occupy peripheral zones. These roles bear different physical and cognitive risks. Fourth, the work product is itself a hazard: a partially built and cured wall whose strength evolves over hours and where workers must approach for inspection, finishing, or steel placement.

The empirical work that does exist confirms the relevance of these factors but does not resolve them. Sawicki et al. (2026) presented the first quantitative comparison of human–robot collaborative shotcrete printing against manual cast concrete in equivalent reinforced beams, observing roughly threefold higher task-level productivity and reduced physical strain (carried weight at 44%, covered distance at 37%, perceived exertion at 63% of manual reference values) . However, it also flagged the high mental demand of the operator of the robotic system as a key finding, with heart rate and blood lactate unchanged between processes. In this case, strain shifted from the body to the mind and the framework that would catch that shift does not yet exist for 3DCP.

Generic collaborative robot (i.e. cobot) frameworks have made progress on adjacent problems. For instance, PRO-MIND (Lagomarsino et al., 2024) adapts robot trajectories using heart-rate variability and frantic-movement estimates of operator stress. The largest closed-loop perceived-safety study to date, with 48 subjects on a Kinova Gen3 cobot, found that heart-rate-based speed modulation reduced productivity but did not improve perceived safety (Tusseyeva et al., 2022). In addition, continuous physiological stress models such as cStress demonstrate that lab-quality recall (88.6% on lab data) drops substantially in the field (median 72%, an 18-percentage-point gap) (Hovsepian et al., 2015). These

findings transfer in principle, but the platforms, the worker roles, and the process do not.

This paper addresses these limitations by proposing a reference architecture that explicitly accounts for platform characteristics, worker roles, and process coupling in 3DCP. The design space of 3DCP HRC is organized into a three-layer taxonomy (Human, Robot, and Site) and instantiate that taxonomy as a site-wide predictive digital twin. This, in turn, acts as a continuously updated, role-aware, forward-simulating model of the print site whose outputs drive the robot's interaction with each worker present.

Related work

Standards landscape

Three regulatory frameworks bear directly on 3DCP HRC. ISO/ASTM 52939:2023 sets quality assurance requirements for additive construction but as noted, excludes EHS aspects of robotic operation from its scope (ISO/ASTM, 2023). ISO 10218-1:2025 and ISO 10218-2:2025 specify safety requirements for industrial robots and integrators respectively, with collaborative-application content (formerly ISO/TS 15066) integrated into the series. The 2025 revisions also clarify functional safety requirements and add cybersecurity provisions (ISO, 2025). The latest European Union (EU) regulation 2023/1230 on machinery, set to apply starting January 2027, introduces specific requirements for AI-based safety functions and treats software performing a safety function as a safety component subject to conformity assessment (European Parliament and Council, 2023). Together, these instruments define the regulatory envelope into which any 3DCP HRC architecture must fit, but none specifies how or which observable signals should drive that fit.

Beyond regulatory frameworks, a substantial body of research has explored the use of wearable and physiological sensing for estimating human affective and cognitive states in collaborative environments.

Psychophysiological monitoring in human–robot collaboration

The WESAD dataset (Schmidt et al., 2018) enabled standardized evaluation of multimodal stress detection from chest- and wrist-worn devices. The original benchmark reported up to 80% accuracy on a three-class problem (baseline, stress, amusement) and up to 93% on the binary stress versus non-stress task. Field studies routinely report accuracy losses relative to lab conditions. For instance, cStress, trained on a rigorous laboratory protocol with 21 participants and validated in a week-long field study with 20 participants, reported median field accuracy of 72% against self-reports compared with 90% in the laboratory (Hovsepian et al., 2015). These ceilings shape what any psychological-state-aware safety system can realistically claim.

In collaborative robotics, two threads matter for the present work. Trajectory-adaptive frameworks such as PRO-MIND (Lagomarsino et al., 2024) close a loop between operator state and robot motion. In this case, Heart Rate Variability (HRV) and frantic-movement features estimate stress and B-spline trajectories are re-optimised to balance smoothness against execution time. The empirical perceived-safety literature provides cautions. For instance, the 48-subject study by Tusseyeva et al. (2022) found that real-time speed reduction based on operator heart rate did not improve perceived safety but did reduce productivity, and that perceived safety improved with experimental habituation regardless of algorithm. The lesson is that physiological closed-loop control is not automatically safer in the user's perception and predictability matters as much as responsiveness.

Although psychophysiological monitoring enables estimation of human state in human–robot collaboration, its interpretation becomes more complex in construction environments where cognitive workload, multi-role interaction, and process constraints dominate human factors.

Human factors in construction robotics

Human factors research in construction robotics remains limited, with the field largely dominated by mechanical, materials, and process-oriented studies (Onososen and Musonda, 2023). In 3D concrete printing, Sawicki et al. (2026) show that collaborative shotcrete printing increases operator mental demand despite reduced physical strain, highlighting cognitive load as a key safety factor even when traditional physiological signals remain unchanged. Complementary simulation-based studies have explored spatial and cognitive aspects of human–robot interaction in construction, including game-based environments for analyzing interaction dynamics (Mansour et al., 2025).

Gaps and contributions

Existing cell-based collaborative robot frameworks do not transfer directly to 3D concrete printing. They assume a single operator role, a fixed and guarded workspace, localized robot hazards, and interruptible processes. On the other hand, 3D concrete printing involves multiple concurrent roles, an evolving open workspace, gantry-scale hazard envelopes, and continuous material deposition where interruptions can compromise structural integrity. Existing regulatory frameworks or data-driven HRC approaches in human–robot collaboration do not resolve these structural mismatches. Despite advances in regulatory frameworks, human state sensing, and HRC methods, there remains no unified representation that integrates human, robot, and site-level dynamics for real-time decision-making in construction environments. Physiological monitoring provides noisy estimates of cognitive and affective states that degrade in field conditions, while existing HRC approaches remain largely reactive and do not incorporate broader contextual or multi-actor site information. In parallel, construction robotics research highlights increasing cognitive workload and complex role interactions that are not captured by conventional sensing or control frameworks.

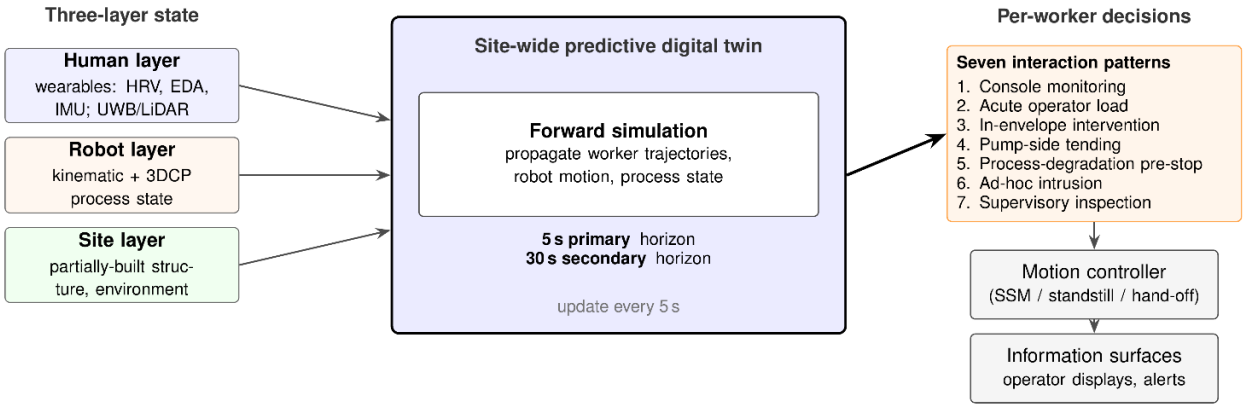

Figure 1: Proposed framework

These limitations reveal a gap between human state estimation, robot control strategies, and the operational realities of 3D concrete printing.

As such, this paper makes three contributions. First, it introduces a three-layer Human–Robot–Site taxonomy defining the required observables and state variables. Second, it develops a predictive digital-twin architecture that instantiates this taxonomy as a site-wide, continuously updated model with short-horizon forward simulation. This explicitly addresses gaps in existing safety provisions not covered by ISO/ASTM 52939 and extends beyond the assumptions of ISO 10218 collaborative robot standards. Third, it proposes a set of seven role-aware interaction patterns that map system states into actionable, standards-aligned robot behaviors for safe and auditable collaboration in 3D concrete printing. Figure 1 illustrates the proposed framework and highlights its three core components, which correspond to the contributions outlined above.

Component 1: The three-layer taxonomy

The proposed taxonomy organizes HRC-relevant observables and state variables into three layers reflecting what must be twinned to support safe collaboration. The three layers correspond to the three independently instrumented domains of the 3DCP print site and include the human counterparts, the robotic system, and the site they share, each with distinct sensing modalities, update cadences, and prediction horizons (Figure 2).

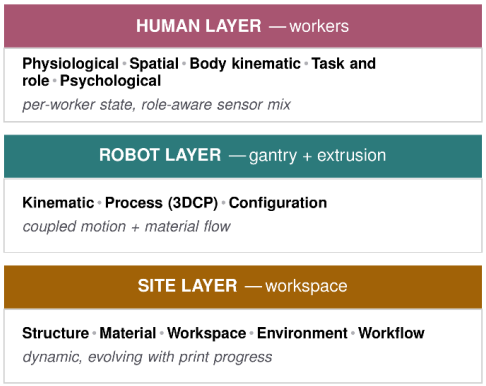

Figure 2: Proposed three-layer taxonomy

Human layer

The Human layer represents each worker present in the work envelope as an instance with five categories of state.

More specifically, the *physiological state* captures cardiovascular and electrodermal indicators relevant to acute stress and cognitive load: heart rate, heart-rate variability (RMSSD, SDNN, low-/high-frequency ratios), electrodermal activity, respiratory rate, and skin temperature. Where consented and operationally feasible, electroencephalography contributes a complementary cognitive-load and fatigue channel. In this case, industrial-grade in-helmet EEG products have demonstrated practicality at scale (e.g., over 5,000 deployed users in mining and heavy-vehicle operation), making it a credible addition to the sensor suite for operator stations rather than for all roles.

The spatial state captures three-dimensional position, velocity vector, body orientation, and a short-horizon predicted trajectory of the worker's torso and effective-arm-reach envelope. This is what enables proximity-based safety to function.

The body kinematic state, drawn from a small set of inertial measurement units (IMUs), captures three-axis acceleration, angular velocity, posture classification (standing, bent, kneeling, prone), activity classification, sudden-event detection (falls, slips, startles), and cumulative physical exertion. This layer differentiates a stationary supervisor from a rebar worker working between layers. Without it, role inference is incomplete.

On the other hand, *the task and role context* is a discrete attribute attached to each worker namely: role (operator, rebar worker, material handler, passer-by, and supervisor), current task, and experience level. More specifically, role determines which of the other state categories matter most for a given worker. For instance, a passer-by needs accurate spatial state but no physiological monitoring whereas an operator needs cognitive-load monitoring but their physical exertion is low. It is worth noting as well that the five-role list reflects the differentiation observed across current 3DCP deployments (Sawicki et al., 2026) and the framework accepts additional roles via the same role-context tag without structural change.

The inferred psychological state is a derived layer producing scalar or categorical estimates of stress, cognitive load, fatigue, and acute fear, computed from the physiological and kinematic channels above. The inference quality is constrained by the performance limits observed in field deployments, as reported in the previous section.

Robot layer

The Robot layer represents the printer as a coupled kinematic-process entity and includes several states

The kinematic and dynamic state includes: (1) position, velocity, and acceleration along the principal axes, (2) predicted trajectory along the planned toolpath, (3) current mass distribution (which on a gantry varies during extrusion as material moves through the system), (4) stopping distance under emergency braking, (5) vibration profile, and (6) instantaneous power and reaction forces. These are needed to compute speed and separation monitoring (SSM) envelopes that respect the platform's actual dynamics rather than an idealized cobot.

The process state is what makes 3DCP distinct. It includes the pump's commanded versus measured flow rate, pump-to-nozzle hose delay and rheological transit time, rheological state at the nozzle (yield stress, viscosity, thixotropic build-up), current toolpath segment, bead, and layer index, and the running gap between commanded velocity and feed rate. A robot whose kinematic state is nominal but whose process state is degrading is approaching a quality failure that may force an unplanned stop, and the safety system needs to know that.

Configuration captures setup-time invariants: bead height (H) and width (W), mix identification, and configured speed limits. These define the operating envelope within which kinematic and process state are interpreted.

Site layer

The Site layer represents the shared workspace as a dynamic structure rather than a static enclosure and includes several components.

The partially-built structure, unique to additive construction, is the most consequential novelty. It includes per-bead geometry, time since deposition (distributed across the structure as different elements were laid at different times), distributed curing state, and the nozzle's current position within the structure. A wall section deposited eight minutes ago is structurally weaker than one deposited eighty minutes ago and a worker leaning on the former is in a different hazard regime than one leaning on the latter. *On the other hand, the material delivery* tracks the pump-to-nozzle hose path and length, batch-plant state, mix supply, and material temperature. These determine when the process state at the nozzle will diverge from commanded values.

The workspace geometry tracks gantry-frame boundaries, hazard zones, sensor coverage maps (where can the proximity layer see, and where are blind spots), and the positioning of all workers and equipment within the envelope.

The *environmental state* includes ambient temperature, humidity, wind, and lighting, all of which influence both worker physiological baselines and concrete curing rates.

The *workflow and scheduling* captures the print-phase index, the schedule against which it is running, and the assignment of personnel to tasks over time. This is what enables the safety system to anticipate, rather than merely react to, role-aware interactions.

In summary, the three human, robot, and site layers are domains of content and are orthogonal to the functional decomposition of the safety controller (typically a fast proximity-tracking pipeline operating in tens of milliseconds and a slower physiological-state pipeline operating in seconds), which is well-established in the literature (Lagomarsino et al., 2024). The novelty here is not the functional split but the content schema that both pipelines need to reference.

Component 2: Predictive digital twin instantiation

A taxonomy describes but an architecture must compute. In this case, the three-layer taxonomy is instantiated as a site-wide predictive digital twin (Figure 1). The three taxonomy layers feed a continuously updated twin state, which forward-simulates worker trajectories, robot motion, and process state at 5 s primary and 30 s secondary horizons, emitting per-worker interaction-pattern decisions every 5 s. Additional details are provided in the following subsections.

Twinning fidelity across layers

Each layer requires a different update cadence and prediction horizon. Human-layer spatial and kinematic states must update at the perception subsystem's native rate (typically 10–30 Hz from UWB or LiDAR) to support proximity tracking. Human-layer physiological state updates at a slower pace consistent with the underlying signal physiology and feature-extraction windows. In this case, five seconds is a defensible primary cadence, matching the shortest meaningful HRV-feature horizon and giving the inference subsystem a stable estimate to publish. On the other hand, the robot-layer kinematic state updates at the controller's native rate (kHz at the joint level, but tens of Hz at the supervisory level relevant for HRC). The robot-layer process state updates at the pump-to-nozzle latency timescale (seconds). The site-layer partially-built structure state updates per layer or per bead, with curing models running on a slow background timer. The environmental state updates on tens-of-seconds intervals.

Developing the forward simulation mechanism

A reactive safety system catches a hazard when it has happened. A predictive system catches it before it happens which is of utmost importance in this study. Accordingly, the predictive digital twin runs a short-horizon forward simulation that propagates worker trajectories, robot motion, and process state forward under their current commands. There is a primary horizon of five seconds and another secondary horizon of thirty

seconds. The horizon is bounded by the prediction error of the spatial models. Beyond five seconds, intent becomes the dominant uncertainty rather than dynamics. The simulation produces, per worker, a probability surface over near-future positions and a corresponding intersection probability with the gantry envelope and process-active zone. Figure 3 illustrates the forward simulation across the primary (5 s) and secondary (30 s) horizons. The supervisory cycle issues a new pattern decision every 5 s based on predicted intersection between worker trajectories and the gantry envelope.

Figure 3: Forward simulation across the primary (5 s) and secondary (30 s) horizons.

Updating cadence and decision cycle

The supervisory decision cycle runs at five-second cadence. At each cycle, the digital twin (1) ingests the latest layer states, (2) computes per-worker forward simulations to the primary and secondary horizons; (3) computes interaction-pattern decisions for each worker, and (4) emits supervisory references to the underlying motion controller. Faster reflexes such as emergency stops and immediate proximity violations remain on a short-loop pipeline and are not gated on the supervisory cycle.

Critically, the digital twin does not collapse its outputs into a single site-wide safety scalar. Roles have different risk profiles and different optimal interactions. A single-scalar output erases that structure. Instead, the digital twin outputs a discrete interaction pattern per worker, drawn from the seven-pattern set described in the following section.

Component 3: Role-aware interaction patterns

Seven interaction patterns were identified, each defined by who the worker is, what state the digital twin estimates, and what response the robot adopts. The seven patterns emerge from cross-tabulating the worker roles observed in current 3DCP deployments (i.e. operator, rebar worker, material handler, supervisor, passer-by) with the dominant trigger types (spatial, physiological, process-state); together they cover the operationally common cases for gantry-based 3DCP, and a deployment may add or specialize patterns without breaking the schema. Table 1 summarizes the seven patterns. Each pattern combines a role qualifier, a state qualifier from one or more taxonomy layers, and a response specification that can be mapped to an ISO 10218-1/2:2025 collaborative-application mode. The advantage of expressing safety responses as a finite pattern set, rather than as a continuous function of state, is auditability. In this case,

Table 1: Seven role-aware interaction patterns and associated information

Pattern	Role	Triggering state	Digital Twin response	ISO 10218 mode
1. Console monitoring	Operator	Cognitive-load and fatigue estimates within nominal range; large spatial separation	Adjust information presentation (alert pacing, notification suppression); no motion change	Automatic operation
2. Acute operator load	Operator	Spike in cognitive-load or fear estimate from console-side wearables	Precautionary slowdown of next path segment; pause before high-consequence action	Speed and separation monitoring (SSM)
3. In-envelope intervention	Rebar worker	Spatial intrusion within envelope during scheduled inter-layer pause	Hand-off mode: motion constrained; re-engagement gated on task-completion signal or timeout	Hand guiding / SSM
4. Pump-side tending	Material handler	Moderate proximity; process-state divergence (commanded vs measured flow)	Monitor degradation; pre-position transition to Pattern 5 if divergence persists	SSM
5. Process-degradation pre-stop	All present	Imminent quality-driven stop predicted from process state	Extend path to graceful transition (end of bead or layer); notify Patterns 3 and 4 of pending pause	Monitored standstill (planned)
6. Ad-hoc intrusion	Passer-by	Spatial intrusion into envelope; no role data available	Standard SSM response; no role-specific or physiological gating	SSM
7. Supervisory inspection	Supervisor	Permitted in-envelope presence with role qualifier; proximity to recently-deposited elements	Moderate motion; consult Site layer to flag low-strength elements on supervisor's path	SSM with site-aware caution

each pattern can be traced to the standards-defined collaborative-application types (ISO, 2025) and to a specific risk hypothesis.

Scenario-based evaluation and discussion

Given the modular structure of the proposed framework (Figure 1), the evaluation focuses on the Human-layer physiological-state inference pipeline. This includes the feasibility of end-to-end signal processing, stress classification, and calibration mechanisms using a proxy multimodal dataset. This choice is motivated by the availability of suitable datasets and the ability to conduct controlled, reproducible testing in isolation. The Robot and Site layers, as well as their integration within the predictive digital twin and interaction patterns, require system-level deployment in construction environments and are therefore reserved for future validation.

Rebar worker during inter-layer pause scenario

Consider a rebar worker who enters the print envelope at t = 0 to install reinforcement during a scheduled inter-layer pause. At the next supervisory cycle (t = 5 s), the spatial subsystem flags intrusion within the envelope. The role-context tag identifies the worker as a rebar worker and the workflow-scheduling layer confirms an inter-layer pause is in progress. The digital twin classifies this configuration as Pattern 3 (i.e. in-envelope intervention) and transitions the gantry to a hand-off mode. Motion is constrained to the SSM-compliant envelope and the supervisory cycle permits re-engagement only upon either an explicit task-completion signal from the rebar worker or the expiration of a configured timeout. The process-state subsystem continues independently. If rheology at the nozzle degrades beyond threshold during the hand-off, Pattern 5 (i.e. process-degradation pre-stop) supersedes Pattern 3, and the gantry extends path completion to a graceful transition (end of bead) rather than executing an immediate halt. After the placer signals completion, the cycle returns to Pattern 1 (i.e. console monitoring) and motion resumes. The example illustrates two framework properties: pattern selection is per worker rather than global, and pattern transitions can be process-driven rather than only space-driven.

Preliminary feasibility check

To verify that the physiological-state pipeline of the Human layer is implementable end-to-end, a preliminary benchmark was conducted using the public WESAD dataset (Schmidt et al., 2018), which provides clean multimodal physiological signals (ECG, EDA, and skin temperature) with standardized stress labels. Although the dataset was not originally collected for construction applications, its multimodal structure provides sufficient signal richness to support a proxy-based evaluation of the proposed framework. In this study, it serves as a controlled proxy for validating preprocessing, windowing, model training, threshold selection, and evaluation procedures prior to the availability of construction-specific data.

Two model classes were evaluated under a strict subject-holdout protocol (train: S2–S11, validation: S13–S14, test: S15–S17) on the binary stress versus non-stress task. The models were (1) XGBoost (Chen and Guestrin, 2016), trained on engineered window-level features (summary statistics and temporal trends), and (2) a Temporal Fusion Transformer (Lim et al., 2021), trained on sequence windows. Signals were segmented into fixed-length windows with 50% overlap. They were standardized per subject using training-set statistics. The decision threshold was selected on the validation set by maximizing the F1 score. It was then applied unchanged to the test set. Each model was evaluated under two settings: with and without per-subject calibration profiles. These profiles consist of short resting segments appended as static covariates. They correspond to the calibration mechanism prescribed by the proposed framework for operator stations. Experiments used a deliberately reduced configuration, including downsampling and a capped number of windows per subject. This configuration was chosen to support rapid iteration. The reported results therefore demonstrate pipeline functionality rather than state-of-the-art performance.

Table 2 reports the Area Under the Receiver Operating Characteristic curve (AUROC), Area Under the Precision–Recall Curve (AUPRC), and F1 on the held-out test split (11,988 windows; stress prevalence ≈ 0.31). AUROC measures the model's ability to distinguish between classes across all decision thresholds. AUPRC is more informative under class imbalance, as it focuses on performance for the positive class. F1 score is the harmonic mean of precision and recall and reflects the balance between false positives and false negatives at a chosen threshold. With calibration profiles enabled, the Temporal Fusion Transformer outperforms the tree-based baseline. With profiles disabled, the sequence model performance collapses while XGBoost remains stable. This indicates stronger reliance of the sequence model on the personalization pathway prescribed by the framework. To ensure comparability, train/validation/test splits and class distributions were kept identical across configurations. The profiles-off configuration was rerun and reproduced identical metrics. Threshold selection was performed exclusively on the validation set.

Table 2: WESAD pipeline feasibility check on the held-out test split

Setting	Model	AUROC	AUPRC	F1
Profiles on	XGBoost	0.712	0.542	0.498
Profiles on	TFT	0.768	0.683	0.576
Profiles off	XGBoost	0.712	0.542	0.498
Profiles off	TFT	0.548	0.354	0.302

These results demonstrate that the Human-layer inference pipeline can support stable stress classification and calibration under controlled conditions, representing an

initial step toward operationalizing the proposed framework.

The seven-pattern model, role-aware response logic, and process-coupled patterns (4 and 5) remain to be evaluated in deployment settings.

Conclusion, limitations, and future work

This paper has presented a three-layer taxonomy (Human, Robot, Site), an instantiating site-wide predictive digital twin for human–robot collaboration in 3D concrete printing, seven role-aware interaction patterns, and a scenario-based evaluation of the Human-layer physiological-state inference pipeline. The proposed taxonomy structures the design space of observables and state variables, while the digital twin operationalizes this structure into a continuously updated model. This model supports seven role-aware interaction patterns mapped onto ISO 10218-1/2:2025 collaborative-application modes. The framework is platform-agnostic across gantry, robot-arm, and crane-based 3DCP systems and is intended as a reference architecture for future deployment and standardization. The work is motivated by a regulatory gap, as ISO/ASTM 52939:2023 excludes the EHS aspects of robotic operation, and by an empirical gap in existing collaborative-robot frameworks, which do not account for process-coupled hazards or multi-role construction environments.

While the paper presents an innovative framework, it does not constitute a deployed system. The main limitation is that the proposed interaction patterns and layered digital twin have not yet been validated in integrated real-world 3D concrete printing deployments. The Human-layer evaluation demonstrates feasibility under controlled conditions, but full system-level validation across Human, Robot, and Site layers remains to be conducted.

Future work will proceed in three directions. First, system-level deployment and validation will be carried out on an operational gantry-based 3DCP platform, including quantitative assessment of false positives and false negatives under scripted hazard scenarios. Second, role inference mechanisms will be developed to enable automatic classification of worker roles from kinematic and contextual signals, reducing reliance on manual role assignment. Third, the interaction pattern set will be formalized as a normative contribution aligned with the ISO 10218 series, alongside engagement with ISO/ASTM TC261/F42 to support future revisions of ISO/ASTM 52939.

SUPPORTING CONSTRUCTION CYBERSECURITY DECISION-MAKING THROUGH A CROWDSOURCING PLATFORM

Muammer Semih Sonkor[1], and Borja García de Soto[1]
[1]S.M.A.R.T. Construction Research Group, Division of Engineering, New York University Abu Dhabi (NYUAD), Saadiyat Island, P.O. Box 129188, Abu Dhabi, United Arab Emirates

Abstract

Construction is increasingly digitalized, and organizations are integrating operational technology, such as robots, into site operations, introducing cyber risks. This paper presents a web-based crowdsourcing platform to collect and analyze human knowledge and to provide recommendations to guide cybersecurity decision-making in the construction sector. Collected insights on risks and mitigations via open-ended questions are converted into recommendations using semantic segmentation, topic modeling, and large language models. The platform was implemented in collaboration with a UAE-based contractor on a lift-assist robot. The resulting recommendations were mapped to the foundational requirements of ISA/IEC 62443, showing alignment with six of the seven requirements in this case study.

Introduction

The construction sector has been undergoing a digital transformation, affecting site tasks. Besides the digitalization of documents and the increasing use of common data environments for data exchange and coordination, construction sites are integrating operational technology (OT), such as robotics, connected equipment, and IoT devices (García de Soto et al., 2020). While these technologies aim to improve productivity and quality, they also introduce new cyber risks into construction environments that are dynamic and often involve close interaction between humans and machines (García de Soto et al., 2020). Therefore, cybersecurity in construction is not only a concern related to confidentiality, integrity, and availability of information and resources, but also a matter of safety.

While cybersecurity emerged as a research topic in the 1970s (Lipner, 2015) and has been widely studied over time, it has not yet received enough attention in the construction domain, leaving essential areas to be explored (Salami Pargoo and Ilbeigi, 2023). This can be explained by the relatively lower maturity of digitalization in the sector (Tambwe et al., 2025) compared to more technologically advanced ones, such as energy and manufacturing. However, the increase in cyberattacks (especially ransomware) targeting construction companies (Check Point, 2025) necessitates investigating approaches suitable for the characteristics of construction projects.

Crowdsourcing is one of the effective mechanisms deployed by companies to address the lack of in-house cybersecurity expertise (Zhao et al., 2023). It has mostly been associated with bug bounty programs in the cybersecurity context, where organizations invite external security experts through an open call to identify and disclose vulnerabilities in defined systems and code bases before they are exploited by malicious actors (Malladi and Subramanian, 2020). Another common application is crowdsourced cyber threat intelligence (CTI), which involves aggregating information from open unstructured sources (e.g., social media) and structured repositories (e.g., vulnerability databases) to detect emerging threats and vulnerabilities (Sun et al., 2020).

While these approaches are highly effective in identifying isolated software vulnerabilities, they do not yield holistic, system-level guidance. Construction sites that integrate complex technologies such as robotics and connected equipment, along with building information modeling (BIM)-enabled information workflows, require deployment-oriented recommendations rather than lists of code-level findings. Such guidance is typically provided by cybersecurity consultants (often at high cost) or by in-house experts who are scarce in the construction sector, according to a recent report (Sophos, 2025). The report involved a survey of 3,700 information technology (IT) professionals from 17 countries, in which 41% of the participants from the construction and property sectors indicated that the lack of expertise was the root cause of falling victim to ransomware attacks (Sophos, 2025).

This study presents a crowdsourcing platform developed for the construction sector that gathers cybersecurity knowledge through structured open-ended questions and converts it into actionable, management-ready recommendations using a reproducible data analysis pipeline. It addresses the need for cost-effective, technology-specific cybersecurity guidance for increasingly digitized and autonomous construction sites. The platform was implemented in collaboration with a UAE-based contractor focusing on a lift-assist robot designed to support blocklaying.

In this study, the input was collected from the contractor's employees, and the resulting recommendations were mapped to ISA/IEC 62443 foundational requirements (FRs) to support systematic cybersecurity decision-making. ISA/IEC 62443 is an international cybersecurity

standard series developed for industrial automation and control systems (IACS) and broader OT environments, defining structured security requirements throughout their lifecycles.

Against this background, this study aims to address the following research questions (RQs):

- (RQ1) How should a crowdsourcing platform and analysis pipeline be structured to convert employee cybersecurity knowledge into actionable, decision-support recommendations for construction management?
- (RQ2) To what extent can internal crowdsourcing capture OT-related cybersecurity needs in construction?

RQ1 is addressed through the proposed platform architecture and the end-to-end analysis workflow presented in the Methodology section. Moreover, RQ2 is addressed by showing the extent to which the identified recommendations cover the ISA/IEC 62443 foundational requirements.

Background and Related Work

This section reviews literature identified through a targeted review of peer-reviewed studies and industry reports on construction cybersecurity and crowdsourcing.

Cybersecurity in Construction

The digital transformation of the construction industry, accelerated by the convergence of information technology (IT) and OT (e.g., autonomous machinery, IoT devices), has significantly expanded the sector's cyberattack surface (Sonkor and García de Soto, 2021). In addition to the increase in ransomware attacks targeting the sector (Check Point, 2025) in recent years, high-profile incidents such as the $25 million deepfake fraud targeting Arup (Elliott, 2025) have shown that the construction industry is on hackers' radar. The growing interest from malicious actors can be explained by the low cybersecurity preparedness among construction companies (QBE, 2024), which makes them easy targets.

To address these challenges, recent research emphasized the need for tailored vulnerability assessment methods and governance frameworks that account for the unique, dynamic nature of construction sites and their complex supply chains (Mantha et al., 2024). Moreover, Salami Pargoo and Ilbeigi (2023) indicated the need for research to develop methodologies to safeguard automated and intelligent systems used in construction projects. In addition to research, several standards and guidelines have been published to address the increasing cyber risks in the construction industry. Some examples are ISO 19650-5, which focuses on security-minded information management in BIM-enabled projects, and the code of practice "Cyber Security in the Built Environment" by the Institution of Engineering and Technology (IET). These documents provide high-level guidance to construction companies and do not focus on specific construction technologies.

Internal Crowdsourcing as a Knowledge Mobilization Mechanism

Crowdsourcing is a collaborative method for solving specific problems by leveraging a dynamic group of people formed through an open call (Pedersen et al., 2013). In cybersecurity, it is commonly utilized through programs such as bug bounties, which involve independent external experts. Although effective in many software contexts, such approaches are not always suitable for OT, where safety and availability considerations come first (Malladi and Subramanian, 2020). These concerns also apply to construction projects that use OT, such as robotic systems, IoT devices, and autonomous machinery, as they interact with the physical environment. In addition, construction systems often involve mixed ownership and responsibility (e.g., vendor-managed remote connectivity, site networks managed by the IT department, operational procedures managed by site teams), complicating external engagement.

An alternative to traditional crowdsourcing is internal crowdsourcing, where companies mobilize distributed employee knowledge for problem-solving or ideation (Ulbrich et al., 2021). One advantage of internal crowdsourcing is employees' better understanding of their organization and its operational conditions (Malhotra et al., 2017). Moreover, intellectual property and confidentiality issues are eliminated because internal participants' employee contracts already address property rights (Malhotra et al., 2017). However, companies often struggle to motivate employees to participate in internal crowdsourcing programs, and monetary rewards alone may not always be sufficient, requiring additional incentives such as recognition (Beretta et al., 2023).

The approach proposed in this study differs from bug bounties in both its participation model and intended output. Rather than expecting the participants to identify isolated code-level vulnerabilities and provide structured technical reports, it collects knowledge through open-ended questions to derive deployment-oriented, technology-specific recommendations for construction management teams. Moreover, the platform introduced in this study was not developed solely for internal crowdsourcing purposes. However, given the challenges of engaging external participants in a cybersecurity case study involving safety-critical technology, participation was limited to the contractor's employees. Therefore, the case study in this paper explores how internal crowdsourcing can be used to support cybersecurity decision-making in construction companies.

Methodology

This study adopts a design science research approach (Hevner et al., 2004), which is characterized by the creation of purposeful and innovative artifacts (in this study, a crowdsourcing platform) to solve identified practical problems.

The research was implemented through an exploratory single-case study (Yin, 2009). This methodological choice is appropriate for investigating the efficacy of new technological interventions in their real-world context, particularly in specialized and complex domains such as construction robotics.

Overview of the Crowdsourcing Platform

The proposed platform is a web-based system that enables construction companies to define a technology to be investigated, provide contextual documentation and technical details, and collect employee or external participant responses to structured open-ended questions. Submissions are then analyzed through a reproducible data analysis pipeline that identifies the common themes and derives actionable recommendations for management.

As shown in Figure 1, the high-level process flow of the proposed crowdsourcing platform involves four steps: (1) challenge creation, (2) response collection, (3) data analysis pipeline ((3a) threats and vulnerabilities and (3b) mitigations), and (4) recommendation synthesis.

System Architecture

The platform follows a standard web application structure, composed of the following main components:

- **Frontend/User Interface (UI):** Django templates (using HTML, CSS, JavaScript) implement (i) a submission dashboard for contributors to see the technical details of the investigated technology and submit free-text responses to open-ended questions, and (ii) a management dashboard for decision-makers to view the recommendations derived from the analysis.
- **Backend data handling:** Django handles HTTP requests and response processing and manages data exchange with the database.
- **Database:** MySQL stores user submissions, metadata, and analysis artifacts (e.g., derived recommendations).
- **Data Analysis Pipeline:** Python modules (separate for "threats and vulnerabilities" and "mitigations") execute the data analysis pipeline that involves data preparation, coherence-based semantic segmentation, topic modeling, and LLM-based topic labeling and summarization. The whole pipeline, including the LLM-based topic labeling and summarization, is executed locally.
- **Recommendation Synthesis:** A Python module performs LLM-based synthesis to fetch the analysis outputs from the database and convert them into a set of cybersecurity recommendations tailored to the investigated technology. The resulting recommendations are stored in the database and displayed on the management dashboard.

Overview of the Case Study

The platform was implemented in collaboration with a UAE-based contractor focusing on the MULE MZ100 (Figure 2) robot from the manufacturer Construction Robotics. The MZ100 is a lift-assist robot designed to support block laying by enabling operator-guided semi-automated lifting and positioning. The system includes an operator control panel at the end effector, load sensors intended to prevent overloads and unsafe movements, and built-in cellular connectivity that provides real-time status data and enables remote service functions (e.g., troubleshooting, diagnostics, software updates). Firmware updates require an on-site technician who connects a dedicated service cable between the machine and a laptop. These features create a mixed cyber-physical exposure profile with both physical interfaces and network-enabled functionality.

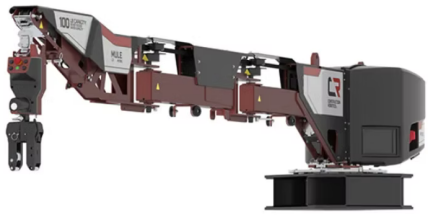

Figure 2. MULE MZ100 by Construction Robotics (Alley-Cassetty, 2026)

The case study was announced as an open call for participation within the company, targeting employees in the Design, Innovation, Digital Construction, and IT departments, as identified by the contractor. Participation was voluntary, and the analysis reported in this paper is based on responses from 11 employees who chose to contribute. The pilot ran asynchronously over two months, and participants were incentivized through the contractor's internal innovation points system managed by the Innovation department. The case study included two thematic lanes and a set of questions for each, presented on the platform: Lane A (Threats and Vulnerabilities; Q1-

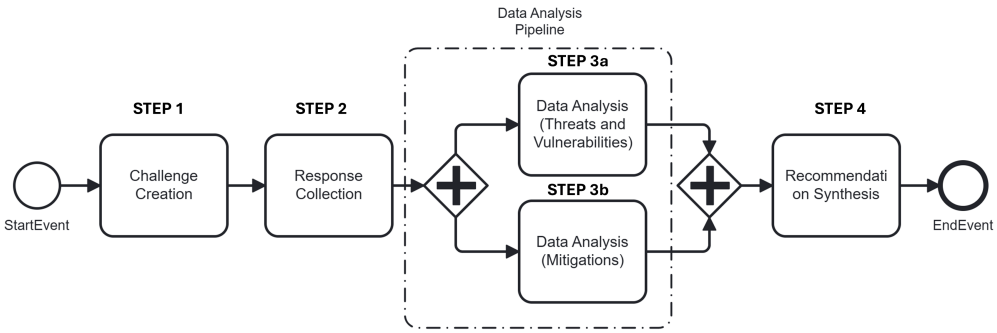

Figure 1. High-level process flow of the proposed crowdsourcing platform

Q4) and Lane B (Mitigations; Q5-Q6). All questions are presented in Table 1.

Table 1. Crowdsourcing questions used in the case study

ID	Questions
Q1	Considering the provided robotic system, what could be done to compromise the data collected? (e.g., sensor readings)
Q2	Considering the provided robotic system, what could be done to disrupt or manipulate its operation?
Q3	In your opinion, what are the most vulnerable components from the cybersecurity perspective? Why?
Q4	If you were an attacker, what would be your motivation to compromise the provided robotic system?
Q5	What would you suggest to make the system less vulnerable?
Q6	What questions should be asked to the vendor before deploying such equipment on site to identify potential cybersecurity issues?

Data Analysis Pipeline

Algorithm 1 summarizes the data analysis pipeline that converts free-text responses collected from the contributors into cybersecurity topics.

Algorithm 1. Text-to-topics data analysis pipeline

// Step 1: Fetch and Prepare the Data
1: Fetch responses from the database:
2: If Lane A: use Q1-Q4 (concatenated)
3: If Lane B: use Q5-Q6 (concatenated)
4: Clean the raw text (e.g., normalize whitespace, remove non-informative artifacts).

// Step 2: Semantic Segmentation (cosine similarity)
5: Split responses into sentences and embed them using SBERT.
6: Generate segmented corpora S_τ by applying cosine similarity thresholding to consecutive sentence embeddings over τ values (Table 2).

// Step 3: Coherence-guided selection of τ^* and k^*
7: For each candidate (τ, k) combination (Table 2), fit BERTopic on S_τ and compute c_v coherence on S_τ.
8: Select (τ^*, k^*) that maximizes c_v.

// Step 4: UMAP Hyperparameter Search (Select u^*)
9: With S_{τ^*} and k^* fixed, fit BERTopic using candidate UMAP settings (Table 2), evaluate with c_v, and select u^*.

// Step 5: HDBSCAN Hyperparameter Search (Select h^*)
10: With S_{τ^*}, k^*, and u^* fixed, fit BERTopic using candidate HDBSCAN settings (Table 2), evaluate with c_v, and select h^*.

// Step 6: Final Topic Model Fitting
11: Fit the final BERTopic model on S_{τ^*} using (k^*, u^*, h^*).
12: Extract topic keywords and representative segments for each non-outlier topic.

// Step 7: Topic Labeling and Summarization
13: Use a locally deployed LLM to generate a short label and summary for each topic (model and configuration reported in Table 2).
14: Store topic labels and summaries in the database.

The whole pipeline presented in Algorithm 1 is executed in parallel for both lanes (1) Lane A: Threats & Vulnerabilities (Q1-Q4) and (2) Lane B: Mitigations (Q5-Q6) to produce two sets of topics, including their summaries and labels. These topics are then synthesized into recommendations for management. In Algorithm 1, S_τ denotes the segmented corpus produced using threshold τ, k denotes the target topic count nr_topics, u^* denotes the selected UMAP configuration (n_neighbors, n_components) that maximizes coherence, and h^* denotes the selected HDBSCAN configuration (min_cluster_size, min_samples) that maximizes coherence.

In all search stages (i.e., Steps 3-5 in Algorithm 1), candidate configurations were evaluated using the c_v coherence metric (Röder et al., 2015) computed on the segmented corpus, and the best configuration was selected using an argmax rule. The options that produced no valid non-outlier topics were assigned a worst-case score (i.e., $-\infty$) to prevent selection. Table 2 presents the thresholds and grid-search values used in Algorithm 1.

Table 2. Values tested for each parameter in Algorithm 1

Step	Component	Parameter(s)	Values tested
Step 2	Semantic segmentation	Similarity threshold (τ)	$\{0.10, 0.15, \ldots, 0.90\}$
Step 3	Initial topic modeling search	nr_topics (k)	$\{5, 6, 7\}$
Step 4	UMAP search	n_neighbors	$\{5, 10, 15, 20, 25, 30, 35\}$
Step 4	UMAP search	n_components	$\{2, 5, 10, 15\}$
Step 5	HDBSCAN search	min_cluster_size	$\{5, 10, 15, 20, 25\}$
Step 5	HDBSCAN search	min_samples	derived from min_cluster_size (see note*)
Step 7	Topic labeling & summarization	Model; temperature	Gemma 3 27B (self-hosted via Ollama); temperature = 0

***Note:** p ∈ $\{0.10, 0.50, 1.00\}$;
min_samples = $max(1, int(p \times min_cluster_size))$

To identify semantic boundaries between consecutive sentences, the pipeline computes cosine similarity between their SBERT embeddings and starts a new segment when the similarity falls below the threshold τ (Steps 2 in Algorithm 1). Cosine similarity was selected since it is independent of vector magnitude, focusing strictly on the semantic orientation of the text. This choice is consistent with the original SBERT study (Reimers and Gurevych, 2019), which used cosine similarity to compare sentence embeddings. Cosine similarity between two embedding vectors (e_i) and (e_{i+1}) is calculated as follows:

$$\mathrm{sim}(\mathrm{e}_i, \mathrm{e}_{i+1}) = \frac{\mathrm{e}_i \cdot \mathrm{e}_{i+1}}{\|\mathrm{e}_i\| \|\mathrm{e}_{i+1}\|} \quad (1)$$

In Step 7 of Algorithm 1, a structured prompt template was used for LLM-based topic labeling and summarization, organized into instruction, context, input data, and output indicator, as suggested by Giray (2023). Lane-specific templates were used to maintain focus on either "Vulnerabilities and Threats" or "Mitigations". The prompt templates are not included in this paper due to page limitations; however, they can be provided upon reasonable request. Moreover, this study does not claim novelty in the individual analytical components of

Algorithm 1, since they are established techniques. Instead, the contribution lies in the proposed coherence-guided pipeline, which iteratively adjusts the semantic segmentation threshold (τ) and topic modeling configuration to maximize the coherence of the final topic-modeling output.

Recommendation Synthesis

To identify actionable recommendations for construction management, the outputs of the two analysis lanes (i.e., topic labels and summaries) were synthesized using a locally deployed LLM. The LLM (i.e., Gemma 3 27B via Ollama) was prompted to generate 5-7 actionable recommendations for construction decision-makers. The pseudocode presented in Algorithm 2 summarizes this procedure.

Algorithm 2. Recommendation synthesis workflow

1: Fetch topic labels and summaries for Lanes A and B from the database:
2: Create a synthesis prompt that instructs the model to:
- act as a Chief Information Security Officer (CISO)
- generate 5-7 actionable recommendations for a construction management team
- use only the provided topic labels and summaries as input (no other assumptions)
- write implementable and technical guidance without extra narration
3: Query the locally deployed LLM.
4: Store the resulting recommendations in the database.

This section (Methodology) addresses RQ1 by describing the proposed platform design and analysis workflow, specifying how employee knowledge was collected, processed, and converted into cybersecurity recommendations for construction management teams.

Results and Discussion

Overview of the Participants and Collected Responses

In this case study, the crowdsourcing platform received contributions from 11 employees across four departments within the collaborating construction company. Employees' departments and the top five keywords extracted from their responses (stop words removed) are presented in Table 3. Across all submissions, the Threats and Vulnerabilities lane (Q1-Q4) contained 1,183 words (108 words per employee submission, on average), whereas the Mitigations lane (Q5-Q6) contained 534 words (49 words per employee submission, on average). This difference is expected given the larger number of questions in the Threats and Vulnerabilities lane.

Platform Outputs: Actionable Recommendations for Construction Management

For traceability, Table 4 and **Error! Reference source not found.** present the topics identified by the data analysis pipeline (Figure 1) for the (i) Threats and Vulnerabilities and (ii) Mitigations lanes, respectively. These topics reflect the main themes that emerged from employees' contributions (e.g., concerns about remote access, data integrity, and physical access points). Topic summaries are not included in this paper due to page limitations; however, they are available in a repository (Sonkor and García de Soto, 2026).

Table 3. List of the contributing employees and top keywords

Employee #	Department	Top 5 Keywords
Employee 1	Design	software, data, network, communication, secure
Employee 2	Design	manipulated, opportunity, troubleshooting, telemetry, firmware
Employee 3	Design	access, program, unauthorized, hacking, mule
Employee 4	Design	remote, connectivity, connect, remotely, unsafe
Employee 5	Design	sensors, data, sensor, signals, confuse
Employee 6	Design	access, data, robot, power, control
Employee 7	Design	data, access, physical, updates, robotic
Employee 8	Design	data, equipment, connected, device, access
Employee 9	Innovation	data, security, access, incorrect, training
Employee 10	Digital Construction	access, data, machine, think, physical
Employee 11	IT	access, unauthorized, public, addresses, system

Table 4. Topics identified for threats and vulnerabilities

ID	Topic Label	Top keywords (weight)
T1	Robotic System Manipulation & Unauthorized Access	robot (0.07), sensor (0.05), weak (0.05), tampering (0.05), access (0.05), power (0.04), command (0.04), manipulation (0.04), input (0.04), feeding false (0.04)
T2	Remote Access & Physical Security Risks	access (0.07), remote (0.07), malicious (0.06), update (0.05), security (0.05), cause (0.04), control (0.04), data (0.04), physical (0.04), remote connectivity (0.03)

Table 5. Topics identified for mitigations

ID	Topic Label	Top keywords (weight)
M1	Robotic Equipment Cybersecurity: Mitigation Strategies	security (0.09), data (0.06), secure (0.06), communication (0.05), vendor (0.05), cyber (0.05), monitoring (0.05), encryption (0.04), defense (0.04), standard (0.04)
M2	Robotic Equipment Access Control & Remote Connectivity	access (0.13), remote (0.07), device (0.04), maybe (0.04), physical (0.04), robot (0.04), remote access (0.04), unauthorized (0.04), authentication (0.04), data (0.03)

The platform's recommendation synthesis step (Figure 1) then identified management-ready controls by using the identified topics as input and an LLM prompt template, ensuring that the recommendations are grounded in crowd-derived themes rather than relying on the LLM's

parametric knowledge. A list of the identified recommendations is presented in Table 6.

Table 6. Recommendations identified by the crowdsourcing platform

ID	Recommendation
R1	Implement physical access controls to the MULE MZ100, including lockable panels covering the service port and a logged, supervised access procedure for any physical interaction with the robot's internal components.
R2	Enforce multi-factor authentication (MFA) for all remote access connections to the MULE MZ100, utilizing a strong authentication method beyond passwords, such as time-based one-time passwords (TOTP) or hardware tokens.
R3	Restrict remote access to the MULE MZ100 to a pre-approved list of authorized personnel and block all incoming connections originating from public IP addresses using firewall rules.
R4	Conduct thorough vendor vetting of Construction Robotics, including a review of their security practices, compliance certifications (e.g., SOC 2), and a detailed questionnaire regarding potential vulnerabilities and incident response plans.
R5	Implement encrypted communication channels for all data transmitted to and from the MULE MZ100, utilizing TLS 1.3 or higher, and verify certificate validity regularly.
R6	Establish a logging system to record all physical and remote access attempts to the MULE MZ100, including timestamps, user IDs, and actions performed, and review these logs regularly for anomalies.
R7	Contractually obligate remote support vendors providing access to the MULE MZ100 to adhere to specific security standards and assume responsibility for any security vulnerabilities introduced through their access or actions.

The recommendations listed in Table 6 are presented as controls based on the identified topics that a construction management team can practically implement. Each recommendation suggests technical actions to safeguard the deployed technology (i.e., MULE MZ100) from different aspects (e.g., integrity, availability) and monitor it to detect potential attacks in a timely manner. Moreover, the recommendations include vendor governance actions (i.e., R4, R7), which are critical in construction OT contexts since vendors often control parts of the system lifecycle (e.g., remote support, update mechanisms) while the construction IT team might be responsible for other parts, such as deployment on site and connectivity. This might make ownership and responsibility boundaries ambiguous in projects.

Mapping Recommendations to ISA/IEC 62443 Foundational Requirements

As mentioned in the Introduction section, ISA/IEC 62443 is an international standards series that establishes cybersecurity requirements for securing IACS. IEC 62443-4-2—a part of this series—structures these requirements around seven component-level FRs (Table 7) to support holistic protection against threats. Although construction OT differs from traditional IACS, robotic equipment such as the MULE MZ100 exhibits exposure patterns comparable to those of traditional IACS (e.g., remote connectivity, maintenance interfaces) and may have operational and safety implications if compromised. In this study, the recommendations were mapped to the ISA/IEC 62443 FRs to provide a standardized way to present which security objectives are addressed, highlight potential gaps, and support interpretation. This mapping is intended to illustrate the alignment of the recommendations with the FRs and does not claim full satisfaction of any of them. The mapping is shown in Table 8.

Table 7. Foundational requirements from ISA/IEC 62443

Foundational Requirement	Description
FR1 - Identification & Authentication Control (IAC)	Ensure all users, services, and devices are uniquely identified and strongly authenticated before any system access is granted.
FR2 - Use Control (UC)	Limit authenticated entities to the minimum necessary actions via role-based authorization and enforceable policies.
FR3 - System Integrity (SI)	Preserve the integrity of software, firmware, and configurations by preventing, detecting, and recovering from unauthorized changes or code execution.
FR4 - Data Confidentiality (DC)	Safeguard data in transit and at rest through robust cryptography, sound key management, and secure handling practices.
FR5 - Restricted Data Flow (RDF)	Constrain communications by segmenting networks and enforcing least-route, allowlisted flows across defined trust boundaries.
FR6 - Timely Response to Events (TRE)	Detect, record, analyze, and act on security-relevant events promptly to contain incidents and support recovery.
FR7 - Resource Availability (RA)	Maintain essential functions during faults or attacks by resisting resource exhaustion, providing resilience/redundancy, and enabling rapid restoration.

Table 8. Mapping of recommendations to ISA/IEC 62443 FRs

Recommendation ID	Mapped Foundational Requirement(s)
R1	• FR2 - Use Control (UC)
R2	• FR1 - Identification & Authentication Control (IAC)
R3	• FR2 - Use Control (UC) • FR5 - Restricted Data Flow (RDF)
R4	• FR3 - System Integrity (SI) • FR6 - Timely Response to Events (TRE)
R5	• FR4 - Data Confidentiality (DC)
R6	• FR6 - Timely Response to Events (TRE)
R7	• FR2 - Use Control (UC) • FR3 - System Integrity (SI)

As shown in Table 8, the identified recommendations collectively address six of the seven ISA/IEC 62443 FRs

(Table 7), indicating alignment with key security objectives and thus addressing RQ2. FR7 (i.e., Resource Availability) is not addressed by any recommendations, suggesting that availability-focused controls were less prominent in employee contributions. This can be explained by both the question design and the participants' lack of cybersecurity expertise. In future case studies, this can be addressed by adding availability-oriented questions during the submission phase and involving participants with deeper knowledge of different facets of cybersecurity.

Discussion in the Construction Context

A key value of the crowdsourcing approach in this study is that it surfaced context-dependent issues that are difficult to derive from generic control catalogs alone. Although the resulting recommendations are preliminary and specific to this case study, they illustrate how employee knowledge can be translated into deployment-oriented site- and technology-specific actions for construction management. The identified recommendations can be grouped into four operational categories relevant to construction decision-making:

- **Physical access management (R1):** Construction equipment is often operated in environments where physical access is difficult to control completely. The MZ100's firmware update process involves on-site connection to a laptop via a dedicated service cable, indicating the existence of service access pathways that should be protected through physical safeguards and clear site procedures.
- **Remote access hardening (R2, R3):** Unlike most industrial facilities, construction sites mostly rely on temporary connectivity (e.g., site Wi-Fi, cellular networks), which increases the likelihood of inconsistent configurations and shared credentials. In this case study, cellular connectivity enables efficient remote software updates and troubleshooting, given the robotic system's potentially changing location as the project progresses; however, it also creates a high-impact threat surface. Safeguarding remote access through MFA and restricting it to a pre-approved list of personnel can reduce the risk during site transitions.
- **Secure communication and monitoring (R5, R6):** Construction projects generate operational data that can influence production planning and site decision-making. Therefore, telemetry and real-time status data introduce integrity concerns. Encryption and certificate validation reduce interception risk, while logging and anomaly review support detection and response.
- **Vendor governance and responsibility allocation (R4, R7):** Construction OT deployments often involve multi-party responsibility, where the vendor may handle remote support and updates, the contractor's IT team may manage connectivity, and site teams may control day-to-day operation and physical access. Due to this fragmented governance, vendor vetting and contractual obligations are essential to clearly define roles, especially when scaling OT deployment across projects and sites.

Limitations

This study has several limitations. First, the proposed platform and data analysis flow were tested on a single case study involving contributions from 11 employees. More case studies are needed to further evaluate the platform across different scenarios. Second, although an open call was made to four departments, including IT, only one IT employee responded. The remaining employees were mostly from the Design department, suggesting lower cybersecurity familiarity than IT personnel. Moreover, the responses were shorter than expected, limiting their breadth. These aspects should be kept in mind while judging the potential of the proposed methodology in this study. Finally, the mapping of the recommendations to ISA/IEC 62443 FRs (Table 8) has not yet been reviewed by external cybersecurity experts. The results should be interpreted as decision-support insights derived from employee knowledge rather than verified statements about exploitable vulnerabilities or compliance.

Conclusions and Future Work

This paper presents a web-based crowdsourcing platform that supports construction cybersecurity decision-making by gathering human knowledge through free-text contributions and converting it into recommendations for management teams. The platform was implemented in collaboration with a UAE-based contractor, and the MULE MZ100 lift-assist robot was selected as the investigated technology. A reproducible data analysis pipeline produced four topics. These topics were synthesized into seven actionable recommendations using a local LLM. The recommendations were mapped to ISA/IEC 62443 FRs to support systematic interpretation. The methodology presented in this paper demonstrates a reproducible pathway from employee inputs to decision-support recommendations, addressing RQ1. Moreover, the mapping of recommendations, with six of seven ISA/IEC 62443 FRs captured, indicates alignment with OT security objectives, addressing RQ2, and highlights Resource Availability (FR7) as a gap to target in future case studies.

Future work will focus on addressing the limitations. First, the mapping of the identified recommendations to ISA/IEC 62443 FRs will be validated by cybersecurity experts. Second, the platform will be deployed across different construction OT scenarios, and a larger participant group with more advanced cybersecurity knowledge will be targeted. Finally, the platform will be expanded to include a retrieval-augmented generation (RAG) engine that leverages relevant cybersecurity documents (e.g., standards, guidelines) to support the identified crowdsourced recommendations.

TRUST LAYERS FOR AUTOMATED BRIDGE MANAGEMENT USING BLOCKCHAIN AND SMART CONTRACTS

Leonardo Zunino[1], Valentina Gatteschi[1], Marco Domaneschi[1], Joan Ramon Casas[2], and Valentina Villa[1]
[1]Politecnico di Torino, Turin, Italy
[2]Universitat Politècnica de Catalunya, Barcelona, Spain

Abstract

Bridge management is increasingly automated through continuous monitoring, AI-based diagnostics, and digitally coordinated interventions. Yet, current workflows rarely provide end-to-end verifiability: sensor datasets, off-chain computations, and resulting maintenance decisions are difficult to audit across multiple stakeholders. This paper proposes a trust-layered architecture that combines decentralized storage, verifiable computation, and blockchain governance to make monitoring-to-action pipelines tamper-evident and reproducible. The paper discusses how smart contracts can orchestrate inspection and maintenance playbooks, while computation integrity can be certified via Trusted Execution Environments or zero-knowledge proofs. Trade-offs in scalability, privacy, and compliance are analyzed, outlining practical deployment patterns for bridge lifecycles.

Introduction

The ongoing digital transformation of civil infrastructure is reshaping how bridges are monitored, assessed, and maintained over their service life. In recent years, Structural Health Monitoring (SHM) systems have evolved from isolated sensing deployments into data-centric platforms capable of continuously observing structural response under real traffic and environmental variability. In parallel, advances in signal processing and Artificial Intelligence (AI) have increased the ability to extract damage-sensitive features, detect anomalies, and support condition-based and predictive maintenance strategies (An et al., 2019; Malekloo et al., 2022; Zinno et al., 2022; Jiménez Rios et al., 2023). Nevertheless, despite the growing availability of monitoring data and diagnostic tools, a persistent gap remains between ”sensing” and ”action”: monitoring outcomes do not automatically translate into traceable engineering decisions or timely interventions.

This gap is not only technical; it is also organizational and procedural. Bridge management workflows involve multiple stakeholders (owners, operators, engineers, authorities, contractors, technology providers) and multiple data sources (sensors, inspections, numerical models, maintenance records). In this multi-actor setting, it becomes difficult to ensure that the data used for diagnosis have not been manipulated, the diagnostic pipeline has been executed on the declared inputs, the decision logic applied to diagnostic results is consistent and auditable, and subsequent actions and approvals remain accountable years after the event. Conventional centralized data management solutions struggle to provide long-term integrity, verifiable provenance, and non-repudiation, especially when information must be exchanged across institutional boundaries and justified retrospectively.

Blockchain technology has been proposed as an enabling layer for tamper-resistant data governance and transparent process automation. Its core properties, immutability, distributed consensus, and the ability to execute smart contracts, provide mechanisms to register evidence, log events, and enforce pre-defined rules without relying on a single trusted intermediary (Christidis and Devetsikiotis, 2016; Casino et al., 2019; Khan et al., 2021; Liu et al., 2024). In the Architecture, Engineering, and Construction domain, blockchain-based approaches have been explored for documentation, contractual automation, and lifecycle information management (Turk and Klinc, 2017; Plevris et al., 2022; Christodoulou and Kalergis, 2024; Zhang et al., 2022, 2023; Adel et al., 2023; Villa et al., 2025; Gioberti et al., 2024; Romani et al., 2025), while, in the SHM field, several studies have considered blockchain to timestamp measurements, certify alarms, or coordinate stakeholders (Xu et al., 2021; Gordan et al., 2022; Gigli et al., 2022; Mariniello et al., 2025). These contributions confirm the potential of blockchain to improve trust and transparency; however, they also reveal a critical limitation: most frameworks implicitly assume that the off-chain computations that produce alarms and indicators are correct and faithfully executed. In detail, blockchain records can certify that an alert was registered, but they do not, by themselves, prove that the alert was obtained by executing the declared algorithm on the declared dataset.

This paper addresses the above limitation by proposing a methodological framework for trust-aware automated bridge management that spans the full path from sensing to intervention. The framework integrates: off-chain monitoring and diagnostics, decentralized or content-addressed storage for scalable data management, blockchain and smart contracts for governance and audit trails, and optional mechanisms for certifying algorithm execution (e.g., Trusted Execution Environments or cryptographic proofs). The objective is not to replace engineering judgment with automation, but to embed verifiability into the digital workflow so that data, computation, decisions, and actions

can be independently checked and retrospectively reconstructed. In this sense, the contribution of the paper is primarily architectural and methodological: it defines a design space of "trust layers" that can be combined to achieve different levels of accountability, performance, and decentralization depending on stakeholder needs and operational constraints.

The remainder of the paper is organized as follows. The next section introduces the end-to-end methodological framework connecting SHM evidence to intervention governance. Then, the core section discusses alternative trust layers and digitalization levels, comparing technologies and architectural options through a structured trade-off analysis and a summary table. Finally, discussion and conclusions outline practical implications and directions for future work.

Methodological Framework: From Sensors to Intervention

The proposed framework follows a design-oriented research approach aimed at structuring a conceptual solution to a recognized gap in current bridge management practice, rather than validating a specific algorithm or implementation. Its development builds on both the existing literature on SHM, digital twins, and blockchain-based infrastructures, and the authors' ongoing research on SHM-driven bridge management.

The resulting framework can therefore be interpreted as a synthesis of established knowledge and research-driven insights, organized into a layered architecture that maps identified trust gaps to corresponding technological mechanisms. This section introduces the resulting end-to-end framework as a technology-agnostic reference process from sensing to intervention, clarifying where trust issues typically arise and how they can be progressively addressed.

The framework starts with sensing and data acquisition. A bridge is monitored through a network of structural and environmental sensors, often complemented by inspections and operational records. These sources produce heterogeneous data. Raw signals, processed time series, extracted features, and supporting documents are generated at different rates and with different formats. For this reason, data are usually managed off-chain using scalable storage. A key point is that data must remain uniquely identifiable over time. In practice, this is achieved by associating each data batch and each derived artefact with a cryptographic fingerprint, so that the same content can always be referenced and checked.

After acquisition, data move through a diagnostic pipeline. Typical steps include cleaning, synchronization, normalization, feature extraction, and anomaly detection. The pipeline produces indicators and alerts that summarize the structural condition. At this stage, automation becomes attractive, but also fragile. If the input data are not reliable, or if the computation is not transparent, then the alert can be disputed and the whole chain loses credibility. This is one of the main motivations for introducing trust layers: not only to protect the final output, but to make the pathway from data to results verifiable.

Diagnostic outputs are then interpreted within a management workflow. The goal is not to turn algorithms into decision-makers. The goal is to connect monitoring evidence to consistent actions. A practical approach is to adopt clear response policies that map alerts to intervention intents, such as enhanced monitoring, rapid assessment, or emergency safeguards. These policies can be prepared offline and updated when needed. When a new alert arrives, the workflow selects the appropriate response and starts the corresponding process. The process includes notifications, deadlines, responsibilities, and approvals. The technical assessment and the final engineering judgement remain off-chain and under human control, especially for safety-critical cases.

Finally, the response is executed and documented. Inspection reports, images, calculations, and contractor deliverables are produced. These artefacts are typically too large and too diverse to be stored on a ledger. However, the framework assumes that they are still linked to the workflow through immutable references. In this way, the system can preserve an auditable trail that connects monitoring evidence, diagnostic outputs, response activation, approvals, and completion proofs.

Overall, the framework provides a simple reference model that separates computation and storage from governance and accountability. It also makes explicit where trust must be reinforced: data provenance, algorithm execution, decision logic, and action traceability. In the next section, these weak points are addressed through a set of digital trust layers that can be combined depending on cost, performance, privacy, and governance requirements. An overview of the framework and the position of the different trust layers along the monitoring-to-intervention pipeline is shown in Figure 1.

Trust Assumptions and Threat Model

The increasing digitalization of bridge monitoring and management implicitly introduces a set of trust assumptions that are often left unspoken. In traditional SHM-based workflows, trust is typically placed in data providers, algorithm developers, system operators, and centralized data platforms. While this model may be sufficient in controlled or single-organization settings, it becomes fragile when monitoring results are used to justify high-impact decisions, involve multiple stakeholders, or must be audited retrospectively.

One of the main risks concerns data integrity. Sensor measurements, processed signals, and derived indicators are usually stored and handled off-chain, often within proprietary platforms. Without explicit integrity guarantees, data can be altered, selectively filtered, or replaced without leaving clear evidence. Even unintentional errors, such as data loss, version mismatches, or undocumented preprocessing changes, can undermine confidence in the moni-

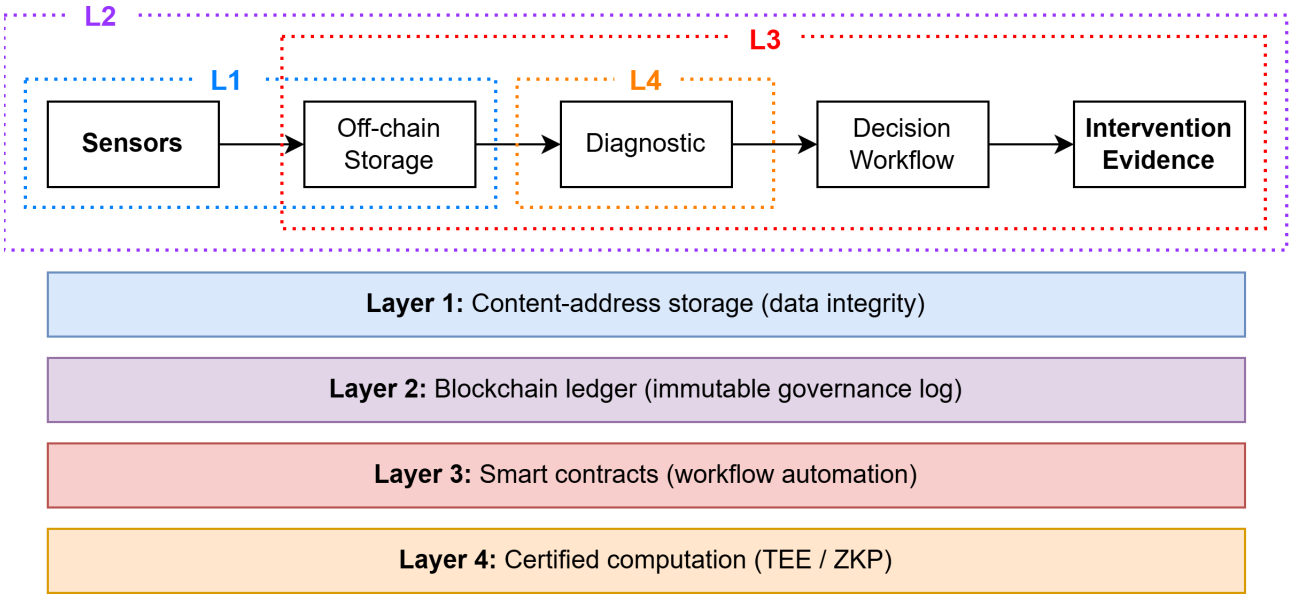

Figure 1: Monitoring-to-intervention workflow and associated trust layers.

toring results when decisions are questioned years later.

A second critical risk is related to opaque computation. Modern SHM pipelines increasingly rely on complex algorithms, including machine learning models and hybrid data-driven approaches. In many cases, the execution of these algorithms is not externally verifiable. Stakeholders must trust that the declared algorithm has been executed on the declared data, following the expected logic. When this assumption is violated, either by misconfiguration, software updates, or deliberate manipulation, the resulting alerts and indicators cannot be independently validated.

Disputes across stakeholders represent another relevant threat. Bridge management typically involves owners, operators, inspectors, engineers, contractors, and authorities, each with different responsibilities and incentives. When an alert triggers inspections, restrictions, or costly interventions, disagreements may arise regarding the correctness of the diagnosis, the timing of the alert, or the appropriateness of the response. In the absence of a shared and immutable audit trail, responsibility attribution becomes difficult and decisions may be contested.

Finally, retrospective accountability poses a long-term challenge. Bridge management decisions are often reviewed long after their execution, for example following incidents, legal disputes, or changes in ownership. At that point, personnel, software, and data platforms may have changed. Traditional monitoring systems rarely provide the guarantees needed to reconstruct the full chain from raw data to final action in a reliable and verifiable manner.

The trust layers introduced in the next section directly address these risks. Rather than assuming fully trusted actors or platforms, the proposed approach progressively reduces trust requirements by making data, computation, decision logic, and actions tamper-evident and auditable. Each layer targets specific weaknesses of traditional monitoring workflows and can be adopted independently or in combination, depending on the required assurance level.

Trust Layers and Digitalization Levels

Building on the reference workflow shown in Figure 1, this section discusses how different trust layers can be combined to strengthen specific stages of the process.

The central idea of the proposed approach is that bridge management digitalization can be equipped with a set of modular ”trust layers”, each providing additional guarantees in terms of integrity, transparency, and accountability. These layers should not be interpreted as mandatory components of a single fixed architecture, but as optional mechanisms that can be selectively adopted and progressively combined to achieve increasing levels of assurance.

In this sense, the framework is both modular and progressive: stakeholders may choose minimal configurations based on off-chain integrity and logging, or adopt more advanced layers (e.g., blockchain governance, smart contracts, or certified computation) depending on performance, privacy, interoperability, and governance requirements. This section introduces the resulting design space and discusses the associated trade-offs.

Layer 1: Content-addressed storage and integrity anchors (e.g., IPFS-like approach)

A first trust layer is achieved by separating data storage from trust in the storage provider. Content-addressed storage assigns a stable identifier to each dataset based on its content digest, enabling any party to verify that retrieved data match the declared identifier. This approach improves long-term traceability and supports distributed access while keeping heavy data off-chain. Limitations include data availability management (pinning/replication), access control design, and operational overhead when integrating with legacy data pipelines.

Layer 2: Blockchain ledger for immutable logs (public vs. consortium vs. private)

A blockchain ledger provides a tamper-resistant timeline of events, data anchors, and governance actions. From an architectural perspective, blockchain deployment can be interpreted along a single dimension with three main configurations: public, consortium, and private networks. Each configuration reflects a different trade-off between decentralization, performance, and governance.

- **Public blockchains** maximize transparency and third-party verifiability, but may raise concerns on transaction costs, throughput, and governance externalities.
- **Consortium / semi-private** networks balance decentralization and performance by restricting validators to identified organizations, improving scalability while preserving shared governance.
- **Private ledgers** provide high performance and administrative control but shift trust toward a single operator and may weaken independent verifiability.

In all cases, practical designs store only compact evidence on-chain (hashes, identifiers, proofs), while keeping datasets and detailed documents off-chain.

Layer 3: Smart contracts for automated and auditable workflows

Smart contracts implement transparent and deterministic rules that are executed on-chain and recorded immutably. In the proposed framework, they do not perform structural analysis or SHM computations, but act as a governance and orchestration layer connecting data, diagnostics, and management actions.

More specifically, different types of smart contracts can be introduced to support distinct functions along the workflow (Xu et al., 2021; Mariniello et al., 2025). These include:

- **Data validation and provenance contracts**, which register dataset identifiers and verify data integrity and quality before use;
- **Diagnostic certification contracts**, which record and validate the outputs of anomaly detection algorithms;
- **Response or workflow contracts**, which activate predefined management procedures based on alert conditions.

Within bridge management, these contracts enable the automation of governance logic, such as classification rules, response activation, deadlines and escalation paths, multi-signature approvals, and auditable milestone recording. For example, when an alert exceeds a predefined threshold, a smart contract may trigger a corresponding response playbook, notify responsible stakeholders, enforce time constraints, and require formal approvals before progressing to subsequent stages.

Importantly, the framework advocates *automation with oversight*: smart contracts formalize and enforce the decision process, but do not replace engineering judgement. All computationally intensive tasks and technical assessments remain off-chain, while smart contracts ensure that actions are consistent, traceable, and accountable across stakeholders.

Layer 4: Certified algorithm execution (TEE and ZKP as alternatives)

Even with data anchors and on-chain governance, a major trust gap remains if diagnostic computation is performed off-chain without verifiable execution. To reduce this gap, the framework introduces optional mechanisms to certify that a declared algorithm was executed on declared data:

- **Trusted Execution Environments (TEE)** provide hardware-isolated execution and remote attestation reports. They offer near-native performance and practical deployability, at the price of relying on hardware vendors and being potentially exposed to implementation and side-channel risks (Sabt et al., 2015).
- **Zero-Knowledge Proofs (ZKP)** can, in principle, provide cryptographic evidence that a computation was executed correctly with respect to its formal semantics, potentially without revealing proprietary details. They offer strong verifiability but may introduce substantial computational overhead and engineering complexity, especially for floating-point intensive pipelines and large datasets (Sun et al., 2021).

In this paper, these mechanisms are treated as part of a design space rather than a mandatory requirement: stakeholders may choose different layers based on the required assurance level and operational constraints.

Summary and trade-off table

The layered structure presented in this section directly reflects the methodological approach described above, where each trust layer corresponds to a specific class of trust gaps identified in the monitoring-to-intervention workflow. Table 1 summarizes the role of each technology and highlights typical advantages and limitations. The table is intended as a practical decision aid when assembling a trust-aware bridge management architecture.

Discussion

The proposed framework frames bridge management as a verifiable digital workflow rather than as a collection of disconnected tools. A key implication is that trust is not a binary property, but a configurable design choice. Different stakeholders and decision contexts require different assurance levels, and the framework allows these to be addressed without enforcing a single technological solution. For example, routine monitoring activities within a single organization may only require basic data integrity and logging mechanisms. In contrast, safety-critical decisions, contractual disputes, or regulatory reporting may benefit from stronger guarantees, such as immutable governance logs or certified computation. By separating the functional workflow from the trust layers, the framework supports incremental adoption and avoids unnecessary overhead where it is not justified.

The discussion also highlights a fundamental tension be-

Table 1: Trust layers and digitalization options: role, benefits, and limitations.

Layer / Technology	Primary contribution	Main limitations / trade-offs
Content-addressed storage (e.g., IPFS-like)	Integrity-by-design through content hashing; scalable off-chain storage; persistent references via content identifiers; facilitates distributed access and reproducible evidence chains.	Data availability management (pinning/replication) required; access control and confidentiality must be handled outside the storage layer; integration effort with existing pipelines.
Blockchain ledger (public)	Strong immutability and broad third-party verifiability; ideal for public audit trails and long-term non-repudiation.	Higher transaction costs and limited throughput; potential privacy concerns for metadata; governance and upgradeability depend on public ecosystem.
Blockchain ledger (consortium / semi-private)	Shared governance among identified participants; improved performance and easier alignment with regulatory/compliance constraints.	Less decentralization than public chains; requires formal consortium arrangements and operational coordination among validators.
Blockchain ledger (private)	High throughput and administrative control; straightforward integration inside a single organisation.	Trust is concentrated in the operator(s); weaker independent verifiability and reduced external auditability.
Smart contracts	Deterministic, auditable workflow logic: automate notifications, deadlines, escalation, multi-signature approvals and immutable event logs.	Correctness/bugs and upgrade governance are critical; legal and organisational alignment needed; smart contracts should orchestrate processes, not replace engineering judgement.
TEE-based execution certification	Hardware-isolated execution with remote attestation; near-native runtime performance; suitable for complex, floating-point-intensive pipelines.	Relies on hardware trust (vendor certificates); vulnerable to side-channel attacks and implementation flaws; attestation proves platform+binary, not full semantic correctness of the algorithm.
ZKP-based computation proofs	Cryptographic binding of input, computation and output; strong mathematical verifiability and optional privacy-preserving proofs.	Potentially very high proof-generation cost for large or floating-point workloads; engineering complexity and immature tooling for some classes of SHM algorithms.

tween transparency and operational constraints. While strong auditability improves accountability, it may conflict with privacy requirements, proprietary algorithms, or regulatory restrictions on data sharing. The proposed architecture mitigates this tension by relying on off-chain storage and selective on-chain anchoring, but careful system design remains essential to prevent sensitive information leakage while preserving verifiability.

Another important aspect concerns the role of automation. Although smart contracts enable deterministic and auditable workflows, they are not intended to replace engineering judgement. In the proposed framework, automation is used to enforce procedures, deadlines, and traceability, while technical assessments and final decisions remain under human control. This distinction is particularly important in bridge management, where safety considerations require conservative and accountable decision-making.

Finally, the comparison between Trusted Execution Environments and Zero-Knowledge Proofs illustrates that certified computation is technically feasible, but context-dependent. Hardware-based approaches currently offer a pragmatic balance between performance and assurance for complex SHM pipelines, while cryptographic proofs provide stronger theoretical guarantees at the cost of higher computational effort. The framework accommodates both approaches, allowing stakeholders to select the most appropriate option for their use case.

Conclusions

This paper proposed a trust-aware methodological framework for automated bridge management that spans the full path from sensing to intervention. The approach integrates scalable off-chain data handling with blockchain-based governance and introduces a layered view of digitalization, where additional "trust layers" can be progressively added to improve integrity, transparency, and accountability.

The core contribution of this paper is the definition of a structured design space and a comparative analysis of the main technologies that enable trust-aware digital workflows. These include content-addressed storage for data integrity, different blockchain deployment models, smart contracts for workflow governance, and mechanisms for certifying algorithm execution such as Trusted Execution Environments and Zero-Knowledge Proofs. By combining these components appropriately, bridge management systems can embed verifiability into digital processes while remaining adaptable to performance, privacy, and organizational constraints.

Future work will focus on several complementary directions. A first line of development concerns the extension of trust layers to additional stages of the infrastructure lifecycle, including sensor-level validation, inspection data certification, and the integration of digital twin updates within verifiable workflows.

A second research direction involves hybrid verification strategies. As zero-knowledge technologies mature and

hardware-based trusted execution evolves, combinations of TEE and cryptographic proofs may reduce trust assumptions while maintaining acceptable performance for data-intensive SHM applications. Evaluating these hybrid approaches in realistic operational settings remains an open challenge.

Further work is also needed to address interoperability and standardization. Integrating trust-aware workflows with existing monitoring platforms, asset management systems, and regulatory reporting processes requires well-defined interfaces and shared data models. Progress in this direction is essential to enable adoption beyond isolated pilots.

Finally, scaling the proposed framework from single assets to bridge networks represents an important step. Network-level deployment would enable coordinated risk assessment, prioritization of interventions, and transparent allocation of resources across multiple infrastructures, aligning the framework with the needs of infrastructure owners and public authorities.

USAGE POLICIES FOR FRAGMENTED DIGITAL PRODUCT PASSPORT DATA RETRIEVAL IN AECO DATA SPACES

Krista van Zandwijk, Ekaterina Petrova, Rik Eshuis and Pieter Pauwels
Eindhoven University of Technology, Eindhoven, The Netherlands

Abstract

Decentralized digital product passports (DPPs) retrieval via data spaces are emerging as a promising approach to enable material reuse in the Architecture, Engineering, Construction, and Operations (AECO) industry. Yet, no DPP-specific operational data space currently exists, and usage policy implementation remains unexplored. Building on Eclipse, this paper develops a proof-of-concept DPP data space, implementing asset registration, usage policy definition, contract negotiation, and authenticated data retrieval. Demonstrated through a suspended ceiling element, the research shows how multiple data providers can offer modular DPP data under differentiated usage policies, offering the first technical validation for decentralized DPP exchange in the AECO industry.

Introduction

To stimulate construction and demolition waste (CDW) reuse, European policies, such as the Construction Products Regulation (CPR) and the Ecodesign for Sustainable Products Regulation (ESPR), mandate the development of Digital Product Passports (DPPs) (European Parliament and European Union Council, 2024b; European Commission, 2025). DPPs are defined as *'a set of data specific to a product that includes information specified in the applicable delegated act and that is accessible via electronic means through a data carrier'* (European Parliament and European Union Council, 2024a, p.28) and aim to support the reuse of CDW by enabling more informed decision-making throughout the value chain (Kovacic et al., 2024). However, their current implementations fall short. In the absence of a common data standard, DPPs are developed as client-specific, non-interoperable formats, and are typically managed as static documents, resulting in incomplete and quickly outdated DPPs (Zhang et al., 2026).

Addressing these limitations requires DPPs to function as dynamic records that continuously reflect up-to-date lifecycle information (Çetin et al., 2023). This, in turn, calls for a shift from centralized data management toward decentralized frameworks, where data remains with the stakeholders who generate and maintain it (Bucher et al., 2025). A promising solution is the data space framework as proposed by the International Data Spaces Association (IDSA), which is *'a data integration concept which does not require common database schemas and physical data integration, but is rather based on distributed data stores and integration on an "as needed" basis on a semantic level'* (Nagel and Lycklama, 2021, p. 7). Data spaces enable federated, secure, and interoperable data retrieval while preserving data sovereignty (International Data Space Association, 2024).

A central mechanism for ensuring sovereignty in data spaces is the specification of usage policies, which define how, by whom, and under what conditions data may be used. Steinbuss et al. (2021, p.11) define usage control as *'specification and enforcement of restrictions regulating what must (not) happen to data'*. Usage control extends traditional access control by enforcing these policies continuously, regulating how data can be processed, aggregated, or shared even after access has been granted (Steinbuss et al., 2021). For DPPs, this would, for example, enable stakeholders to disclose only the information necessary for circular practices, such as material composition, demountability instructions, or maintenance history, while restricting the use of commercially sensitive data, preventing unauthorized redistribution.

However, no dedicated data space exists for DPP creation and management in the Architecture, Engineering, Construction, and Operations (AECO) industry, and consequently, no usage policies have been established to govern DPP data retrieval. Prior research has not investigated the implementation of these policies, leaving it unclear how an end-to-end technical pipeline can operationalize usage policies to allow multiple data providers with differing data types and related protection needs to share DPP data securely and effectively.

To address this, this paper explores the first domain-specific investigation of usage policy formulation for AECO DPP data retrieval. It demonstrates a proof-of-concept DPP data space that implements the full technical pipeline, including asset registration, access and usage policy definition, contract negotiation, and authenticated data retrieval. The approach is validated in a real construction case, where three distinct data providers, each with differentiated and stakeholder-motivated usage policies, offer their data and one data consumer retrieves it.

The remainder of the paper is structured as follows. The next Section presents a systematic literature review following the PRISMA methodology (Page et al., 2021), covering related work on data spaces, usage policies, and DPPs. The Methodology Section then describes the development

of the end-to-end technical pipeline. The prototype is tested in a real construction environment, illustrating the data offering and retrieval process for a suspended ceiling component from a demonstrator project in the Netherlands, with the results presented in the Results Section. Finally, the last Section concludes with a discussion of the findings and outlines directions for future research.

Related Work

Data Space Architecture

The International Data Space (IDS) Reference Architecture Model (RAM) 4, developed by the International Data Spaces Association (IDSA), is the most widely adopted system architecture to develop data spaces (Gabellini et al., 2025). As shown in Figure 1, each data space participant has a verified digital identity and an IDS Connector, which form the core of the data space. The verified digital identity, authenticated and authorized by the identity provider, ensures trust and accountability, while the connector acts as a secure gateway, enabling controlled data access while keeping data stored at its source. Data providers define usage policies that specify how their data may be accessed and used. The data space itself does not store the actual data; it only exchanges metadata and enforces policies, while the real data flows directly between connectors once all requirements are met (International Data Space Association, 2024). Beyond these core components, the IDS framework includes several federated services that support data space operations. A Broker enables the publication and discovery of dataset metadata, while the Vocabulary Hub ensures semantic interoperability through shared ontologies. The App Store offers certified applications for data processing, transforming, or integration, and a Clearing House ensures accountability by monitoring, logging, and verifying data-sharing activities.

Few studies have examined the application of data spaces in the AECO industry. Cuno et al. (2019) proposed an urban data space model based on a German municipal case, while Gil et al. (2024) developed a regulatory framework that uses a building data space to automate and digitize building permit processes. Demonstrating its applicability in circular construction, Hagedorn et al. (2025) validated the integration of data space principles with Information container for linked document delivery (ICDD). Complementing these technical contributions, van Zandwijk et al. (2025) examined how data spaces should be designed at the User Interface (UI) level to meet user needs and align with existing AECO workflows.

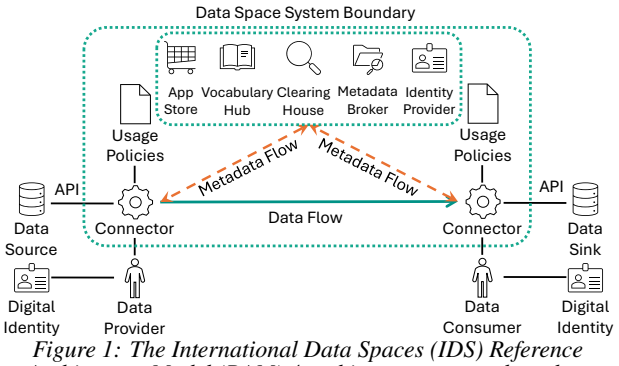

Figure 1: The International Data Spaces (IDS) Reference Architecture Model (RAM) 4 and its components, based on International Data Space Association (2024).

Usage Policies

Usage policies and contract negotiation lie at the core of data offers and retrieval within a data space. When offering data, data providers attach a usage policy specifying what data consumers are allowed to do with the data once they have authorized access. In IDS, these policies are described in JSON-based contracts with a fixed structure, consisting of contract metadata and a set of usage control policy rules that define permissions, prohibitions, and obligations for data usage, as shown in Figure 2. Steinbuss et al. (2021) propose 21 classes of usage control rules, which can be combined to create tailored policies covering a wide range of mechanisms, including constraints on users, systems, locations, purposes, time, or security level, as well as rules for modification, logging, notifications, redistribution, encryption, and contractual conditions.

The usage control policy can be specified using the IDS Usage Control Language (UCL), a technology-independent, machine-readable language based on W3C's Open Digital Rights Language (ODRL) and represented in JSON-LD (Steinbuss et al., 2021). While ODRL can express usage rules, it lacks built-in enforcement capabilities, requiring external systems or additional machine-readable policy languages to implement and monitor compliance (Petrova-Antonova et al., 2026). Although enforcement is essential for a trusted data space where usage policies are effective, it is beyond the scope of this study and remains an important topic for future research. Existing research on usage control in data spaces focuses predominantly on the technical aspects of usage policy creation, negotiation, and enforcement. For example, Yang et al. (2022) propose a negotiation scheme for IDS usage policy generation, while Munoz-Arcentales et al. (2020) implement and validate a FIWARE-based architecture that enforces usage control across multi-organization environments. Similarly, Dam et al. (2023) formalize domain-specific usage-control patterns in ODRL for mobility data spaces.

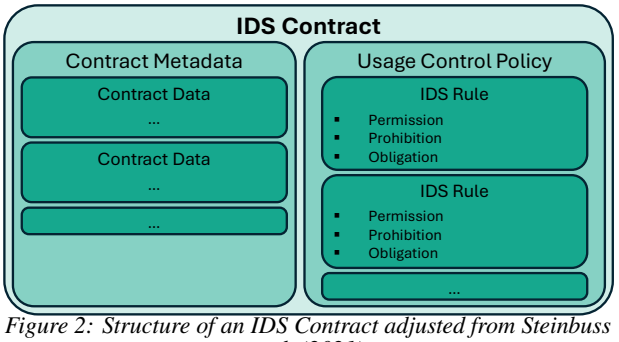

Figure 2: Structure of an IDS Contract adjusted from Steinbuss et al. (2021).

However, to the best of the authors' knowledge, no prior work investigates the implementation and negotiation of usage policies for DPP data retrieval in the AECO industry. AECO data is often complex, multi-stakeholder related, and commercially sensitive, making dedicated data spaces and tailored usage policies particularly important for this domain. The absence of domain-specific studies shows the need to explore how usage policies can support trustworthy, compliant, and efficient DPP data retrieval in circular construction contexts.

Digital Passports

Digital passports, first mentioned in 1982, gained momentum after the 2017 Buildings as Material Banks (BAMB) report (van Capelleveen et al., 2023), with the ESPR and revised CPR establishing EU-wide frameworks and registries for construction products and materials. Despite this progress, the implementation of DPPs is still evolving due to two key challenges. First, the absence of a fully standardized regulatory framework creates uncertainty about what information a DPP should contain. Second, there is no standardized digital infrastructure to support the generation, retrieval, and maintenance of DPP data across stakeholders.

Several studies have investigated the information requirements for digital passports. For example, Çetin et al. (2023) investigate data needs and actual data availability in the existing building stock, identifying eight relevant categories, including building general information, product general information, product properties, product safety, health and environment, product operational aspects, and product end-of-life aspects. Similarly, Akbarieh (2023) conducts a literature review of 146 publications and groups information needs into six categories, ranging from general information to properties requirements for safe transformation, intervention, circular information, to structural considerations. Complementing these perspectives, Byers et al. (2024b) propose a taxonomy for information acquisition to support material reuse, distinguishing between material reuse actions, information properties, and information sources.

Next to that, a variety of infrastructures have been proposed to enable DPP data exchange and retrieval. Based on a cross-domain review of 186 publications, Zhang et al. (2026) identify Distributed Ledger Technologies (DLT), ontology and knowledge-graph–based approaches, Digital Twins, and sector-specific systems such as BIM and Digital Building Logbooks (DBLs) as the most common technologies used in the construction industry. Centralized platforms, as discussed in Kovacic et al. (2024), offer structured, updatable repositories but compromise data sovereignty and frequently yield incomplete datasets due to interoperability limitations between these platforms. DLT-based systems, as proposed by Byers et al. (2024a), support decentralized trust and immutable provenance, yet they do not provide fine-grained, dynamic, and enforceable usage policies without additional off-chain mechanisms (Rohrschneider et al., 2026). Linked Data and ontology-driven frameworks, such as the work of Kebede et al. (2024), offer machine-readable semantics and flexible querying, but similarly lack mechanisms for enforcing peer-to-peer usage rules during cross-organizational exchanges (Zhang et al., 2026). Emerging work on dataspace based DPPs by Gallina et al. (2025) and Belova et al. (2025) illustrate the potential of data spaces to overcome these limitations. Gallina et al. (2025) developed a data space prototype for dynamic DPP management in an industrial case of a furniture dealer. They explores various possibilities enabled by data spaces and ontologies while identifying several challenges, such as missing standards and procedures concerning trust and data usage control. Belova et al. (2025) propose an initial architecture of a DPP system using data spaces and Knowledge Graphs, using carbon foot printing in the wood processing industry as context. Their focus lie in the proposal of a conceptual architecture, and the specific usage policies are outside the scope. Zhang et al. (2026) identify a persistent privacy–security trade-off in current DPP implementations, recognizing that additional technologies are often needed to achieve the needed privacy and security levels. However, this typically address only secure access control, not usage control. Data spaces address this gap by providing both fine-grained access control and enforceable usage control.

Methodology

To explore how usage policies can support DPP data retrieval in an AECO data space, this research simulates the retrieval of DPP information from a real-life demonstrator project using a suspended ceiling element. The simulation evaluates how modular DPPs can be shared while respecting data providers' data sharing constraints. This Section introduces the case study, the modular DPP structure, the data space prototype, and the simulation setup.

Case Introduction

The research builds on the Foppingadreef project, a renovation project of a Dutch bank's headquarters. Originally constructed in 1985, the building underwent renovation and expansion in 2022, unconsciously aligning with the three step process for reuse proposed by Bellini et al. (2024), which consists of collecting information, performing information-driven evaluations, and planning for reuse. Although the renovation comprises thousands of construction elements, this study specifically focuses on the reuse of a suspended ceiling. At the start of the renovation, the building contained an estimated 82,665 ceiling panels, which were in good condition and easily demountable. During the renovation, one-third of these panels were reused on-site, while the remaining two-thirds were repurposed in another building. This requires DPP data sharing in a complex multi-actor environment where well-defined usage policies are essential to enable secure and dynamic DPP data retrieval.

DPP creation

Since the Foppingadreef was built in 1985, no DPPs or BIM models existed at the start of renovation, an issue also identified by Çetin et al. (2023). Therefore, a material inventory was created listing all visible building elements and their properties, including suspended ceilings. For these elements, the collected data was converted into a modular DPP using the networked DPP ontology by Jansen et al. (2024). Modular DPPs are necessary to achieve scalable and cost-effective DPP solutions in complex, multi-actor environments, such as the AECO industry (Zhang et al., 2026).

The DPP ontology network developed by Jansen et al. (2024) is sector-agnostic, meaning it is not tailored specifically to construction materials and may therefore be too generic to capture sector-specific nuances. Nevertheless, Jansen et al. (2024) aligned their ontology with the requirements of the ESPR, ensuring compliance with emerging regulatory requirements. Another suitable ontology is the modular DPP ontology proposed by Kebede et al. (2024), which is explicitly designed for products in the built environment. However, as this ontology is not published online, the present study adopts the published ontology of Jansen et al. (2024).

Although this study adopts the DPP ontology network for demonstration, data spaces support heterogeneous data models, as long as each dataset is accompanied by the appropriate documentation. In practice, various data standards can coexist within the same data space. The DPP ontology network is used in this research to illustrate how a complete end-to-end pipeline operates, but alternative data models or ontologies can also be used. Nevertheless, mapping different ontologies for an interoperable, scalable DPP system is beyond the scope of this research.

The DPP ontology network comprises five interconnected parts; The *DPP Ontology Design Pattern (ODP)*, which introduces the core concepts *Product* and *DPP* and their part–whole relations; The *DPP Core*, which refines the *Product* concept into subclasses such as components, materials, and substances in line with EU directives like the ESPR; The *DPP Information* module, which models the various types of information a DPP may contain through reified information objects, such as characteristics, product quality, and certification data; The *Product Composition* module, which represents detailed part–whole relationships, including substances of concern; And finally, the *DPP Provenance* module, which supports tracking of actors and temporal validity associated with the DPP data.

To create this modular DPP, the data from the material inventory is supplemented with mock-up data, as the inventory only contains information obtainable through visual inspection and therefore lacks essential elements such as certificates, repair instructions, and fire safety documentation. Since this research focuses on retrieving DPP data via usage policies rather than creating a complete and fully accurate DPP, the enriched, partially synthetic DPP is considered sufficiently robust to demonstrate and validate the proposed concept.

Data Space Environment

A small-scale data space is created using the Eclipse Minimum Data Space (MVDS) framework[1]. The MVDS code enables the creation of a small-scale demo data space compliant with current standards, including the IDS Dataspace Protocol and Gaia-X–aligned trust and identity mechanisms. The Eclipse MVDS is chosen over IDSA's MVDS[2] as it represents the state-of-the-art in open-source data space implementations (Gabellini et al., 2025).

As shown in Figure 3, the MVDS consists of only the core components required to establish a functional data space: a connector and an identity hub for both data providers and consumers. Each connector includes an internal catalog that describes the metadata of the provided data and the associated policies. The provider's connector has two catalogs: a private catalog, accessible only to the data provider, and a shared catalog, which is accessible to other participants who meet the access policies defined for the catalog. The identity hubs use decentralized identifiers (DIDs), but in this demo, identities and credentials are pre-created and manually seeded. The dynamic issuance of verifiable credentials by trusted authorities lies beyond the scope of this study.

The MVDS code is run locally on Linux via IntelliJ, which provides configurations for consumer and provider connectors, identity hubs, the provider catalog server, and a compound 'dataspace' setup to start all runtimes simultaneously. A NGINX instance hosts the issuer's DID document, with port mapping aligned to the expected DID. Once the runtimes are running, the data space is initialized using the provided seed.sh script to set up the Participant Contexts and enable connector-to-connector communication. REST API interactions can then be executed via the included Postman collection.

Scenario simulation & Policy formulation

To demonstrate the full technical pipeline, the research build upon a scenario in which multiple data providers offer different parts of a modular DPP with a single data consumer, conceptually shown in Figure 4. Three actors

[1] https://github.com/eclipse-edc/MinimumViableDataspace

[2] https://github.com/International-Data-Spaces-Association/IDS-testbed

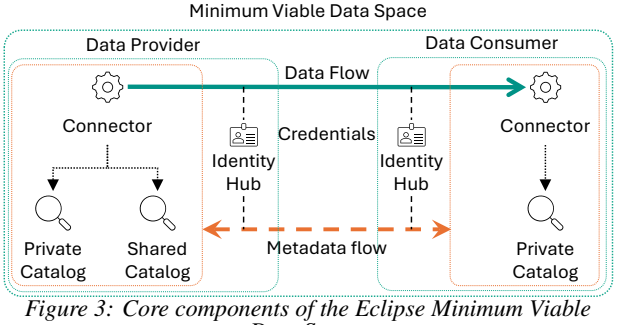

Figure 3: Core components of the Eclipse Minimum Viable Data Space.

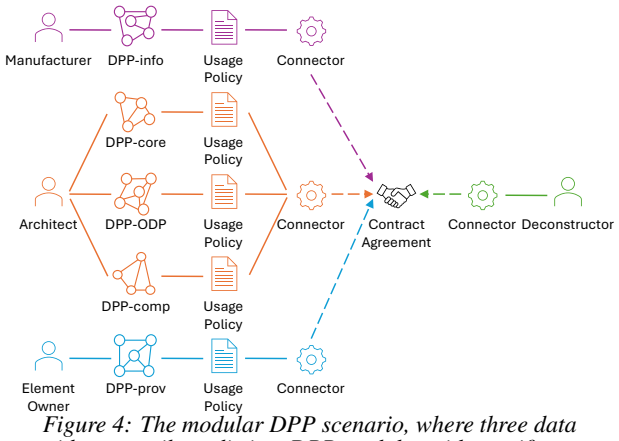

Figure 4: The modular DPP scenario, where three data providers contribute distinct DPP modules with specific usage policies, all accessed by a single data consumer.

act as data providers: the manufacturer, the architect, and the element owner. Each contributes specific DPP modules: the manufacturer supplies DPP-info; the architect provides DPP-core, DPP-ODP, and DPP-comp, and the element owner supplies DPP-prov. Verstraete et al. (2025) argues that data providers are reluctant to share data with other stakeholders, and Dam et al. (2023) argues that different data providers may have different data sharing constraints depending on their role and data offer. Hence, each data offer has its own sharing constraints and therefore usage policy. The manufacturer protects competitive information and limits liability by allowing DPP-info access only for safety, planning, and compliance during the deconstruction project. The architect safeguards intellectual property by permitting read-only access while prohibiting modification, redistribution, and printing. The element owner prioritizes privacy, requiring one-time read access, mandatory deletion within 24 hours, and notifications upon access. The usage policy for the architect is shown in Listing 1. This IDS contract permits the data consumer to read and display the specified dataset, while prohibiting modification, distribution, or printing.

These policies and constraints are hypothetical mock-up scenarios designed to demonstrate the proof of concept. However, the specific differences in usage policies per stakeholder group and data type for DPP data in the AECO industry is unexplored. Therefore, this research builds upon these fictitious scenarios to illustrate the modular DPP approach, but future work should explore specific differences in usage policies per stakeholder groups and data types.

Listing 1 Example of an IDS Usage Policy describing permitted and prohibited actions for using the DPP-core asset.

Results

The Eclipse MVDS provides a small-scale data space where participants can offer and retrieve data through a six-step process, as illustrated in Figure 5. This Section describes each step of this process in detail. Sequence diagrams for all steps are available on GitHub[3], but are not shown here due to space constraints.

Creating the Asset and the Usage Policies

First, the data offer must be registered in the connector by the data provider. This registration should include a short description of the dataset and the base URL that can be used to access the data. Next, several policies need to be defined. The first is an access policy, which ensures that only participants with an active membership credential are allowed to use the asset. The second is a data usage policy, which specifies how the data can be processed and allows the data provider to enforce different usage rules

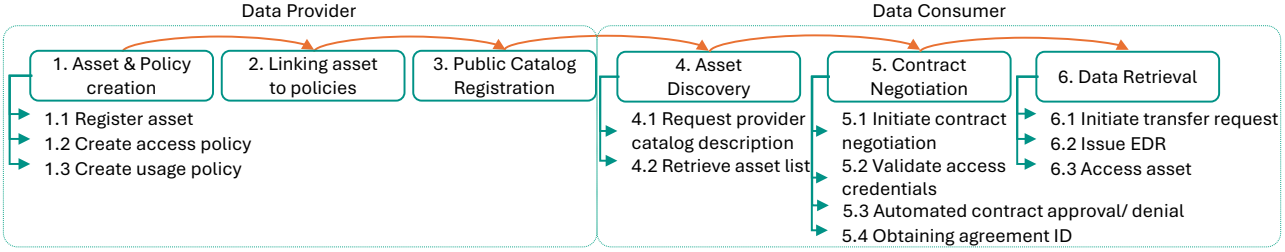

Figure 5: Six-step process outlining how data providers and consumers offer and retrieve DPP data within the data space.

depending on the type of data or the requirements of the data provider. The usage policy for the architect is already shown in Listing 1. Finally, these policies are linked to the specific asset through a contract definition, ensuring that the rules apply whenever the asset is accessed.

Public Catalog Registration

The data now has a dedicated policy but is not yet discoverable in the data space. To make it visible, the asset must be registered in the shared catalog of the provider's connector and linked with its access and usage policies. Only participants who satisfy the access policy can discover the asset, and those meeting the usage policy can access and use it under the defined conditions.

Asset Discovery

Next, the data consumer can explore available data offers. Assuming that they meet the access policy, they request the catalog from the data provider's connector, retrieving the list of exposed assets. The data consumer then queries the cached catalogs to identify the applicable policies for contract negotiation, enabling an informed decision on which data to request.

Contract Negotiation

Based on this information, the consumer initiates a contract negotiation, of which the process is shown in Figure 6. The data provider's connector verifies the data consumer's DID against the access policies. If the data consumer complies with the predefined terms, the negotiation is automatically accepted, and rejected otherwise. For now, this means that the negotiation process functions as a contract validation mechanism rather than an interactive bilateral negotiation, which is something that should be explored in future research. Once approved, the consumer receives a contract agreement ID to initiate the data transfer.

Data Retrieval

Using the agreement ID, the data consumer initiate the data transfer. The transfer is tracked via transfer processes, and the consumer retrieves the corresponding Endpoint Data Reference (EDR) to get the data address and authorization token. Finally, the data consumer uses this information to access the data from the data provider.

Following this process, the manufacturer, architect, and element owner each provide their respective DPP modules for the suspended ceiling element. The deconstructor retrieves each module in accordance with the corresponding usage policies, ensuring compliance with each provider's constraints. By repeating this process for all relevant assets, the deconstructor obtains access to the modular DPP data for the ceiling element.

Conclusion

This paper demonstrates how usage policies can enable modular and decentralized DPP data provision and retrieval within an AECO data space, using a suspended ceiling element as example. The research shows how building-product data supplied by multiple data providers can be offered and retrieved using differentiated usage policies. In doing so, the study contributes an exploratory proof-of-concept DPP data space that implements the complete technical workflow, including asset registration, access and usage policy definition, contract negotiation, and authenticated data retrieval. Because this research is based on hypothetical scenarios and a limited set of generic policy templates, it should be considered as an initial exploration rather than a mature implementation of usage poli-

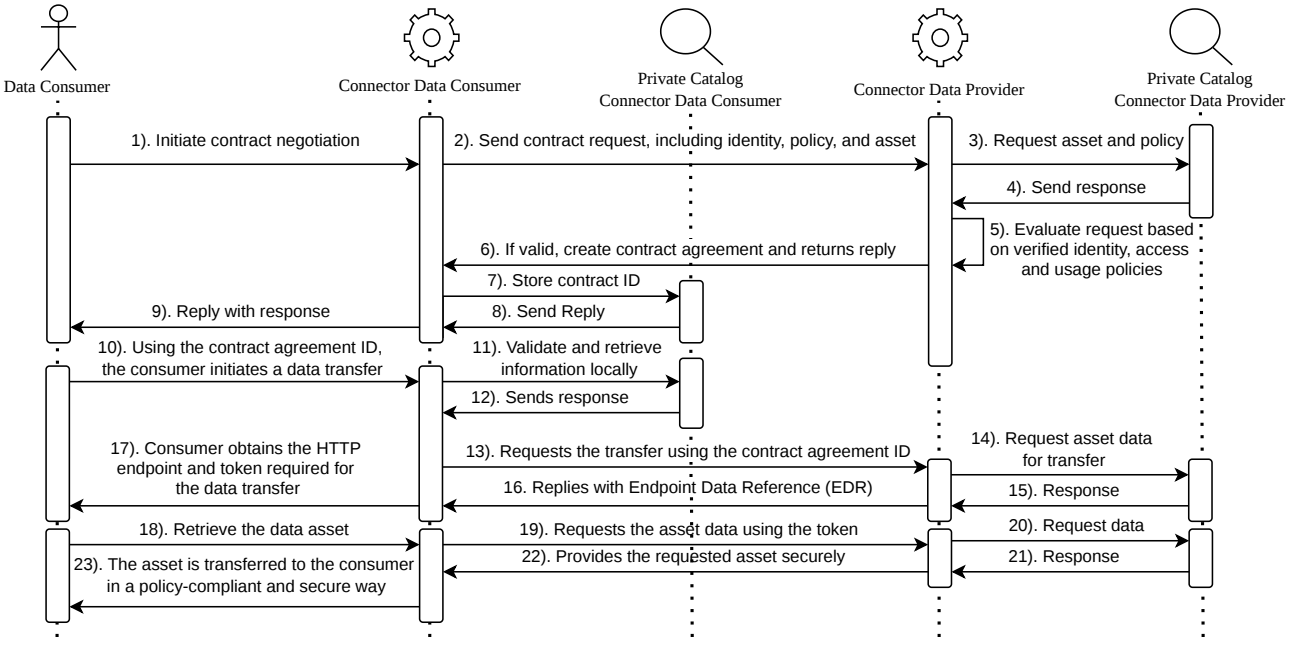

Figure 6: Sequence diagram showing contract negotiation and data retrieval between data provider and consumer.

cies in the AECO domain. Advancing toward operational deployment will require future research in several directions.

First, further work is needed to understand which specific usage-policy requirements AECO stakeholders have when sharing product-related data. Real-world needs must be validated to determine whether existing IDS policy templates are sufficient or require domain-specific extensions. As also highlighted by Bastiaansen et al. (2020), future research should therefore examine stakeholder- and data-specific policy needs while also developing more efficient negotiation mechanisms that prevent repetitive, module-by-module contracting and thus support both scalable and flexible DPP retrieval for data consumers.

Second, defining a usage policy is only one part of effective data governance; enforcing and monitoring compliance is another issue, as demonstrated in Cimmino et al. (2025). Future research should investigate mechanisms to verify policy adherence both within and beyond the boundaries the data space.

Third, as also highlighted by Sołtysiński et al. (2025), usage policies rely on the trustworthiness of digital identities associated with both data providers and consumers. Future work should explore how self-sovereign decentralized identities and trust frameworks interact with usage control and how they can be integrated into AECO data spaces.

Abstract

This study examines social media public response and discourse patterns to critical infrastructure cyber disruptions through a reddit based multi-dimensional sentiment analysis of the Florida water treatment plant incident. Results from 300 most relevant posts indicate that discourse is highly time-sensitive (e.g., 90% of total engagement occurred within first six hours). Security concern emerged as the dominant sentiment (~50%), while humor and sarcasm (~26%) reflected social coping dynamics. The findings highlight how online community signals can inform crisis communication and public trust strategies, rather than technical cybersecurity management, to support more transparent, trust-oriented CI protection efforts.

Introduction

Critical Infrastructure (CI) constituting of facilities such as roads, bridges, power grids, nuclear facilities, water and wastewater distribution systems, and flood protection mechanisms are vital for any country's economy, security, and societal well-being. These are considered critical because of their functional significance, whose disruption could have severe consequences on public safety, health, and economic prosperity. For instance, the U.S. Department of Homeland Security (DHS, 2020) defines CI as "*the physical and cyber systems and assets so vital that their incapacitation or destruction would have a debilitating impact on our physical or economic security or public health or safety*". Similarly, the European Programme for Critical Infrastructure Protection (EPCIP) highlights the need for uniform protection levels, minimal single points of failure, and rapid recovery arrangements across the European Union (EC, 2006).

Traditionally, these systems and processes were operated, maintained, monitored, and inspected within their respective functional capabilities with little to no overlap among different CIs. For example, transportation network had no direct linkages on their operational synergies when compared to flood protection mechanisms. Technological advancements enabled synergistic, strategic, and efficient integration of different CIs. The growing interdependencies and technological integrations among CIs amplify their complexity, as disruptions in one sector can cascade into others, exacerbating the impact of failures (Mantha et al., 2024). Moreover, the increasing reliance on cyber-physical integration for real-time monitoring and control, where physical systems are interconnected with cyber systems, introduces vulnerabilities that make these infrastructures susceptible to cyberattacks. In an era of human-centred digital transformation, social media platforms serve as a crucial medium for connecting end users with policymakers, offering a dynamic space to share concerns, disseminate information, and respond to crises in real time. Such vulnerabilities can compromise the physical systems they govern, potentially leading to catastrophic failures (Palleti et al., 2021). This study critically examines these vulnerabilities of CIs to cyberattacks and explores the implications to ensure the resilience of such essential systems. Understanding public responses through social media can provide actionable insights that incorporate public feedback, fostering a more adaptive and resilient approach to managing cyber crises. Cyberattacks on these CI assets pose a severe threat to physical systems, potentially rendering them inoperable, delegating control to unauthorized entities, or compromising sensitive data (Pacheco et al., 2019). The interconnected nature of CI, while essential for meeting performance and design specifications, exacerbates these risks. Interdependencies among infrastructures mean that faults or attacks on one CI can cascade into others, leading to complex and unforeseen disruptions (Rinaldi et al., 2002). Such escalation can disrupt operations, initiate feedback loops, and amplify disturbances across interconnected systems (Palletti et al., 2021).

Despite significant advancements in securing networked control systems, existing technologies remain inadequate to address the fast-evolving threat landscape (Stellios et al., 2018). Furthermore, as technology advances, malicious actors continue to exploit vulnerabilities, using increasingly sophisticated tools to compromise systems (Tounsi and Rais, 2018). These disruptions inconvenience the public, disrupting daily life and eroding trust in essential services. Efforts to address these cybersecurity challenges vary internationally. For instance, the European Union Agency for Cybersecurity (ENISA) promotes a collaborative, multi-stakeholder approach to securing CI, with an emphasis on public-private partnerships and citizen engagement (Bossong and Wagner, 2017). In contrast, countries such as Japan and South Korea emphasize top-down regulatory frameworks with centralized response mechanisms (Aggarwal and

Reddie, 2018). These diverse models of policy and engagement reflect contextual differences in governance, digital infrastructure maturity, and cultural attitudes toward public trust in technology (Krishna et al., 2023). However, across these diverse international approaches it is important to understand community responses to cyberattacks necessitating the need for this research.

Social media analysis can serve as an early detection mechanism, offering valuable insights into public sentiment, concerns, and evolving perceptions of cybersecurity incidents, thus playing a pivotal role in shaping adaptive cybersecurity frameworks within the architecture engineering construction and facility management (AECFM) industry. In this context, understanding public reactions to cyberattacks can offer valuable insights for enhancing cybersecurity strategies and future infrastructure resilience. This study seeks to answer two research questions, 1) How does the public respond on social media during a cyberattack on critical infrastructure assets, and what patterns emerge in their engagement? 2) How can insights from non-expert public responses inform crisis communication and public trust strategies for future infrastructure projects?

To address these research questions, literature review section critically explores existing research, methodology section details the research methodology and case selection strategy, in which a case study approach is used focusing on the Florida water plant hack (CISA, 2021). Specifically, this case study was chosen due to its public involvement and reaction which is critical in the context of this study. Following this, the results and discussion section discusses the findings on how people react to the identified cyberattack. Finally, the conclusions and future work section details the contributions to theory, practice, study limitations and future research directions.

Literature Review

Cybersecurity Challenges of Critical Infrastructure

Critical infrastructure (CI) encompasses systems and functions essential for society's uninterrupted functioning, such as energy grids, transportation networks, water supply systems, and smart city technologies (Lehto, 2022). In recent years, cyberattacks targeting CI and critical information infrastructures have become increasingly frequent, complex, and targeted, as attackers grow more professional and sophisticated (Tounsi and Rais, 2018). These cyberattacks can disrupt or damage physical infrastructure by infiltrating digital systems controlling critical processes, leading to catastrophic consequences without requiring a physical assault. Such attacks may not only damage physical systems but also pollute environments, disrupt vital services, and compromise public safety.

The evolving nature of cyber threats compounds the challenges of defending against these attacks. Identifying the source, motive, and trajectory of an attack is notoriously difficult due to the global scope of cyberspace and blurred boundaries between national, international, public, and private interests (Lehto, 2013). Rapid technological advancements further complicate this landscape (Garcia de Soto et al., 2022), making it difficult to anticipate and mitigate new forms of threats. While existing literature emphasizes intrusion detection and prevention methods (Baykara and Das, 2018), these measures are often inadequate to address the dynamic and pervasive nature of modern cyber threats.

Human factors play a significant role in cyberattacks, often serving as the weakest link in cybersecurity. Reports indicate that employee errors account for a majority of data breaches, frequently exploited through social engineering tactics (Romanosky, 2016). At the same time, attackers leverage sophisticated techniques to exploit cyber-physical systems in critical sectors such as energy, water, and transportation, causing disruptions with far-reaching implications for public safety, economic stability, and trust (Stellios et al., 2018). For instance, cyberattacks have the potential to contaminate water supplies, disrupt electricity grids, or compromise transportation systems, highlighting the severe societal impacts of such crises (George et al., 2024).

Technical vulnerabilities in CI systems commonly stemming from legacy hardware and software, insufficient authentication protocols, and poor segmentation between IT and operational technology networks provide additional context for public responses (Sonkor and Garcia de Soto, 2021). Systems such as programmable logic controllers, SCADA platforms, and human–machine interfaces often lack robust cybersecurity measures because they were not originally designed with digital threats in mind (Stellios et al., 2018). These technical weaknesses can be considered important contextual factors affecting public perception and emotional response. Thus, the growing overlap of technical and social vulnerabilities, increased attack frequency, and severity of cyber incidents necessitates framing cyberattacks on CI as socio-technical crises.

Cyber Attacks as Socio-Technical Crises

Crisis, as a concept, encapsulates human reactions to significant disruptions or misfortunes, ranging from personal losses to large-scale societal events. Multiple frameworks help understand crises, including the Protective Action Decision Model (Heath et al., 2018), sensemaking theory (Maitlis and Christianson, 2014), and Situational Crisis Communication Theory (Coombs, 2007). Prior work has applied structured emotional trajectory models to interpret public reactions during disruptive events. While qualitative interpretations of emotional evolution remain useful, recent research increasingly treats crises as socio-technical phenomena observable through large-scale digital traces and measurable public discourse patterns.

The growing availability of social media data has enabled quantitative analysis of public responses to crises using natural language processing (NLP), network analysis, and engagement metrics. Social media platforms such as Reddit function as real-time participatory environments where users interpret events, assign accountability, and construct risk narratives during unfolding crises.

Comparative platform studies show that different social media environments generate distinct thematic and emotional patterns due to their structural affordances and communication norms (Kwon and Park, 2023). Reddit supports longer-form, focused and threaded discussions that enable users to express nuanced opinions and collectively interpret uncertain or controversial events, like group discussions and focused interviews. Quantitative social media research demonstrates that online discussions can reveal hidden facets of societal reactions, identify topic-aligned communities, and track the evolution of narratives (Goel and Sharma, 2020).

Network-based and linguistic analyses further show that language characteristics and engagement patterns influence how cohesive online communities form and how discourse evolves over time (Arazzi et al., 2023). Prior studies indicate that discussions of vulnerabilities and threats often emerge earlier or with deeper engagement on Reddit compared with other platforms, highlighting its potential as an early indicator of public awareness and concern (Horawalavithana et al., 2019).

These advances position social media as both a communication channel and a measurable socio-technical sensor for crisis dynamics. Quantitative analyses using sentiment scoring, topic modelling, and engagement metrics allow researchers to capture temporal shifts in public perception and identify dominant narratives surrounding risk, trust, and accountability. In addition, systematic reviews of Reddit-based research emphasize the importance of considering platform-specific norms, subreddit cultures, and ethical considerations when interpreting findings (Proferes et al., 2021).

Within this study, cyberattacks on CI are conceptualized as socio-technical crises that unfold through both technical disruption and public interpretation across decentralized online communities. Quantitative, thread-level analysis of Reddit discussions provides a means to observe how users collectively interpret infrastructure vulnerabilities, assign responsibility, and express trust or concern in real time. This framing integrates crisis theory with computational social media analytics, enabling the measurement of public sentiment trajectories and engagement patterns during cyber incidents.

Research Gaps and Contributions

The following are the three main research gaps based on the aforementioned discussion.

1)Human trust dynamics gap: There is limited evidence-based understanding of how decentralized online communities shape public trust, risk perception, and accountability narratives following cyberattacks on CI.

2)Methodological gap: Most existing studies focus on technical threat detection or rely on single-platform, polarity-based sentiment analyses, offering only partial insights into how public discourse and crisis narratives evolve in real time.

3)Analytical gap: Quantitative social media research has largely emphasized topic detection, vulnerability mentions, or information diffusion patterns, with limited use of multi-dimensional sentiment, engagement-aware metrics, and thread-level analysis to capture nuanced public reactions.

This study therefore contributes to advancing empirical understanding of public response dynamics during CI cyber disruptions by treating social media discourse as a measurable feedback signal for cybersecurity communication and resilience. The aims are to: (1) quantify key sentiment distributions in early-stage discussions, (2) examine thread-level and engagement dynamics shaping trust and risk narratives through the lens of Situational Crisis Communication Theory (SCCT), and (3) identify dominant discourse patterns that can inform more transparent and trust-oriented cybersecurity communication.

Methodology

The following interconnected subsections provide a coherent approach for quantifying public response patterns and addressing the study's objectives.

Research Design and Case Context

This study adopts a quantitative social media analysis approach to examine public responses to a CI cyber disruption through Reddit discourse. Cyberattacks on infrastructure systems often generate rapid and emotionally varied public reactions that unfold in real time across digital platforms. Social media platforms, particularly Reddit, provide a valuable data source for capturing these reactions because of their threaded discussion structure, relative anonymity, and capacity for detailed user commentary (Proferes et al., 2021). Unlike survey-based approaches that capture retrospective perceptions, Reddit discussions enable observation of emergent public sentiment during the early stages of a crisis, making them suitable for examining evolving trust, accountability, and risk narratives.

Building on prior qualitative work that examined emotional trajectories in cyber crisis discourse, this study extends the analysis through a quantitative, thread-level, multi-dimensional sentiment framework. The goal is to empirically capture how decentralized online communities interpret and respond to cyber disruptions affecting CI, with a particular focus on measurable sentiment patterns and engagement dynamics. While this study relies on a single-incident design, this approach aligns with recent sentiment literature that leverages single-case events to establish deep, thread-level analytical baselines (Goel & Sharma, 2020; Kahlawi et al., 2025; Ninan et al., 2025). Furthermore, it has to be noted that Reddit discussions enable the observation of emergent public sentiment during the early stages of a crisis as a first step, making them suitable for examining evolving trust, accountability, and risk narratives.

Data Source and Collection

Reddit was selected as the primary data source because its subreddit-based structure facilitates focused, topic-specific discussions and supports longer-form discourse compared with microblogging platforms. Previous

research shows that Reddit often hosts deeper and more sustained conversations on cybersecurity and infrastructure-related issues, making it a suitable platform for capturing nuanced public reactions (Horawalavithana et al., 2019). Furthermore, Reddit's threaded architecture enables analysis of conversational dynamics across original posts, comments, and replies.

Data were collected from relevant public subreddits discussing the selected cyber incident within the first week following the event. Figure 1 shows the pseudo code developed to achieve the same. The collection window was chosen to capture early public reactions, which are often critical in shaping trust and risk perception narratives during crises. Prior research suggests that the initial hours and days following a disruptive event are particularly influential in establishing dominant public narratives (Maitlis & Christianson, 2014).

The final reviewed, filtered, and cleaned dataset consisted of 300 posts spanned across 15 total subreddits, 20 original posts (OP), 66 comments, 214 replies. Data cleaning involved removing duplicate posts, irrelevant discussions, spam, and posts lacking substantive textual content. Only posts directly related to the incident and public reaction were retained. All data were drawn from publicly accessible Reddit threads and anonymized prior to analysis.

```
BEGIN PROCEDURE
  Load structured CSV containing Reddit posts and comments

  FOR EACH post/comment in dataset:
    Build thread context (chain parent comments for replies)

    Analyze relevance using OpenAI gpt-5.2-2025-12-11
      // Outputs: Relevant_to_attack, Relevant_to_thread + explanations

    Analyze sentiment tags using OpenAI gpt-5.2-2025-12-11
      // Outputs: 20 boolean tags + explanation
      // Tags: Denial, Anger, Bargaining, Acceptance, Anxiety, etc.

    Record results (relevance + tags + explanations) to dataset
  END FOR

  Save enhanced CSV with analysis results
END PROCEDURE
```

Figure 1: Pseudo code developed to pull the Redditt Data

Unit of Analysis and Data Preparation

The unit of analysis in this study is the individual Reddit post, defined as any original post (OP), comment, or reply within a discussion thread. This approach allows for capturing both primary narratives and conversational responses, providing a more comprehensive understanding of discourse dynamics. Previous research highlights that analyzing threaded discussions rather than isolated posts yields richer insights into collective sensemaking processes during crises (Kahlawi et al., 2025).

Each post was assigned a unique identifier and categorized by type (OP, comment, reply), subreddit, and time of posting. Basic engagement metrics including upvotes and interaction structure were recorded to support engagement-weighted analysis. Textual data were preprocessed by removing URLs, emojis where necessary for clarity, and non-relevant formatting while preserving semantic meaning. Posts were retained in their original wording to maintain contextual integrity for sentiment tagging.

Multi-Dimensional Sentiment Framework

To capture the emotional and interpretive dimensions of public response, this study applies a multi-dimensional sentiment framework consisting of eight categories namely 1) Denial, 2) Anger, 3) Bargaining, 4) Depression, 5) Acceptance, 6) Security Concern, 7) Sarcasm, and 8) Humor. Five of these categories (i.e., 1 to 5) were derived from the Kübler-Ross model of emotional response to crisis (Kübler-Ross, 1969). This model has been widely applied beyond grief contexts to understand reactions to disruptive societal events and organizational crises (Ninan et al., 2025). Its structured progression provides a useful lens for examining how individuals process shock, assign blame, and eventually move toward adaptation following a disruptive event.

However, applying the Kübler-Ross model alone is insufficient for analyzing social media discourse. To address this, these methods were calibrated for a sentiment analysis of a crisis response which augments the baseline emotional framework with interpretive and coping mechanisms such as humor and sarcasm, which function as social responses to uncertainty and stress. Including humor, sarcasm, and security concern allows for capturing these communicative behaviors that may not fit neatly within traditional emotional stages, making the framework defensible for digital discourse. Humor has been shown to act as a psychological coping strategy during crises, enabling individuals to process fear and anxiety collectively (Martin and Ford, 2018). Similarly, sarcasm is frequently used in online discourse to express skepticism, critique institutions, or signal distrust (Filatova, 2012). Including humor and sarcasm as distinct categories allows for capturing these communicative behaviors that may not fit neatly within traditional emotional stages. The category security concern was added to explicitly capture expressions of risk awareness, vulnerability perception, and calls for cybersecurity improvements. Prior research indicates that public discourse following cyber incidents often centers on perceived system weaknesses and demands for accountability, making this a distinct and analytically relevant category (Tounsi & Rais, 2018). Together, these eight categories provide a comprehensive framework for analyzing both emotional and interpretive dimensions of public response.

Sentiment Tagging Procedure

Sentiment tagging was conducted using a large language model (LLM) assisted classification process supported by manual verification through the algorithm logic represented as pseudocode in Figure 2. Each post was assigned sentiment categories based on its tone and intent. Where posts contained multiple sentiments, the most salient sentiment was selected to maintain consistency, but the others were preserved and allocated in quantitative aggregation. To improve tagging reliability, a subset of posts (e.g., 10% randomly sampled) were manually reviewed to confirm alignment between automated classification and contextual interpretation. While identifying sarcasm computationally has historically been

a significant challenge for traditional algorithms, modern Large Language Models have demonstrated high accuracy in emulating human experts' evaluation of complex public sentiments on social media (Kim & Kim, 2025). Furthermore, recent NLP literature confirms that advanced LLMs are highly reliable in detecting contextual sarcasm and irony in digital discourse. Consequently, verification threshold is also sufficient to confirm alignment. This hybrid approach effectively combines computational efficiency with human interpretive oversight, which is the recommended standard in current social media sentiment analysis research (Kim & Kim, 2025). Tagged data were then further analyzed to identify overall distribution patterns and dominant narrative themes

To improve tagging reliability, a subset of posts (e.g., about 10% randomly sampled) were manually reviewed to confirm alignment between automated classification and contextual interpretation. This hybrid approach combines computational efficiency with human interpretive oversight, which is recommended in social media sentiment analysis research (Kim & Kim, 2025). Tagged data were then further analyzed to identify overall distribution patterns and dominant narrative themes.

Engagement Metrics and Quantitative Analysis

Quantitative analysis focused on both frequency based and engagement-weighted metrics. Frequency counts were used to determine the proportion of posts associated with each sentiment category. Engagement-weighted metrics considered upvotes and reply structures to account for the visibility and influence of posts within discussions (Fottner et al., 2022). Engagement weighting is important because highly endorsed posts often shape perceived consensus within online communities (Arazzi et al., 2023). By examining both raw counts and engagement-adjusted measures, the analysis captures not only what sentiments are expressed but also which sentiments gain traction within the community. Descriptive statistics were used to summarize sentiment distributions, while cross tabulations examined variations across post types such as OP and comments.

Temporal and Thread-Level Analysis

Temporal analysis examined how sentiment distribution evolved during the initial response window. Posts were grouped by time intervals to identify early narrative formation and shifts in dominant sentiments. Previous research suggests that early discourse patterns can strongly influence long-term public perception of crises (Coombs, 2007). Thread-level analysis examined how sentiments propagated within discussions. This included identifying whether certain sentiments were more likely to appear in original posts versus replies, and whether humor or sarcasm functioned as responses to expressions of concern or anger.

Reliability and Ethical Considerations

As discussed earlier, to ensure analytical consistency, a subset of posts were manually reviewed to validate sentiment classifications. Tagging procedures and aggregation methods were documented to support reproducibility. Results were compared using both raw and engagement-weighted counts to compare and contrast stability of findings. All data analyzed were publicly available Reddit posts. Usernames were not recorded or reported, and findings are presented in aggregate form. No interaction with users occurred, and the study adheres to standard ethical practices for research using publicly accessible social media data (Proferes et al., 2021).

```
BEGIN PROCEDURE
  Load structured CSV containing Reddit posts and comments

  FOR EACH post/comment in dataset:
    Build thread context (chain parent comments for replies)

    Analyze relevance using OpenAI gpt-5.2-2025-12-11
      // Outputs: Relevant_to_attack, Relevant_to_thread + explanations

    Analyze sentiment tags using OpenAI gpt-5.2-2025-12-11
      // Outputs: 20 boolean tags + explanation
      // Tags: Denial, Anger, Bargaining, Acceptance, Anxiety, etc.

    Record results (relevance + tags + explanations) to dataset
  END FOR

  Save enhanced CSV with analysis results
END PROCEDURE
```

Figure 2: Pseudo code developed to conduct multi-dimensional sentiment tagging and analysis

Results and Discussion

This section presents the quantitative findings specifically, sentiment distribution and engagement patterns summarized in first, while thread-level dynamics and interpretation in the second. Lastly, implications and limitations connecting the results to broader cybersecurity and resilience considerations are detailed.

Sentiment Distribution and Engagement Patterns

The final filtered most relevant dataset comprised 300 posts across 15 subreddits within the early-response window following the cyber incident, including 20 OPs (6.7%), 66 comments (i.e., response made to an OP) (22%), and 214 replies (i.e., response made to a comment) (71.3%). The initial extraction yielded a larger candidate set, including 30 OPs after automated relevance tagging and manual contextual verification, this was refined to 20 original posts retained for analysis. A similar two-stage filtering process was applied to comments and replies, where non-relevant or context-detached items were removed. This hybrid human-in-the-loop screening ensured that only posts directly tied to the incident and its interpretation were included in the quantitative analysis.

Across the dataset, as can be seen in Figure 3, security concern appeared in almost half (50%) of all posts, emerging as the dominant sentiment category and reflecting widespread public attention to infrastructure vulnerability, system reliability, and accountability. Expressions of Anger (~20–25%) and Denial (<5%) were also present, particularly in original posts where users reacted to initial reports or questioned the severity and legitimacy of the incident. At the same time, Humor (~20%) and Sarcasm (~25–30%) appeared consistently across comments and replies, suggesting the use of coping and critique mechanisms common in online discourse during disruptive events. The remaining Kübler-Ross–

derived categories namely bargaining, depression, and acceptance (<15%) appeared in smaller but notable proportions, indicating a gradual shift in tone as discussions progressed from initial shock and skepticism toward reflection and normalization.

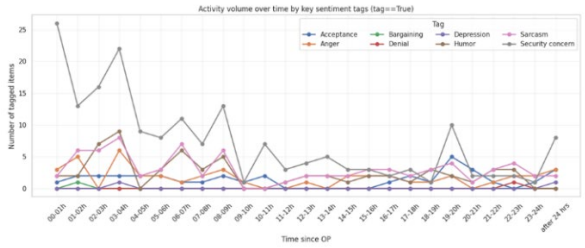

Figure 3: Temporal distribution of activity across different sentiments

Figure 4 reveals from the engagement patterns that a large proportion of total interactions occurred within the earliest hours of discussion. Nearly 50% posts were generated within the first six hours, while approximately 90% of cumulative engagement score was concentrated in this same early period, underscoring the rapid formation of public narratives. High-engagement posts were not always those expressing the most frequent sentiment, rather, posts combining concern with critique or humor often attracted the most interaction. The highest average endorsement per item occurred within the first hour after posting, suggesting that early contributions disproportionately shaped perceived credibility and importance. While original posts frequently introduced concerns or questions about the incident, replies tended to amplify or reinterpret these narratives, often through humor or sarcasm. This distribution highlights how public reaction to cyber disruptions unfolds through layered conversational dynamics rather than isolated expressions.

The analytical workflow used to generate relevance and sentiment tags involved automated LLM-assisted tagging followed by targeted human validation across sampled posts, ensuring alignment between computational classification and contextual interpretation. This process confirmed consistency between automated outputs and manual review, supporting the reliability of the final curated dataset and subsequent quantitative aggregation.

Thread-Level Dynamics and Interpretation

Thread-level analysis as shown in Figures 5 and 6 demonstrates that Reddit discussions function as decentralized spaces for collective sensemaking during infrastructure-related crises. For example, left to right represented from 0 (OP) to 1 (comment) to 2 (replies) and so on. Initial posts typically framed the event in terms of risk and vulnerability while comments and replies elaborated on these themes through personal interpretations, technical speculation, or institutional critique. For instance, security concern score – grey dropped from 73% to 47% while anger – orange increased to 23% and other sentiments peaked in the latter depths of discussions. Notably, denial is the least with about 1.6% which corroborates what was observed through the anger sentiment statistics observed. Activity volume peaked at early reply layers with most interaction occurring within the first two levels of response (layers 0,1 score > 1600 while layer 4 score ~ 400), indicating that collective interpretation emerges quickly once discussions begin. In several threads, expressions of concern were followed by humorous or sarcastic remarks that reframed the incident in more accessible or socially resonant terms (e.g., also evident from color tones in layers 1 and more but nonexistent in 0). Such patterns suggest that humor and sarcasm operate not merely as distractions but as mechanisms through which users negotiate uncertainty and express skepticism or distrust.

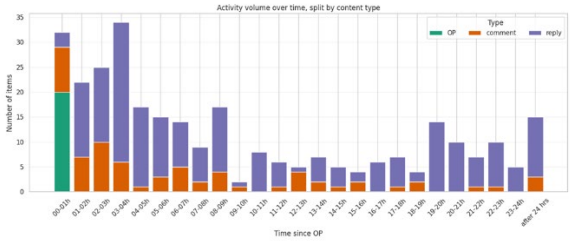

Figure 4: Distribution of activity type and volume over time

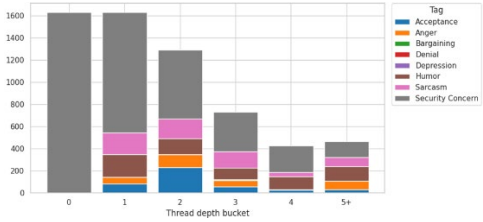

Figure 5: Thread depth weighted scores across sentiments

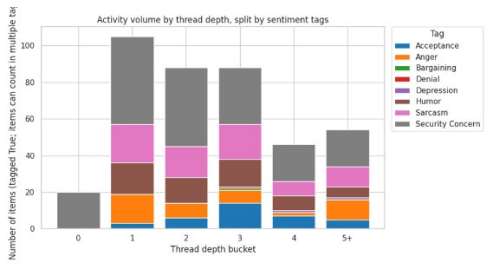

Figure 6: Thread depth activity across sentiments

The presence of Denial (rare at deeper levels) and Bargaining (moderate mid-thread presence) sentiments indicates attempts by some users to minimize perceived risk or reinterpret the incident's implications. Over time, however, these sentiments often gave way to Acceptance-oriented content (blue) in later discussion layers, reflecting normalization of systemic vulnerability discussions. This progression reflects the dynamic, non-linear nature of public response to disruptive events and supports the use of a multi-dimensional sentiment framework that captures both emotional and interpretive reactions.

From an analytical standpoint, these findings address previously identified gaps in understanding how decentralized online communities shape trust and risk narratives following cyber incidents. As guided by Situational Crisis Communication Theory (SCCT), the non-expert nature of this data is not a limitation but the

focal point of the study. The sample reflects public speculation, uninformed opinion, and casual commentary, which provides a direct, measurable lens into how sentiment evolves and which narratives gain traction to help agencies tailor their messaging and manage trust. The results demonstrate that public discourse is not only measurable but also structured by engagement dynamics that influence which narratives gain prominence during a crisis response. The iterative reduction from the initial candidate dataset including the refinement from 30 to 20 original posts and corresponding filtering across comments and replies also highlights the importance of combining automated tagging with human contextual verification when interpreting crisis-related social media discourse. By examining thread-level interactions rather than isolated posts, the analysis highlights how trust, skepticism, and concern are negotiated collectively within online communities. This supports the view of social media platforms as socio-technical environments where public perception and crisis interpretation co-evolve.

Implications and Study Limitations

The findings suggest that early-stage social media discourse can serve as a valuable feedback signal for cybersecurity communication and infrastructure governance, particularly within the architecture, engineering, construction, and facility management (AECFM) industry. The prominence of security concern across posts indicates strong public awareness of infrastructure vulnerabilities, while the prevalence of humor and sarcasm highlights the need for communication strategies that acknowledge and address public skepticism. Monitoring sentiment distributions and engagement patterns may help agencies and infrastructure developers identify emerging trust deficits and adjust messaging accordingly, aligning closely with SCCT principles. For AECFM practitioners, while based on a single-incident design, this approach offers an essential first step for integrating public perception into adaptive communication and lifecycle management strategies, thereby supporting more transparent and trust-oriented responses to cyber disruptions.

Several limitations should be acknowledged. First, the analysis focuses on a single incident within a limited early-response window, which may restrict the generalizability of findings. Second, Reddit users represent a specific subset of the broader population, and their discourse may not reflect wider public opinion. Third, while the multi-dimensional sentiment framework captures a range of emotional and interpretive responses, categorizing complex posts into single dominant sentiments may overlook nuance. Finally, LLM-assisted tagging introduces potential classification variability despite manual verification. These limitations highlight the need for broader comparative analysis across multiple incidents and longer timeframes. Expanding the dataset to include additional cyber events and cross-sector infrastructure contexts will enable more robust identification of recurring patterns and improve the generalizability of findings.

Conclusions and Ongoing Work

This study contributes to the existing body of knowledge by providing empirical, quantitative evidence on how decentralized online communities respond to CI cyber disruptions. By analyzing 300 Reddit posts across 15 subreddits, the study identifies dominant sentiment patterns, engagement dynamics, and thread-level interactions that shape public interpretations of cyber incidents. The findings show that security concern emerges as a primary narrative driver, while humor and sarcasm play significant roles in mediating public reaction and critique. These observations demonstrate how early-stage online discourse forms rapidly, concentrates engagement, and amplifies particular narratives that influence public perception. Such insights are relevant for cybersecurity agencies, infrastructure operators, policymakers, and specifically AEC professionals seeking to embed human-centered resilience into future infrastructure projects. By addressing AEC infrastructure vulnerabilities directly, these findings provide actionable suggestions for the industry to proactively incorporate public feedback into lean-inspired cybersecurity frameworks and facility management crisis response strategies.

However, the study is subject to several limitations. It focuses on a single incident and a short early-response window, which may not capture longer-term discourse evolution or variations across sectors and regions. The dataset is limited to Reddit users, whose demographic and behavioral characteristics may differ from the broader population. Therefore, it is worth noting that presented analysis and discussion serves as an initial methodological first step rather than a generalized conclusion. To address these limitations, ongoing work is expanding the dataset to include multiple cyber incidents across different infrastructure sectors and geographic contexts to validate these pattern claims and improve generalizability. This extended analysis will support the development of more robust, evidence-based frameworks for integrating social media feedback into cybersecurity communication and resilience planning, ultimately contributing to more adaptive and human-centred approaches to infrastructure protection.

DEFINING A BLOCKCHAIN-VERIFIED SPECIMEN PASSPORT FOR 3DCP STANDARDISATION

Giancarlo Di Marco[1], Davide Lombardi[1], and Theodoros Dounas[2]
[1]Xi'an Jiaotong-Liverpool University, Suzhou, CN
[2]Heriot-Watt University, Edinburgh, UK

Abstract

3D Concrete Printing (3DCP) adoption is limited by prescriptive standards that cannot accommodate interdependent process parameters (e.g., nozzle speed, layer height, curing) affecting mechanical performance. Current approaches lack a tamper-proof, end-to-end linkage between production parameters and mechanical outcomes. We propose a blockchain-verified 3D-Printed Concrete specimen passport, defining its data schema, smart-contract logic, and integration with performance-based standardisation. The passport records production process, mechanical profile, and a 28-day compressive strength grade. Blockchain's immutable ledger and smart contracts automatically verify performance claims and assign 3DCP grades, enabling flexible, auditable certification. This provides a foundational reference for data-driven 3DCP compliance, fostering industrial adoption.

Introduction

The construction industry faces a digital transformation, driven by the convergence of advanced manufacturing technologies, digital information systems, and distributed ledger technologies (Lavagna et al., 2023; Samarasinghe and Wood, 2021). Among these innovations, 3DCP represents a paradigm shift in construction methodology, offering unprecedented design freedom, material efficiency, and potential for automation (Buswell et al., 2018). Unlike conventional cast concrete, where material properties can be reasonably predicted from standardised mix designs and controlled curing conditions, 3DPC mechanical properties are determined by a complex interplay of process parameters, including extrusion pressure, printing speed, layer deposition timing, and environmental conditions, that directly influence the mechanical performance of the final element (Wolfs et al., 2019). This variability, particularly affecting the interlayer adhesion, represents a fundamental challenge to structural certification and has been identified as a primary obstacle to the integration of 3DCP into regulated construction practice (Di Marco et al., 2025; Diks, 2019; Van Der Putten et al., 2022).

The general approach to traditional construction standardisation is based on the required concrete performance, which depends on design and operational conditions and is obtained through corresponding concrete mix variation; however, traditional quality assurance methods, developed for relatively simple casting processes, lack the granularity, transparency, and immutability required to establish robust traceability and stakeholder trust in digitally fabricated construction elements (Elghaish et al., 2023). Current standardisation efforts (ICC-ES, 2022; ISO/ASTM, 2023) provide foundational quality assurance requirements but do not yet offer a mechanism for immutable, end-to-end traceability of process parameters to performance outcomes. Therefore, the establishment of a unified, verifiable framework for certifying the mechanical performance and production integrity of additively manufactured concrete elements must be framed in a flexible standardisation paradigm, due to the already mentioned extreme variability of the process, and entail a layer of transparency, auditability, and traceability.

Blockchain technology, originally developed as the underlying infrastructure for cryptocurrencies, has emerged as a promising solution for addressing trust, transparency, and traceability challenges across various industries (Li et al., 2019; Turk and Klinc, 2017). In the construction sector, blockchain applications have been explored for supply chain management, contract execution, and information flow coordination (Darabseh and Poças Martins, 2023; Ye et al., 2023). The technology's core characteristics, decentralisation, immutability, transparency, and cryptographic security, align closely with the requirements for robust quality assurance in advanced manufacturing contexts.

The concept of digital passports for construction materials has recently gained traction as a mechanism for documenting the lifecycle history of construction materials and components, particularly in the context of circular economy initiatives (Senarathne et al., 2025; Trubina et al., 2024). Material passports serve as comprehensive digital records that capture information about material composition, origin, processing history, and performance characteristics, enabling informed decision-making regarding reuse, recycling, and end-of-life management (Kc et al., 2025). The EU's Digital Product Passport (DPP) (Damvakeraki and Vlachos, 2024), mandated by the Ecodesign for Sustainable Products Regulation (ESPR), is redefining product information management for construction products by requiring standardised, machine-readable digital records that accompany products throughout their lifecycle.

Stakeholder studies have identified improved traceability and resource efficiency as key benefits, alongside integration with Building Information Modelling (BIM) (Ruismäki et al., 2025). Blockchain-based material passport systems have been proposed to address the unreliability of centralised databases in construction's dispersed supply chain, with researchers arguing that blockchain enables decentralised, transparent, and immutable information management (Kc et al., 2026). Furthermore, blockchain has been explored for additive manufacturing traceability, including cloud 4D printing service platforms and digital twin creation for trusted data provenance (Liu et al., 2025).

Building on these foundations but focusing specifically on 3DCP specimen certification within a performance-based standardisation framework—a context not yet addressed in the literature—this paper introduces a blockchain-verified material passport specifically designed for 3DPC specimens. The proposed system cryptographically anchors a comprehensive data record that spans from digital design through material sourcing to real-time fabrication monitoring and final performance validation. The 3DPC specimen passport constitutes the cornerstone of a performance-based standardisation framework. By creating an immutable and auditable chain of custody, the system addresses the core challenges of 3DCP standardisation while mitigating information asymmetry among stakeholders.

Without a digital passport system for 3DCP, the construction industry faces several foreseeable consequences: each printed element would require case-by-case regulatory approval, significantly delaying project timelines and increasing costs; the lack of tamper-proof traceability would enable data manipulation, undermining trust among clients, insurers, and regulators; performance data from one print batch could not be reliably linked to subsequent batches, preventing continuous quality improvement and statistical process control; the construction sector would miss the opportunity to align with emerging EU Digital Product Passport regulations, which are rapidly redefining supply chain transparency for construction products.

Related work

Standardisation paradigms for 3DCP

The effective management of industrial production necessitates a strong approach to standardisation, which can fundamentally be characterised by two distinct philosophical paradigms: prescriptive and flexible.

The prescriptive approach is grounded in the principles of scientific management and statistical control (Shewhart, 1930). This paradigm seeks to achieve uniformity, interchangeability, and repeatability by specifying precise dimensions, values, tolerances, and processes. It operates on the principle that variation is a primary source of quality defects. The primary objective of this approach is to eliminate deviations and ensure perfect adherence to predefined specifications. This is illustrated by models such as Technical Specifications, which offer formal, detailed descriptions of requirements (ISO/IEC, 2021), and Geometrical Product Specifications (GPS), an international standards system that defines geometrical features—including form, position, and size—on technical drawings with clarity (Henzold, 2021; ISO 8015, 2011).

The second paradigm adopts a flexible approach, guided by systems theory and the necessity for strategic adaptability (Baldwin and Clark, 2000; Sanchez and Mahoney, 1996). This approach establishes clear goals, performance criteria, and interfaces while allowing considerable autonomy in the methods used to achieve these objectives. Its purpose is to ensure interoperability and alignment of goals across diverse and dynamic production environments without hindering innovation. A prominent model in this regard is Performance-Based Standards, which define the required functional outcomes without dictating specific technical solutions, thus fostering innovation in design and materials. (Foliente, 2000).

Prescriptive standards are primarily applied to critical, high-volume, or safety-sensitive components to ensure a fundamental level of quality and interchangeability. In contrast, flexible standards operate at the system and architectural levels, fostering product diversity, process innovation, and adaptability to change. This hybrid approach, integrating the rigidity of prescriptive models with the flexibility of adaptive models, serves as a hallmark of strong and competitive industrial operations (Sanchez and Mahoney, 1996).

Blockchain technology in construction supply chains

Blockchain technology has attracted significant attention from the construction sector as a potential solution to longstanding challenges related to information management, trust, and coordination among fragmented stakeholders (Wilson et al., 2024). Li et al. conducted a systematic review of blockchain applications in the built environment and construction industry, identifying key use cases including supply chain management, contract execution, and asset lifecycle management (Li et al., 2019). Their conceptual models highlight blockchain's potential to address information asymmetry, reduce transaction costs, and enhance transparency across construction project networks.

Turk and Klinc explored the potential of blockchain technology for construction management, emphasising its ability to create immutable transaction records and enable automated contract execution via smart contracts (Turk and Klinc, 2017). Their work identified several promising application areas, including payment automation, supply chain traceability, and quality documentation. However, they also noted significant challenges related to scalability, interoperability, and the need for industry-wide standards.

More recent research has focused on practical implementations and integration frameworks. Darabseh et al. presented a novel framework for blockchain orchestration and implementation in construction, developing a blueprint for blockchain applications using

Hyperledger Firefly (Darabseh and Poças Martins, 2023). Their work provides practical perspectives on infrastructure requirements and deployment strategies, building upon earlier Ethereum-based implementations. Wilson et al. proposed a multilayer blockchain framework for provenance tracking in construction supply chains, addressing critical challenges in verifiability, scalability, privacy, and interoperability through a privacy-centric solution that combines decentralised and centralised storage (Wilson et al., 2024).

Material passports and circular economy

Material passports have emerged as a critical tool for enabling circular-economy practices in the construction sector, providing comprehensive documentation of material characteristics, origins, and lifecycle histories. Trubina et al. conducted an in-depth analysis of digital technologies and material passports for circularity in buildings, highlighting the significant potential of integrating material passports with BIM, artificial intelligence, scanning technologies, blockchain, and the Internet of Things (Trubina et al., 2024). Senarathne et al. developed a standardised materials passport framework to unlock the full circular potential of the construction industry, incorporating technologies such as BIM, blockchain, QR codes, and radio-frequency identification (Senarathne et al., 2025). Dounas et al. introduced an innovative approach using Non-Fungible Tokens (NFTs) on the blockchain to build components, creating a digital infrastructure layer that can integrate with AEC supply chains (Dounas et al., 2021). Their work on non-fungible building components demonstrates how smart contracts can enable material passports and circular economies, providing an infrastructure for whole-life-cycle BIM and the digital encapsulation of value in architectural design.

3D printed concrete–quality control and standardisation challenges

The field of 3D printed concrete has experienced rapid growth over the past decade, yet significant challenges remain in quality control and standardisation. Buswell et al. provided a comprehensive roadmap for 3DPC research, identifying key technical challenges including material development, process control, structural performance prediction, and the development of testing protocols and standards (Buswell et al., 2018). A critical challenge in 3DPC quality assurance is the influence of process parameters on interlayer adhesion, which directly affects the mechanical performance and structural integrity of printed elements. Wolfs et al. investigated the hardened properties of 3D printed concrete, specifically examining how process parameters influence interlayer adhesion (Wolfs et al., 2019). Their research demonstrated that factors such as time gap between layer deposition, printing speed, and material rheology significantly affect bond strength between layers, introducing variability that must be carefully controlled and documented for structural applications. Di Marco et al. advanced the field by developing stress-informed non-planar slicing strategies for 3D concrete printing, demonstrating how computational design approaches can optimise print paths to enhance structural performance (Di Marco et al., 2025). Their work highlights the complex relationship between digital design, process execution, and final mechanical properties, underscoring the need for comprehensive documentation systems that can capture this entire chain of causality. In another work, Di Marco et al. outlined a list of 3DCP process parameters that contribute to defining the mechanical performance and grade of 3DPC (Di Marco and Cheung, 2025). The 3DPC standardisation challenge extends beyond technical testing protocols to encompass broader issues of certification, liability, and regulatory acceptance. Traditional concrete standards, developed for cast-in-place and precast applications, do not adequately address the unique characteristics of layer-by-layer additive manufacturing. The absence of established standards creates uncertainty for designers, contractors, and regulatory authorities, hindering the technology's adoption in structural applications.

Research gaps, aims, and objectives

The lack of a shared, validated standardisation framework undermines the industry's adoption of 3DCP, constituting the principal research gap. Working towards a hybrid standardisation model, our broader research endeavour proposes adopting a blockchain-enabled, decentralised framework to collect production reports, detect production-to-grade patterns, and derive, validate, and distribute production standards. This paper focuses exclusively on the foundational first objective: to define a 3DPC specimen passport.

Methodology

A hybrid approach at the intersection of design science methods and decentralised science is adopted, i.e. the recording of artefacts and governance onto blockchains for the production of new knowledge. A new blockchain-verified 3DPC specimen passport is built on a multi-layered architecture that integrates a digital twin for performance prediction and optimisation, blockchain storage, smart contract execution, and a user interface. Its architecture follows principles established in recent blockchain for construction applications (Darabseh and Poças Martins, 2023; Wilson et al., 2024), while incorporating specific adaptations for the unique requirements of 3DPC quality assurance.

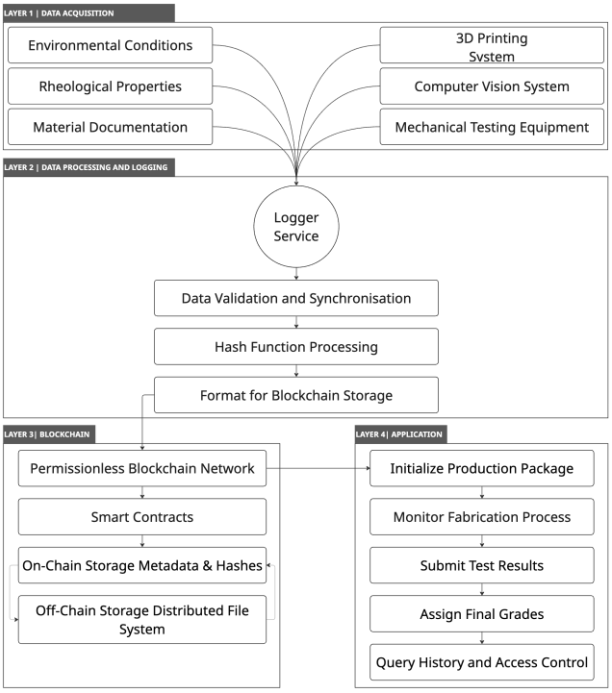

Figure 1: Framework layered structure

The system comprises four primary layers (Figure 1):

- Data Acquisition Layer: This layer encompasses all data sources that capture information about the 3DPC specimen fabrication process. It includes material batch documentation, in-line rheology monitoring, environmental conditions monitoring during printing and curing, machine control data from the robotic printer, computer vision imaging for geometric quality assessment, and mechanical testing conditions and results for performance validation.
- Data Processing and Logging Layer: A dedicated Logger Service processes raw sensor data, synchronises timestamps, performs data validation, and formats information for blockchain storage. This layer implements hash functions for large data objects (such as G-code files and vision data) to enable efficient on-chain storage while maintaining data integrity verification capabilities.
- Blockchain Layer: The core of the system utilises a permissionless blockchain network to store specimen passport data and execute smart contracts. Following best practices for construction applications (Ye et al., 2023), the system employs a hybrid on-chain/off-chain storage strategy: critical metadata and cryptographic hashes are stored on-chain, while large data objects are stored in distributed file systems, with their hashes recorded on the blockchain for verification.
- Application Layer: User-facing interfaces enable stakeholders to initialise production packages, monitor fabrication progress, submit test results, assign final grades, and query the complete history of any 3DPC element. Access control mechanisms ensure that different stakeholders have the appropriate permissions to view and modify data.

Study

An extensive material characterisation campaign with 60 cases of specimen tracking (an excerpt of the results is shown in Table 1) conducted in our robotic workshop, allowed to obtain a precise understanding of the connection between process parameters and the final 3DPC grade.

Table 1: Specimen Tracking and Grade

Specimen ID	250612-004	250612-001
Temperature (°C)	23.9	23.9
Humidity (%RH)	82.8	82.8
Concrete (kg)	82.3	99.5
Water (l)	12.35	14.9
Added Water (l)	0	0
w/i	0.15	0.15
Load orientation	Parallel	Perpendicular
Strength (MPa)	16.4	37.0
Grade	M15	M35

With reference to Figure 1, this was equivalent to implementing the data acquisition layer of the framework.

Framework overview

Beyond the basic material passport, our system manages the whole lifecycle of the 3DPC specimen, from production process to mechanical tests. The framework is purpose-built for construction 3DCP, addressing the issues of data manipulation, production logs can be altered after a failure; lack of independent verification – a single party often certifies its own prints; fragmented traceability, material provenance, process parameters, and test results are stored in disconnected systems, making root-cause analysis nearly impossible.

The material passport for 3DPC specimens is structured as a comprehensive Production Package containing 13 distinct information elements (Table 2), each serving a specific role in establishing traceability and enabling quality verification.

Table 2: Specimen Passport

Information	What it indicates
Production Package ID & Metadata	A unique identifier for the specific print job and its basic context.
Raw Material IDs & Certificates	The specific batch and origin of constituent materials (cement, aggregates, admixtures).
Target Mix Design	The intended material composition (e.g., water-to-cement ratio, admixture doses).

Target Rheological Properties	The desired workability and printability of the concrete (yield stress, viscosity).
Print G-code (Digital File Hash)	The exact instructions for the robotic printer's toolpath.
Environmental Targets	The intended ambient conditions (Temperature, Relative Humidity) for the print.
In-Process Sensor Data	The real-time state of the material and process (pressure, flow rate, actual rheology).
In-Process Vision & Scan Data	The visual and geometric quality of the print during fabrication (bead shape, layer alignment).
Mechanical Performance Data	The achieved structural properties of the printed element (compressive/flexural strength).
Final Assigned Grade	A holistic quality score (e.g., Grade M20) for the finished element.
Final Certification Hash	A digital seal that locks the package and confirms its integrity and completeness.

This structure draws upon material passport frameworks developed for circular construction (Senarathne et al., 2025; Trubina et al., 2024), but extends them with additive-manufacturing-specific fields required by emerging standards (ICC-ES, 2022; ISO/ASTM, 2023).

The experimental implementation of the decentralised material passport system for 3DPC samples is designed using blockchain technology to ensure immutable data provenance and transparent validation processes. The system architecture comprises three core smart contracts deployed on an Ethereum Virtual Machine (EVM)-compatible blockchain, integrated with the InterPlanetary File System (IPFS) for distributed data storage. This hybrid approach balances the need for permanent, tamper-proof record-keeping on the blockchain with the practical requirements for storing large volumes of scientific data off-chain.

The **ProductionPassportNFT** contract serves as the central registry, implementing the ERC-721 non-fungible token standard to create unique digital identities for each concrete production run. The **ValidationRegistry** contract implements a decentralised validation mechanism that requires consensus among multiple independent validators, addressing the critical need for peer review in scientific data. The **DataProvenance** contract maintains a comprehensive chain of custody, tracking materials from sourcing through final testing to ensure complete traceability of the production process.

The architecture follows a modular design principle, with each smart contract addressing a specific aspect of the material passport lifecycle (Figure 2). This modular architecture provides several advantages for scientific research collaboration. First, it enables different laboratories to participate in the ecosystem without requiring a central coordinating authority. Second, it allows each contract component to evolve independently as standards and requirements evolve. Third, it facilitates regulatory compliance by clearly separating concerns for data certification, validation, and provenance tracking. Fourth, it enables integration with existing Laboratory Information Management Systems (LIMS) through well-defined interfaces.

ProductionPassportNFT smart contract

The ProductionPassportNFT contract uses the OpenZeppelin ERC-721 implementation, providing the foundational framework for creating and managing production passports as non-fungible tokens. Each NFT represents a single production run and contains metadata linking on-chain records to off-chain scientific data stored on IPFS. The use of the ERC721 NFT standard provides inherent transferability, enabling production passports to be licensed or transferred between institutions while maintaining complete provenance of ownership. The contract addresses a fundamental challenge in scientific data management: how to create permanent, tamper-proof records of experimental work while accommodating the iterative nature of scientific workflows. Unlike traditional database systems, where records can be modified or deleted, blockchain-based records are immutable once finalised. However, the contract recognises that scientific data often requires revision before final publication—preliminary results may need correction, additional tests may provide new insights, or methodological improvements may necessitate data updates. The contract resolves this tension through a versioning system that allows updates before finalisation while ensuring absolute immutability after certification. The NFT standard ensures global uniqueness and verifiable ownership history. In construction, this enables a digital chain of custody – an auditor can see who minted, validated, and currently holds the passport.

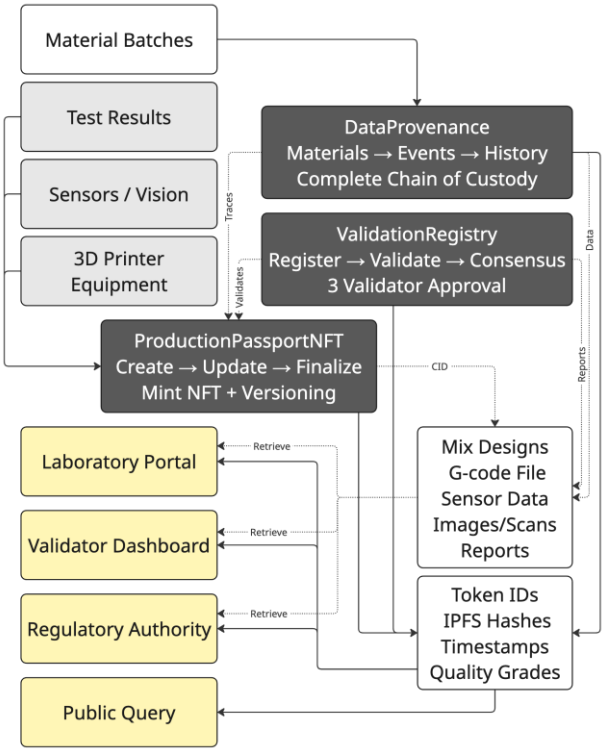

Figure 2: Blockchain-based System Architecture

Three mappings maintain contract state: passports maps token IDs to passport data structures, packageIdToToken enables lookup of token IDs by human-readable package identifiers, and _tokenIdCounter maintains the next available token ID for minting. Events are declared for all state-changing operations, enabling off-chain applications to efficiently monitor contract activity without polling every transaction.

ValidationRegistry smart contract

The ValidationRegistry contract implements a multi-validator consensus mechanism that replicates peer-review processes in scientific research (Lombardi et al., 2020). Unlike centralised validation systems, where a single authority determines data validity, this contract requires consensus from multiple independent validators, reducing bias and increasing trust in validated results. Requiring consensus among three independent validators (e.g., two accredited labs + one owner's engineer) replicates academic peer review. Collusion becomes harder, and the system provides a publicly auditable record of who approved what and when.

The architecture addresses several challenges inherent in decentralised validation. First, it must prevent collusion where validators coordinate to approve invalid data. The three-validator requirement increases the cost of such collusion and makes it more likely that at least one validator will act honestly. Second, it must maintain validator accountability while preserving the ability for legitimate criticism. The reputation scoring system provides a quantitative measure of validator reliability without creating barriers to participation. Third, it must balance transparency (all validations are publicly recorded) with practicality (validators are not penalized for disagreement with the eventual consensus).

DataProvenance Smart Contract

The DataProvenance contract implements comprehensive chain-of-custody tracking for materials and processes, addressing the critical need for traceability in construction materials. Unlike validation (which assesses quality) or certification (which attests to final results), provenance tracking creates a minute-by-minute history of everything that happened during production. This granular tracking serves multiple purposes: it enables root-cause analysis when quality issues arise, provides evidence of regulatory compliance, supports continuous improvement through statistical analysis, and increases transparency for end users who want to understand exactly how their concrete was manufactured.

The described blockchain-based architecture recognises two distinct types of provenance data that require different tracking mechanisms. Material provenance tracks the sources and certification of raw materials. These two provenance types are complementary: material provenance ensures quality inputs, while process provenance ensures proper handling of those inputs.

Summary of scientific rationalisation.

Each design decision is driven by a documented weakness in current 3DCP practice:

- NFT identity → solves counterfeit or duplicate batch records.
- Multi-validator consensus → solves the single-point-of-trust problem.
- Granular provenance → solves the traceability gap in layer-wise failures.
- Hybrid IPFS/blockchain → solves the data volume vs. immutability trade-off.
- Versioning → solves the tension between iterative research and final compliance.

Discussion and conclusions

This work is a fundamental part of the broader general aim to establish a flexible standardisation paradigm for 3DCP, encompassing diverse material choices and hardware configurations, and advocating the adoption of a decentralised framework underpinned by blockchain technology to enable verifiable compliance and traceability whilst fostering innovation. In this context, the 3DPC specimen passport enables traceability and auditability of different material choices and hardware configurations.

The introduction of a 3DPC specimen passport, as proposed in this study, represents a pragmatic step towards reconciling innovation and accountability in digital fabrication. This digital identity, encompassing the complete lifecycle of a printed element, from specific ink recipe and admixture ratios to hardware configuration and environmental conditions, shifts the paradigm of quality assurance to verifiable parameters and required performance. It functions as a cornerstone for enhanced traceability and auditability, creating an immutable record

that moves beyond batch-level documentation to unit-specific provenance, enabling a flexible, performance-based standardisation model. Rather than enforcing uniformity, the passport system accommodates heterogeneity in materials and hardware by recording these variables as intrinsic data points within a compliance framework. Rather than mandating identical processes (prescriptive standardisation), this flexible standardisation defines permissible performance envelopes and requisite data integrity; notably, this approach allows connecting 3DCP to existing standards (e.g., conventional concrete grade). A printer using a novel geopolymer and another using a traditional cementitious mix can both be deemed compliant if their respective passport data demonstrate that the final printed specimen meets the same structural and durability benchmarks. This fosters an ecosystem where technological diversification and experimentation are not hindered by standardisation but are instead its documented foundation.

In conclusion, the specimen passport is posited as an enabler of a responsive, evidence-based regulatory environment. By providing a mechanism to audit performance against specific production choices, it allows standardisation to evolve from a restrictive checklist into a dynamic framework that actively supports the tailored and innovative application of 3DCP technology.

Limitations and future work

The current implementation of the 3DPC specimen passport relies on manual input of process data; however, the reliable, auditable collection of process data should be ensured by adopting digital technologies and IoT equipment. Furthermore, the integrity of the data chain, from sensor to passport must be safeguarded, potentially through blockchain or other distributed ledger technologies, to prevent tampering and establish trust. Widespread adoption will also require industry-wide agreement on the minimal dataset for a viable passport, the definition of a 3DCP ontology, and its integration into existing BIM and quality management workflows, highlighting the current interoperability gaps include missing LIMS integration, material-type standardisation, and BIM connectivity. In the current stage, the preliminary identification of process parameters relevant to the determination of mechanical performance was finalised, based on material characterisation campaigns, and the design of the system architecture and smart contracts has been completed. The next stage will consist of embedding computer vision data in the implementing the blockchain; therefore, no EVM platform has been chosen nor tokenisation mechanism was presented in this paper. Future work will prioritise Layer 2 (Figure 1) deployment for cost reduction, governance token implementation enabling decentralised control and validator rewards, automated reputation systems, cross-chain accessibility, data marketplace integration, API development for existing systems, and regulatory pilot programs demonstrating compliance benefits and practical viability.

GOVERNING CONSTRUCTION MATERIAL REUSE AS A BLOCKCHAIN COMMONS: OSTROM'S DESIGN PRINCIPLES AND EU DIGITAL PRODUCT PASSPORTS

Abstract

Scotland's construction industry operates at a circularity rate of just 1.3%, exemplifying a wider EU governance failure: the Construction Products Regulation and Ecodesign for Sustainable Products Regulation mandate Digital Product Passports (DPPs) for construction materials, assuming linear supply chains, with no governance for reclaimed material re-entry. This paper applies Ostrom's principles for commons governance to a blockchain-based marketplace for construction material reuse. Using hybrid methods, we present a deployed prototype architecture of seven smart contracts, built on VeChainThor and implemented as the TRACE platform (trace.adventurous.systems), designed for EU DPP compliance while implementing commons governance for material reuse's institutional context.

Introduction

The construction industry is responsible for approximately 37% of global CO^2 emissions and consumes roughly half of all extracted materials worldwide (UNEP, 2022). In Scotland, despite ambitious circular economy targets, the construction sector achieves a circularity rate of only 1.3% (Zero Waste Scotland, 2024)—a figure that reflects a broader EU-wide challenge, as the governance infrastructure for material reuse does not yet exist in any member state. The vast majority of demolition materials are downcycled or landfilled rather than reused in their original form. Beyond an environmental failure this is a governance failure: the institutional infrastructure required to coordinate material reuse across fragmented stakeholders does not exist.

Two converging policy developments create both urgency and opportunity. First, the EU's revised Construction Products Regulation (CPR), which entered into force on 7 January 2025, mandates Digital Product Passports for construction products, requiring structured digital records of material composition, environmental performance, and compliance data (European Commission, 2024a). Second, the Ecodesign for Sustainable Products Regulation (ESPR, EU 2024/1781) establishes the broader DPP framework, specifying JSON-LD data formats, GS1 Digital Link identifiers, and tiered access controls for consumers, professionals, and regulators (European Commission, 2024b). Construction product DPPs are expected to become mandatory between 2029 and 2032 through phased harmonised standards.

However, these regulations are designed for linear supply chains: a manufacturer produces a product, declares its performance, and places it on the market with a CE marking and accompanying DPP. The regulatory framework offers no model for what happens when a construction material is deconstructed from a building, assessed for condition, and re-enters circulation through a community-run reuse hub. Who issues the DPP for a reclaimed steel beam? Under what authority? With what quality assurance mechanisms? How are disputes resolved when the 'manufacturer' is a volunteer-run charity?

We argue that this governance vacuum is precisely the institutional challenge that Elinor Ostrom's (1990) design principles for managing common-pool resources can address. Construction materials available for reuse constitute a shared resource that is rivalrous (one builder's use of a reclaimed beam excludes another's) and partially excludable (access requires knowledge of availability and logistics coordination). The community of reuse hubs, suppliers, and buyers face classic commons dilemmas: how to maintain quality without central authority, how to share information without exploitation, and how to distribute costs and benefits fairly across heterogeneous participants.

This paper presents findings from the TRACE (Transforming Resources and Advancing Circular Economy) project, which develops a blockchain-based digital marketplace for construction material reuse hubs. We address the following research question: *How can Ostrom's design principles for commons governance inform the design of EU DPP-compliant blockchain infrastructure for construction material reuse?*

Related work

Ostrom's design principles and digital commons

Ostrom's (1990) eight design principles for successful commons governance—clearly defined boundaries, congruence between appropriation and provision rules, collective-choice arrangements, monitoring, graduated sanctions, conflict-resolution mechanisms, minimal recognition of rights to organise, and nested enterprises—were originally derived from analysis of natural resource commons. Subsequent work has extended these principles

to digital contexts. Schweik and English (2012) applied the framework to open-source software communities. Fuster Morell (2014) adapted it to online creation communities. Most relevant to this research, Rozas et al. (2021) systematically mapped Ostrom's principles to six blockchain affordances: tokenisation, self-enforcement and autonomy of rules, decentralisation of authority, transparency, and codification of trust through cryptographic mechanisms. The Mozilla Foundation's practical framework (Ruhaak et al., 2021) further operationalised Ostrom for data commons governance.

EU digital product passports for construction

The EU's DPP framework represents the most significant regulatory development in construction product information management in decades. The revised CPR (EU 2024/1305) folds DPPs into the CE marking workflow, requiring Declarations of Performance and Conformity to be digitally accessible alongside environmental data including Global Warming Potential, which becomes mandatory from 2026 (European Commission, 2024a). The ESPR (EU 2024/1781) establishes horizontal DPP requirements: machine-readable structured data (JSON-LD aligned with Schema.org), persistent unique product identifiers (GS1 GTIN with serial-level granularity via GS1 Digital Link), QR code or NFC data carriers, tiered access controls, and mandatory third-party backup storage (European Commission, 2024b). Environmental product data must align with EN 15804+A2 standards for lifecycle assessment.

Critically, these regulations assume a manufacturer-to-market linear chain. The ESPR designates the 'economic operator'—typically manufacturer or importer—as responsible for creating and maintaining the DPP (European Commission, 2024b). For reclaimed materials, this responsibility chain breaks: the original manufacturer may no longer exist, the material's properties may have changed through use and ageing, and the entity placing the reclaimed material on the market is typically a small reuse hub or social enterprise with limited resources for conformity assessment. This institutional gap is the specific problem our research addresses.

Blockchain for construction material traceability

Blockchain applications in construction have focused primarily on material traceability and supply chain transparency. Dounas et al (2021) and Lombardi (2022) provided the first comprehensive treatment of non fungible tokens on blockchain based smart contracts for building components for construction, covering smart contracts, non-fungible tokens for building components. Circularise (Amsterdam) and ReCheck (Netherlands) have implemented blockchain-based material identity systems, while the EU BAMB (Buildings as Material Banks) project explored material passport concepts. However, these implementations share a common limitation: they treat blockchain as a technical ledger for recording provenance, without addressing the governance question of who has authority to assert material properties, how quality disputes are resolved, and how collective decisions about standards and parameters are made. Circularise, for example, records material data but relies on manufacturer self-declaration, leaving the governance vacuum unchanged when no manufacturer exists. BAMB developed material passport schemas without addressing the institutional infrastructure required to issue, verify, and dispute those passports in a commons setting. This gap—between technical traceability and institutional governance—is precisely what this research addresses through the Ostrom framework.

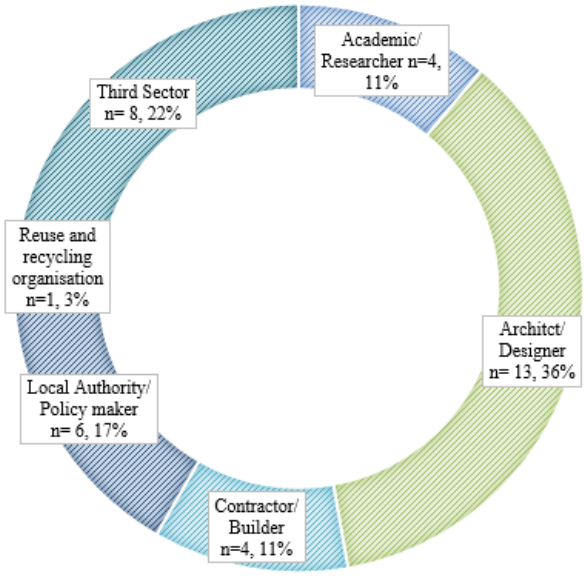

Figure 1: distribution of stakeholders' professional backgrounds

Methodology

Oversized This research follows a Design Science Research (DSR) methodology (Hevner et al., 2004) structured through a Design Thinking process (Stanford d.school, 2010). The current paper reports on the Empathise, Define, and Ideate phases, with the prototype architecture now implemented and deployed as the TRACE platform on VeChainThor.

Data collection

Four participatory workshops were conducted with 36 stakeholders across six categories: architects (n=6), third-sector organisations (n=7), local authorities (n=6), academics (n=5), contractors (n=6), and reuse organisations (n=6). Workshops were organised around four thematic areas: (1) materials and practical use, (2) trust and quality, (3) information and decision-making, and (4) process and experience. Each workshop used Microsoft Teams with Miro whiteboards for collaborative data capture. Discussions were recorded and transcribed with participant consent.

Analytical framework

Data was analysed using a hybrid deductive-inductive framework. The primary method followed Gioia et al.'s

(2013) approach: first-order codes captured participant language, second-order themes represented researcher-interpreted patterns, and aggregate dimensions mapped to theoretical constructs. An Ostrom Institutional Analysis and Development (IAD) overlay was applied to code for action arenas, rules-in-use, biophysical conditions, community attributes, and outcomes. This dual-layer analysis enabled systematic translation from stakeholder insights to governance requirements to prototype specifications.

Findings

Thematic analysis revealed three critical governance gaps that consistently surfaced across all stakeholder categories and all four thematic areas: (1) assurance mechanisms—the absence of verification pathways for reclaimed material quality; (2) logistics infrastructure—the lack of coordination systems for material availability and movement; and (3) information systems—the absence of structured digital records comparable to those available for new construction products. These gaps map systematically onto Ostrom's design principles, as presented below.

Boundaries and material viability (P1)

Stakeholders identified clear material viability hierarchies. Mineral-based materials (stone, slate, granite), brick and masonry, and structural timber were considered most viable for reuse due to durability and professional familiarity. Concrete, moisture-sensitive timber, and specification-specific steel were cited as most challenging. Participants consistently demanded clear boundary definitions: what materials qualify for reuse, under what conditions, and with what documentation. In Ostrom's terms, the resource system requires clearly defined boundaries before appropriation rules can function.

Monitoring and trust infrastructure (P4)

Trust emerged as the dominant concern across all stakeholder groups, particularly intensified by the post-Grenfell regulatory environment. Participants emphasised that reclaimed materials must be supported by documentation comparable to new-material technical data sheets. Third-party verification, recognised certification schemes, and professional expertise were identified as essential. Current checking practices rely on a combination of document-led assurance (certificates, warranties), expert-led assessment (structural engineer reports, visual grading), and operational boundary-setting (focusing on lower-risk applications). The absence of systematic monitoring mechanisms was identified as the primary barrier to scaling reuse beyond informal, relationship-dependent exchanges, in some cases with public procurement as a stimulus for circular practices.

Information asymmetry and collective choice (P3)

Decision-critical information identified by stakeholders included precise specifications (quantity, dimensions, cost, performance data), testing and certification evidence, and traceability data establishing provenance. A significant finding was the distinction between essential information (compliance and risk data) and desirable information (embodied carbon data, material history). Stakeholders from all categories expressed that current information sourcing is informal and relationship-dependent, particularly for smaller projects, while regulated buildings require substantially higher documentation standards. This asymmetry maps to Ostrom's collective-choice arrangements: stakeholders need voice in determining what information standards are required at what levels.

Congruence and cost distribution (P2)

A persistent temporal mismatch emerged: the costs of material documentation and quality assurance are borne at the point of reclamation, while the benefits accrue at the point of reuse—potentially months or years later. Third-sector organisations expressed concern that documentation costs could create barriers for smaller hubs operating on minimal budgets. Participants identified that a viable system must distribute costs proportionally to benefits derived, aligning with Ostrom's congruence principle.

Prototype architecture: implementation and design

Based on the governance requirements derived from stakeholder analysis, Ostrom mapping, and EU DPP technical specifications, we have implemented a prototype architecture comprising seven smart contracts integrated through a commons governance layer. The prototype is deployed as the TRACE platform (trace.adventurous.systems), built on VeChainThor—an EVM-compatible enterprise blockchain with built-in fee delegation (enabling users to interact without holding cryptocurrency), multi-clause batch transactions, and an energy-efficient proof-of-authority consensus model aligned with sustainability goals. The architecture follows a 'thin on-chain, rich off-chain' philosophy: the full material passport data resides in a conventional database (PostgreSQL) as structured JSON-LD, while the blockchain stores content hashes for integrity verification, ownership records, marketplace escrow logic, and governance votes. The frontend is implemented as a Progressive Web App (Next.js 14), accessible at trace.adventurous.systems, with a QR code scanner enabling public passport verification without any blockchain knowledge.

EU DPP-compliant material passport layer

The material passport data model is designed from the ground up for ESPR and CPR compliance. Each passport is structured as JSON-LD aligned with Schema.org and GS1 Web Vocabulary, carrying: a globally unique GS1 GTIN identifier with serial-level granularity; a GS1 Digital Link URI resolvable via QR code scanning; environmental data structured per EN 15804+A2 (including Global Warming Potential); and tiered access controls separating public, professional, and regulatory data views as mandated by the ESPR.

For reclaimed materials entering circular reuse, the core DPP schema is extended with fields capturing: the source

building and deconstruction context, condition assessment scores (structural, aesthetic, environmental), photographic evidence, estimated remaining useful life,

MaterialRegistry (P1: Boundaries) anchors material passport hashes on-chain, providing tamper-evidence for off-chain JSON-LD data. Each registered material

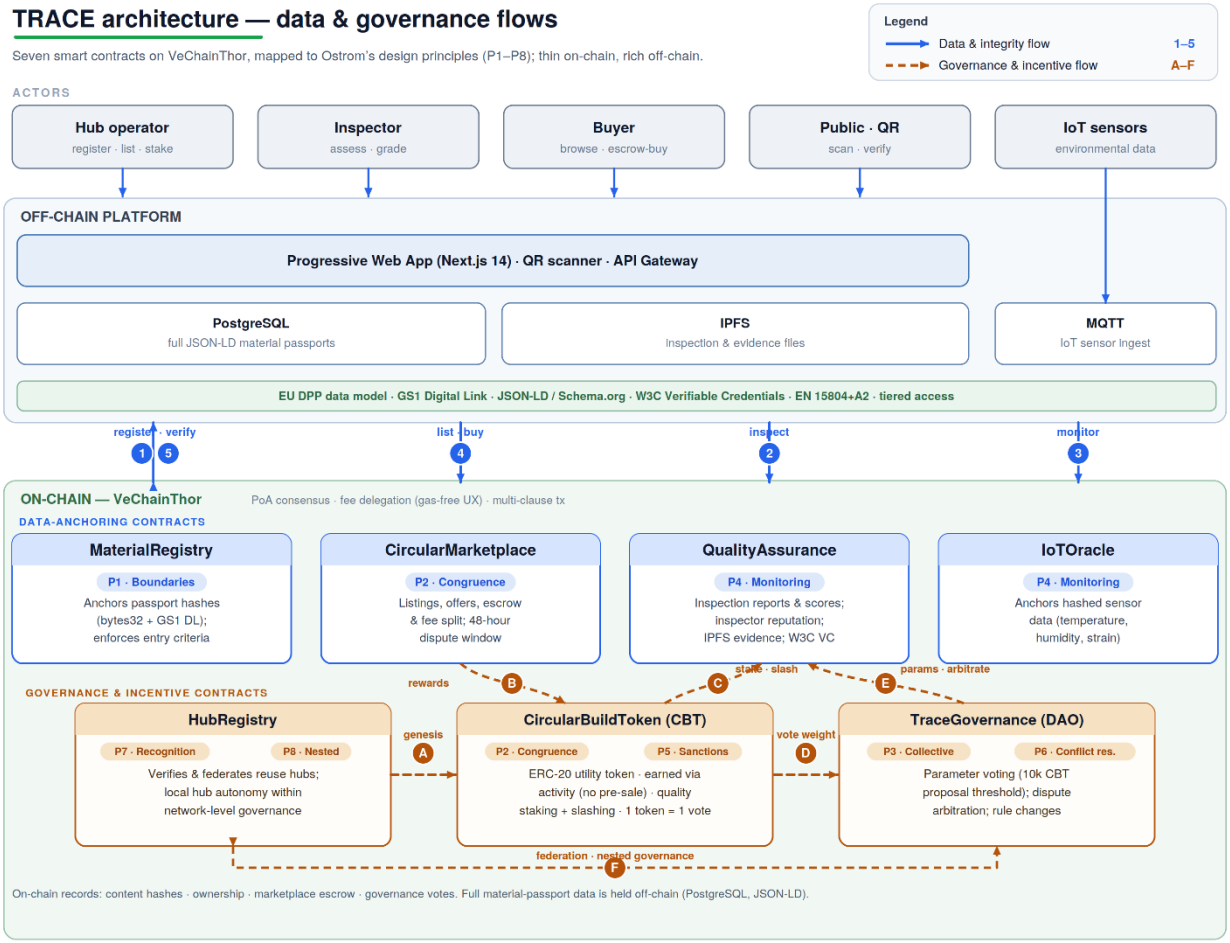

Figure 2: Implemented software architecture (deployed at trace.adventurous.systems)

and critically, the carbon savings achieved by reusing versus manufacturing new—data not captured by the standard DPP framework but essential for circular economy accounting. The extended schema also explicitly captures material-specific technical performance data referenced to applicable standards (EN 1995 for timber, EN 1992 for concrete, EN 1993 for steel), measured residual properties, and recommended use-class constraints, since reclaimed materials must continue to satisfy performance requirements in their new application context. Quality certifications are issued as W3C Verifiable Credentials (VCDM 2.0), enabling cryptographic verification of inspector qualifications and assessment results without requiring trust in a central authority. This directly addresses the ESPR's requirement for conformity assessment while providing a decentralised alternative to the manufacturer-issued Declaration of Performance that does not exist for reclaimed materials.

Smart contract modules

Seven smart contracts implement the on-chain governance layer, each mapped to specific Ostrom principles and DPP requirements (Table 1):

receives a unique bytes32 identifier linked to its GS1 Digital Link URI. The contract enforces entry criteria—minimum documentation requirements that must be met before a material can be registered—implementing the boundary definitions demanded by stakeholders.

CircularMarketplace (P2: Congruence) manages listing creation, offer handling, escrow, and fund release with configurable fee distribution. A 48-hour dispute window after delivery confirmation provides buyer protection. Fee structures are adjustable through governance to ensure costs remain proportional to benefits, addressing the temporal mismatch identified in workshops.

CircularBuildToken (CBT) is an ERC-20 utility token serving as the governance and incentive mechanism. CBT is not a payment currency; material purchases settle in fiat via conventional payment rails. CBT provides governance weight (one token, one vote), quality staking (hubs stake CBT against material quality claims, with slashing for disputes), and activity rewards (minted for registering complete passports, completing transactions, and providing quality reviews). The initial CBT supply is bootstrapped through a genesis allocation to verified founding hubs (Stirling Reuse Hub and network partners),

with subsequent supply minted exclusively through verified on-platform activity—there is no pre-sale or speculative allocation. This design ensures governance weight is earned through participation rather than purchase, directly implementing Ostrom's congruence principle at the token level. The staking mechanism implements Ostrom's graduated sanctions (P5): first disputes result in partial CBT slashing; repeated violations escalate to hub suspension.

QualityAssurance (P4: Monitoring) records inspection reports on-chain with inspector reputation tracking. Each report stores material ID, multi-dimensional quality scores, and an IPFS reference to the full inspection documentation. Inspector reputation accumulates from successful (undisputed) inspections, creating an emergent quality assurance system that does not depend on a single certifying authority—essential for reclaimed materials where no manufacturer exists to issue conformity declarations.

IoTOracle (P4: Monitoring, automated) receives hashed sensor data from environmental monitoring systems (temperature, humidity, structural strain), providing on-chain evidence that storage conditions were maintained. For the prototype, QR code scanning serves as the primary physical-digital bridge, with IoT sensor integration as a secondary capability.

TraceGovernance (P3: Collective Choice, P6: Conflict Resolution) implements a Decentralised Autonomous Organisation for platform parameter voting, dispute arbitration, and community rule changes. A proposal threshold of 10,000 CBT ensures only committed participants can propose changes, while all token holders can vote. This provides the structured collective-choice and conflict-resolution mechanisms that stakeholders identified as absent from current informal reuse practices.

HubRegistry (P7: Recognition of Rights, P8: Nested Enterprises) manages the federation of reuse hubs. Each hub registers on-chain with its operator address and metadata hash, receives platform verification, and operates semi-autonomously within the network. This addresses the regulatory gap where reuse hubs are not recognised as 'economic operators' under the CPR: the HubRegistry creates a parallel institutional recognition system governed by the commons rather than by the state.

Bridging the regulatory gap

The architecture specifically addresses the institutional gap between EU DPP regulations and circular economy practice through three mechanisms. First, *DPP issuance for reclaimed materials*: where the ESPR assigns DPP responsibility to the manufacturer or importer, the TRACE system assigns it to the verified reuse hub, with quality assurance distributed across the inspector network rather than concentrated in a single entity. Second, *conformity assessment through commons governance*: where the CPR requires manufacturer-issued Declarations of Performance, the TRACE system substitutes blockchain-anchored quality assessments issued as W3C Verifiable Credentials by reputation-scored inspectors, governed by DAO-set standards. Third, *federated authority*: where EU regulations assume national market surveillance authorities, the TRACE system implements Ostrom's nested enterprises principle, with local hub autonomy operating within network-level governance—a structure that could complement rather than replace regulatory oversight.

Discussion

The mapping presented in Table 1 reveals a systematic correspondence between Ostrom's governance requirements, stakeholder-identified gaps, EU DPP technical requirements, and blockchain smart contract capabilities. This is not coincidental: the EU DPP framework and Ostrom's principles both address the fundamental challenge of governing shared information resources, but from different institutional perspectives. The EU approach is top-down and regulatory, designed for hierarchical supply chains with identifiable responsible entities. Ostrom's approach is bottom-up and institutional, designed for polycentric governance where authority is distributed across self-organising participants.

The circular economy's material reuse context sits awkwardly between these two models. Materials that have been deconstructed and re-enter circulation require the structured data and consumer protection that EU DPP regulations provide, but they lack the institutional infrastructure (manufacturer, importer, notified body) through which those regulations are implemented. Our findings suggest that Ostrom-governed blockchain infrastructure can fill this gap—not as a replacement for regulatory oversight, but as a complementary institutional layer that enables reuse hubs to issue EU-compliant material passports through a collectively governed, reputation-based system. It is important to be clear on regulatory positioning: the TRACE system does not claim to issue legally binding DPPs under current EU law, where formal authority remains with recognised economic operators. Rather, it demonstrates the institutional and technical architecture that a future regulatory adaptation—such as recognition of 'verified reuse hub' as an economic operator category under CPR delegated acts—would need to build upon. This is consistent with the EU's own approach to DPP implementation, which explicitly anticipates stakeholder-driven standard development through delegated acts. Construction companies managing material reuse independently of hubs would interface with the same schema and smart contract layer, with the HubRegistry federation providing the interoperability layer between actors.

Several limitations must be acknowledged. First, while the prototype is now deployed and operational at trace.adventurous.systems, empirical evaluation at scale remains ongoing; the Stirling Reuse Hub pilot currently underway will provide the first rigorous assessment of adoption, usability, and governance effectiveness in practice.

Table 1: Mapping of Ostrom's design principles to stakeholder evidence, EU DPP requirements, and implemented blockchain features (TRACE platform).

Ostrom Principle	Workshop Evidence	Governance Gap	EU DPP Requirement	TRACE Smart Contract
P1: Boundaries	Material viability hierarchies; demand for clear grading standards	No defined criteria for reuse eligibility	Unique product identifier (GTIN); product classification	MaterialRegistry: entry criteria, passport hash anchoring
P2: Congruence	Cost-benefit temporal mismatch; small hub burden	Documentation costs borne at reclamation, not reuse	Proportionate compliance based on product risk	CBT token: rewards proportional to contribution; fee distribution
P3: Collective choice	All groups want voice in quality standards	No forum for stakeholder input on reuse standards	Delegated acts developed via stakeholder consultation	GovernanceDAO: parameter voting, proposal system
P4: Monitoring	Trust as dominant barrier; post-Grenfell anxiety	No systematic quality verification for reclaimed materials	Conformity assessment; Declaration of Performance	QualityAssurance: inspector reports, reputation; IoTOracle
P5: Graduated sanctions	Need for accountability without excluding marginal suppliers	No penalty mechanism for quality misrepresentation	Market surveillance; penalties for non-compliance	CBT staking/slashing: graduated penalties for disputes
P6: Conflict resolution	Current disputes resolved informally; need structure	No arbitration mechanism for reuse transactions	National market surveillance authorities	GovernanceDAO: arbitration workflow, evidence-based resolution
P7: Recognition of rights	Regulatory uncertainty; building control unfamiliarity	Reuse hubs not recognised as 'economic operators' under CPR	Economic operator registration; EOID	HubRegistry: on-chain hub verification and federation
P8: Nested enterprises	Local vs regional coordination needs; independence desired	Siloed hub operations; no network coordination	Interoperability between DPP systems across sectors	HubRegistry: federated architecture; cross-hub protocols

Second, the regulatory compatibility we describe is architectural (schema compliance, identifier standards) rather than legal—formal recognition of blockchain-issued DPPs under EU law remains an open question. Third, the digital literacy requirements of blockchain interaction present barriers for some reuse hub staff, particularly older volunteers. The prototype addresses this through a 'blockchain-invisible' design where the user interface abstracts away wallet management and on-chain transactions. Fourth, the physical-digital verification gap persists: a blockchain record cannot independently verify that a reclaimed beam has the structural properties claimed. The quality assurance system mitigates but does not eliminate this fundamental limitation.

The broader implication extends beyond construction. As EU DPP requirements expand across product categories through 2030, every sector with significant secondary material flows—textiles, electronics, furniture—will face the same institutional gap: regulation designed for manufacturing supply chains applied to contexts where products re-enter circulation through informal or community-based channels. The commons governance approach demonstrated here may offer a transferable institutional model.

Conclusion

This paper has presented a theoretically grounded approach to governing construction material reuse as a digital commons, bridging Ostrom's design principles with the EU's emerging Digital Product Passport regulatory framework through blockchain smart contracts. Our contribution is twofold. First, we provide empirical evidence from 36 stakeholder workshop participants that the governance challenges of construction material reuse map systematically onto Ostrom's eight design principles, identifying assurance, logistics, and information systems as the three critical gaps. Second, we present a deployed seven-contract prototype architecture, implemented on VeChainThor and accessible at trace.adventurous.systems, that is simultaneously EU DPP-compliant (JSON-LD, GS1 Digital Link, W3C Verifiable Credentials, EN 15804+A2) and commons-governed (DAO voting, reputation-based quality assurance, graduated sanctions, federated hub architecture).

The key finding is that EU DPP regulations and Ostrom's governance principles are not competing frameworks but complementary layers: the regulations define *what* data a material passport must contain, while Ostrom's principles define *how* the institutional infrastructure for issuing and

governing those passports should be organised in contexts—such as material reuse—where the regulatory assumption of a responsible manufacturer does not hold.

The TRACE prototype is now deployed and operational at trace.adventurous.systems, with ongoing pilot evaluation at Stirling Reuse Hub providing empirical assessment of whether blockchain-enabled commons governance can deliver the trust, traceability, and coordination that stakeholders identified as prerequisites for scaling construction material reuse in Scotland and beyond.

Figure 3 presents the public landing page of the running platform. The deployed system operationalises the architecture described above through a deliberately blockchain-invisible interface: a visitor can browse the materials marketplace, register or list reclaimed materials, or scan a passport QR code to verify a material's integrity against its on-chain hash—none of which requires a cryptocurrency wallet or any blockchain knowledge. The landing page foregrounds the three commitments that distinguish the platform—EU Digital Product Passport compliance, blockchain-anchored integrity on VeChainThor, and circular-economy traceability of deconstruction origin, condition grade, carbon savings and reuse history—while the seven-contract governance layer of Figure 2 operates entirely beneath this surface. To our knowledge, this is among the first publicly accessible material-passport platforms to pair EU DPP-aligned data structures with an Ostrom-grounded commons-governance layer, and it constitutes the live system on which the Stirling Reuse Hub pilot is now being evaluated.

BLOCKCHAIN-ENABLED REAL ESTATE OWNERSHIP TRANSFER IN BELGIUM: A HYBRID INSTITUTIONAL FRAMEWORK

Aishuak Kerimzhanova[1], Theodoros Dounas[2]
[1]University of Antwerp, Antwerp, Belgium
[2]Heriot-Watt University, Edinburgh, Scotland, UK

Abstract

This paper addresses the tension between blockchain's technical potential and the need for legal compliance in highly regulated property markets. Drawing on Institutional Cryptoeconomics, we propose a hybrid governance architecture for real estate transactions in Belgium that complements, rather than replaces, existing legal frameworks. The system combines smart contracts for automated escrow and settlement, an AI-based assistant to reduce ex ante coordination costs, and civil notaries as institutional oracles for legal validation. By embedding algorithms within mandated structures, this "trustworthy" governance model aims to reduce transaction costs while ensuring regulatory alignment, offering a scalable template for adoption in real estate.

Introduction

Real estate transactions are among the most institutionally complex forms of economic exchange, characterised by high asset values, long settlement periods, illiquidity, and substantial information asymmetry (Garmaise & Moskowitz, 2004). As a result, buyers and sellers rely on third parties who perform authentication functions and act as trust intermediaries. Although these intermediaries generate institutional trust, they also impose high transaction costs and cause significant time delays (Nooteboom, 2005).

Blockchain technology has been widely proposed as a technical solution to real estate inefficiencies through its immutable records, transparent distributed ledger, and automated transactions enabled by smart contracts (Konashevych, 2021). Early academic and industry discussions framed blockchain as a "trustless" technology capable of disintermediating traditional institutions (The Economist, 2015).

However, empirical evidence from pilot projects and case studies increasingly demonstrates that fully decentralised models are difficult to integrate with the legal and regulatory frameworks governing real estate markets. Notably, a famous example of the Swedish blockchain and land registry initiative, although technologically successful, has been abandoned in favour of a non-blockchain solution, showcasing that technical feasibility alone is insufficient for institutional adoption (Proskurovska & Dörry, 2022).

Although prior studies have explored the use of blockchain technology in land administration and property transactions, they primarily focus on technical feasibility or propose universal solutions. As a result, limited attention has been given to how such systems can be institutionally embedded to complement, rather than replace, mandatory legal frameworks. This limitation is particularly important, as blockchain-based solutions cannot yet be uniformly applied across jurisdictions; real estate regulations vary significantly even among EU member states. Furthermore, the growing importance of circular real estate and circular construction introduces additional requirements for data continuity and lifecycle management that blockchain can support (Shojaei & Naderi, 2024).

To address this gap, this paper adopts the perspective of Institutional Cryptoeconomics (IC), which conceptualises blockchain not merely as a technical tool but as an institutional technology capable of reducing transaction and coordination costs within an economy (Allen et al., 2020). Drawing on the Transaction Cost Economics (TCE) theory of Williamson (1985), blockchain is viewed as a mechanism that reduces ex post enforcement and verification costs through smart contracts, while some ex ante costs, such as drafting, information processing, and negotiation, remain unresolved.

Building on this theoretical foundation and a gap in the literature, this study develops a hybrid "trustworthy" governance framework for blockchain-enabled real estate transactions in Belgium. The framework aims to provide security, transparency, and automation through blockchain immutability and smart contract execution, while assigning legal certainty and trust to Belgian civil law notaries as institutional oracles. Additionally, the framework introduces an AI-based assistant to reduce ex ante transaction costs associated with bounded rationality and procedural complexity.

Point of departure

This study builds on three interconnected literature topics that together motivate the need for a hybrid, institutionally grounded approach to blockchain-enabled real estate transactions. First, prior research on blockchain in real estate and land administration reveals a consistent gap between technical feasibility and real-world adoption. Second, the literature on trust demonstrates that trust is

not merely a social construct or a technological outcome but an institutionally produced condition. Third, IC conceptualises blockchain as an institutional technology that can reduce coordination and transaction costs within an economy. Together, these three topics feed into the central proposition of this study that blockchain-based real estate systems require institutional embedding rather than purely technical design.

Blockchain technology in real estate and land administration

The application of blockchain technology in real estate and land administration has been a growing topic both in academic research and industry practice. Existing studies suggest that blockchain can address many persistent challenges in real estate, such as inefficiency, fraud, corruption, and high transaction costs (Allessie et al., 2019; Kempe, 2017; Konashevych, 2021). These challenges are commonly associated with unreliable or missing land registrations, lengthy administrative processes, and the structural illiquidity of real estate assets (Shuaib et al., 2020; Wong et al., 2012). Due to the manual, paper-based, and fragmented nature of records, they are prone to errors, fraud, and corruption (Ameyaw & de Vries, 2021).

Distributed Ledger Technology (DLT) has been proposed as a technical solution to reduce these inefficiencies by enabling immutable records and automated transaction execution via smart contracts (Konashevych, 2021). Empirical studies suggest that DLTs can reduce information asymmetries between market participants and improve transparency (Chen & Yu, 2024). Several frameworks have been proposed to operationalise these claims. For example, Shuaib et al. (2020) present an 11-step ownership transfer model, while Verma et al. (2024) and Mohanty et al. (2025) develop blockchain frameworks for property registration and operations, reporting improvements in security, efficiency, and transparency. Bărbuţă & Alexandrescu (2024) further extend the design space by proposing dNFTs as updatable on-chain property representations.

However, recent academic research increasingly highlights that blockchain adoption faces greater constraints from legal and regulatory compliance and the complexity of system integration than from technical feasibility alone (Ajayi et al., 2026; Akhmetbek & Špaček, 2021). Podshivalov (2022) similarly argues that blockchain implementation in real estate registration should be introduced gradually alongside the development of appropriate legal and regulatory frameworks. Case studies of pilot projects show that fully decentralised systems rarely align with the legal frameworks governing real estate markets (Proskurovska, 2023). A notable example is the Swedish Lantmäteriet initiative, which was the first to test blockchain technology for property conveyance but did not advance beyond the pilot phase. Instead, the system was replaced by a non-blockchain platform, Tambur (Proskurovska & Dörry, 2022). Proskurovska (2023) explains that this results from a mix of resistance from existing institutions and incompatibilities with current strategies aimed at financial stability.

These findings thus support a shift from technological optimism toward institutionally embedded adoption strategies. Rather than advocating full-scale disruption, several authors argue for a hybrid approach rather than a full-scale process (Allessie et al., 2019; Bennett et al., 2021; Saari et al., 2022).

Trust

Across the literature, trust was found to influence market confidence and participation directly (Gurun & Booth, 2024), which in turn affects price formation (CFA Institute, 2022). While Nakamoto (2008) introduced blockchain as a technology that does not require trust, in which users rely on cryptographic protocols, consensus mechanisms, and immutable ledgers, subsequent research has challenged this assumption. Blockchain can facilitate a form of institution-based trust by increasing transparency and enabling automated execution (Chen & Yu, 2024; Lumineau et al., 2021). However, it does not eliminate the need for trust altogether. Instead, trust remains embedded in social, legal, and organisational contexts (Szabo, 2017). Furthermore, trust was found to be a crucial prerequisite for blockchain adoption rather than its outcome (Dupuis et al., 2021). Adoption depends on socio-cultural factors (Mutambik et al., 2024), governance structures (Li et al., 2023), and the overall usability of blockchain-based applications (Smits & Hulstijn, 2020).

In land administration, legal and regulatory compliance has been identified as a key factor in stakeholder trust (Ajayi et al., 2026). This suggests that algorithms alone cannot produce trust in blockchain-enabled real estate transactions; they must be anchored in institutional validation and legal enforceability.

Institutional cryptoeconomics and hybrid governance

IC conceptualises blockchain not only as a database technology but also as a new institutional technology for governing the “knowledge commons” (Berg et al., 2019). IC applies the principles of New Institutional Economics (Coase, 1937; Williamson, 2000) to explain how blockchain technology reduces the “costs of trust” and coordination within an economy. The central principle of IC is the reduction of transaction costs (Davidson & Potts, 2022). Transaction costs arise from three primary constraints: bounded rationality, opportunism, and asset specificity (Williamson, 1985). Berg et al. (2019) demonstrate that blockchain technology can be analysed through Williamson’s (1985) framework. While smart contracts can reduce ex post costs, such as enforcement and monitoring, through automated execution and transparency, they do not eliminate ex ante costs related to drafting, negotiation, and information processing. Moreover, a smart contract designer might still engage in fraudulent activities during the design process (Davidson & Potts, 2022), giving rise to the so-called "oracle problem” (Caldarelli, 2020). Recent research, therefore, highlights the emergence of hybrid governance models, in

which algorithmic mechanisms coexist with social institutions (Bennett et al., 2021; Lumineau et al., 2021; Saari et al., 2022). Such models combine the efficiency of automation with the legitimacy of traditional institutions. In real estate, this hybridisation is not optional but structurally required due to the legal, high-value, and high-risk nature of ownership rights.

Institutional context

EU regulatory framework

The European Commission has adopted several legislative measures to regulate crypto-assets and protect consumers and investors (EU, 2026). Crypto-assets classified as financial instruments are regulated under MiFID II and must comply with the same rules as traditional financial instruments (ESMA, 2025). Other crypto-assets are governed by the Markets in Crypto-Assets Regulation (MiCA). Data protection remains a major concern, especially regarding compliance with the General Data Protection Regulation (GDPR) and the "right to be forgotten" (Zafar, 2025). The European Data Protection Board (EDPB) has addressed this by issuing guidelines on processing personal data through blockchain technologies (EDPB, 2025): storing personal data directly on the blockchain should be avoided, except for identifiers or proof of identity. Personal data should be stored off-chain, with cryptographic proof on the blockchain. This approach allows the "right to be forgotten" to be enforced by deleting data off-chain.

Belgian real estate law

The main regulations governing the purchase of real estate are set out in the Belgian Civil Code, particularly Book 3, entitled "Assets," as of 1 September 2021. Additionally, the transaction process follows the general rules of contract law in Book 5, entitled "Obligations". The real estate ownership and registry system in Belgium was described in detail by van de Werve (2025) in Deloitte's Legal Handbook:

The process of purchasing property in Belgium generally involves two main steps: signing a private sales agreement and executing a deed before a Belgian civil-law notary. Within four months of signing the private sales contract, it must be registered with the mortgage registry office and the land registry (Kadaster). The registered titles in Kadaster are for informational purposes only and do not serve as confirmation of ownership. Civil law notaries play a crucial, legally mandated role in Belgian real estate transactions. Their duties include validating the transfer deed, verifying the identities of the parties, collecting registration fees, ensuring there are no encumbrances, and confirming compliance with urban planning and land use laws. The Royal Decree strictly regulates Belgian notarial fees, which are consistent across regions and are set on a proportionally progressive scale based on the property's value.

The process of real estate purchase and registration in Belgium differs from, for example, Sweden, where real estate transactions do not require notarization (Fjellström, 2025). Instead, their system is heavily dependent on real estate brokers that mediate over 90% of all housing sales in Sweden (Proskurovska & Dörry, 2022). Notably, during the transaction, they are typically granted the power of attorney, which allows them to access and handle personal data of the involved parties (Proskurovska, 2023). These differences underline the importance of national legal systems in the development of blockchain-enabled real estate transaction solutions.

Methodology

This study employs a Design Science Research (DSR) methodology to develop a hybrid governance framework for blockchain-enabled real estate transactions in Belgium. Following Hevner et al. (2004) and Peffers et al. (2007), DSR is appropriate as it focuses on creating innovative artefacts that address identified problems in real-world contexts. This paper covers Phases 1-3: problem identification, objectives definition, and artefact design, leaving development, demonstration, and evaluation for future work.

DSR phases 1-2: problem identification and objective definition

Prior blockchain implementations in land administration, notably Sweden's Lantmäteriet pilot, demonstrate that technical feasibility alone is insufficient for institutional adoption (Proskurovska & Dörry, 2022). The problem is further complicated by three factors: high transaction costs resulting from information asymmetry and intermediary fees, regulatory requirements mandating notarial involvement in Belgian property transfers, and the absence of frameworks that meaningfully integrate blockchain with existing legal structures rather than attempting to replace them.

This phase involved a literature review across three domains: blockchain applications in real estate and land administration, trust mechanisms in property transactions, and hybrid governance models. The review reveals a critical gap between fully decentralised "trustless" blockchain implementations and the regulatory realities of property markets, motivating the development of a hybrid institutional architecture.

DSR phase 3: artefact design

The artefact is a hybrid governance architecture comprising technical components, institutional interfaces, and procedural workflows, organised into four interconnected activities: Institutional Actor Modelling, Transaction Workflow Architecture, Technical Component Specification, and Regulatory Compliance.

Proposed hybrid transaction architecture

The proposed framework integrates three governance components:

(1) blockchain and smart contracts for automated execution and record-keeping, (2) an AI-assistant for information processing and coordination, and (3) civil law notaries as institutional oracles responsible for legal validation and enforcement. The platform is governed as a permissioned consortium, with node validation rights

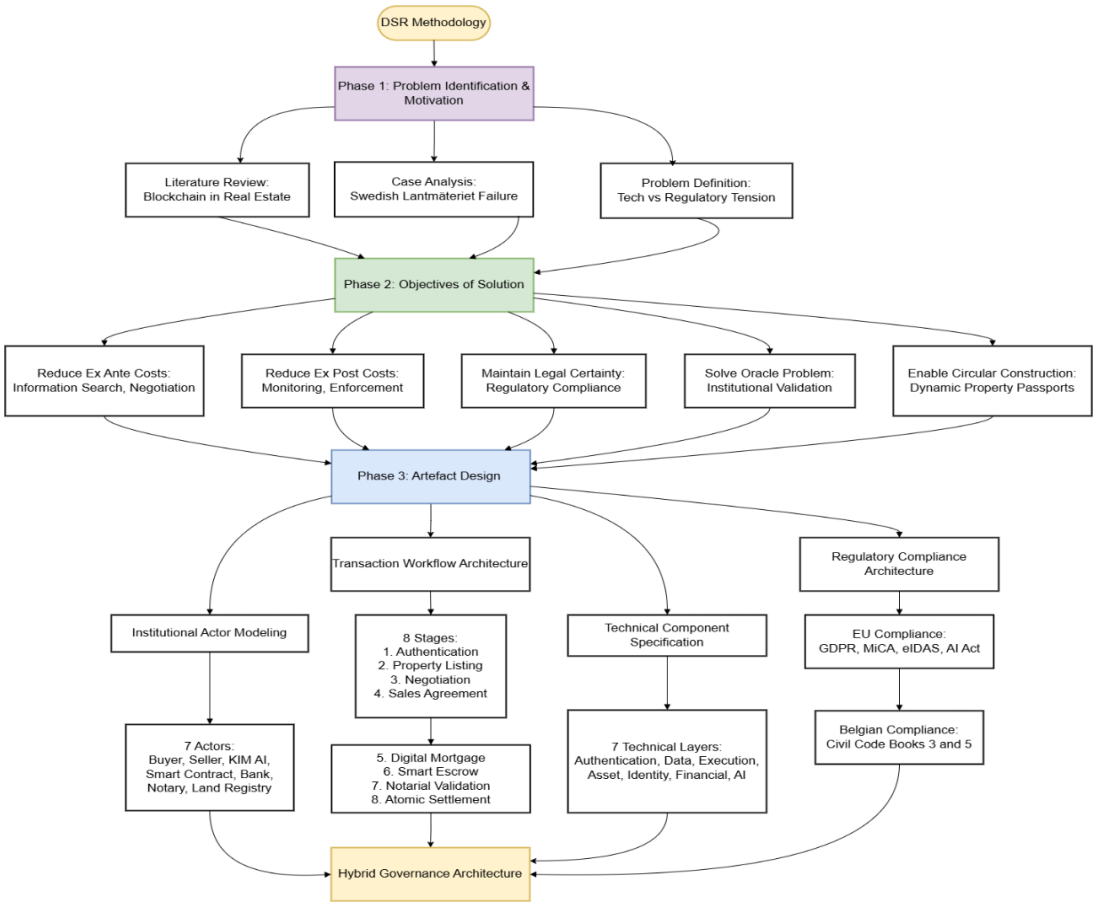

Figure 1: Phases 1-3 of the DSR methodology employed for this paper.

restricted to a defined set of institutional participants. In the Belgian context, the proposed consortium comprises civil law notaries represented through the Federation of Notaries (Fednot), the land registry, and participating mortgage banks. Platform operation and KIM's infrastructure would be managed by a neutral technical operator under contractual obligations to the consortium.

Figure 2 illustrates the sequence diagram of the proposed eight-stage transaction workflow. The framework involves the following actors:

- **Buyer (Alice) and Seller (Bob)**: the primary transacting parties.
- **AI-based assistant (KIM - Kunstmatige Intelligentie Makelaar):** KIM operates through a perceive-reason-act cycle without requiring explicit human instruction at each stage. Its agentic capabilities include: (1) independent calls to government APIs, including the Kadaster, soil databases, regional EPC registries, and municipal urban planning systems; (2) multi-source synthesis of retrieved data; (3) document generation, such as standardised property listings and the Private Sales Agreement (PSA). By automating property searches, data retrieval, document preparation, and eligibility coordination, which are currently performed by real estate agents, KIM could reduce their role and, in turn, lower ex ante costs associated with bounded rationality and information asymmetry (Williamson, 1985). Importantly, KIM's outputs are decision support, not autonomous determinations – all binding actions require a notary's authorisation. To ensure compliance with the EU AI Act (Regulation (EU) 2024/1689), KIM is architecturally restricted to a "limited-risk" or "transparency-obligated" AI system.
- **Smart contract (DLT)**: the execution layer that governs the escrow, suspensive conditions, and atomic settlement, deployed on a permissioned consortium blockchain.
- **Mortgage bank**: responsible for credit risk assessment and issuance of MiCA-compliant E-Money Tokens (EMTs).
- **Notary**: acts as an institutional oracle and legal authority.
- **Land registry and mortgage Office**: maintains off-chain records of ownership and encumbrances.

Stage 1: authentication

To ensure non-repudiation and compliance with Belgian AML/KYC requirements, the framework integrates the Belgian digital identity solution, Itsme, as the primary authentication mechanism. Under eIDAS (Regulation (EU) No 910/2014), a Qualified Electronic Signature (QES) generated via Itsme has the same legal validity as a handwritten signature. Both Alice and Bob authenticate

via Itsme, each receiving cryptographic credentials derived from their respective Itsme-based verifications. These credentials enable participants to generate zero-knowledge proofs (ZKPs) demonstrating that they are legally authorised to participate in property transactions without revealing their personal data to the platform or the blockchain.

Stage 2: property listing and data verification

Bob submits property information to the platform. KIM verifies ownership status through the land registry's API and retrieves certified property-related data from governmental databases, including cadastral records, energy performance certificates (EPCs), soil reports, and urban planning documentation. Based on these inputs, KIM helps Bob to generate a standardised property listing. For Alice, KIM provides decision support by filtering properties according to her preferences and explains the necessary steps and the legally complex documentation.

Stage 3: viewing and price negotiation

KIM schedules a property viewing for Alice using Bob's preferences, ensuring that both Alice and Bob are authorised participants before the address is shared to reduce security risks. If Alice submits a bid, KIM initiates a privacy-preserving eligibility verification workflow in which Alice interacts directly with the mortgage bank's secure system via Itsme. The Mortgage Bank, after an internal off-chain evaluation, sends the signed via Itsme attestation to the platform, reducing opportunism and lowering risk.

Stage 4: private sales agreement

Once Bob accepts Alice's bid via the platform, KIM generates a Private Sales Agreement (PSA) with the agreed price and conditions. Both Bob and Alice sign the PSA via Itsme. A cryptographic hash of the signed PSA is anchored on the blockchain to prevent both Bob from taking a higher offer after agreeing to Alice's or Alice from lowering her offer at the last minute.

Stage 5: digital mortgage

Alice formally applies for a mortgage. Once approved, the Mortgage Bank issues a conditional payment commitment to the smart contract. Funds are represented as EMTs, ensuring regulatory alignment with EU law.

Stage 6: smart escrow

After the PSA is signed and mortgage approval is granted, Alice sends the deposit to the smart contract escrow in EMTs. The Mortgage Bank transfers the remaining amount to the same smart contract escrow in EMTs. The funds are released only when the notary signs the deed off-chain and authorises execution of the smart contract. This mechanism reduces ex post enforcement costs by automating escrow management while preserving legal safeguards.

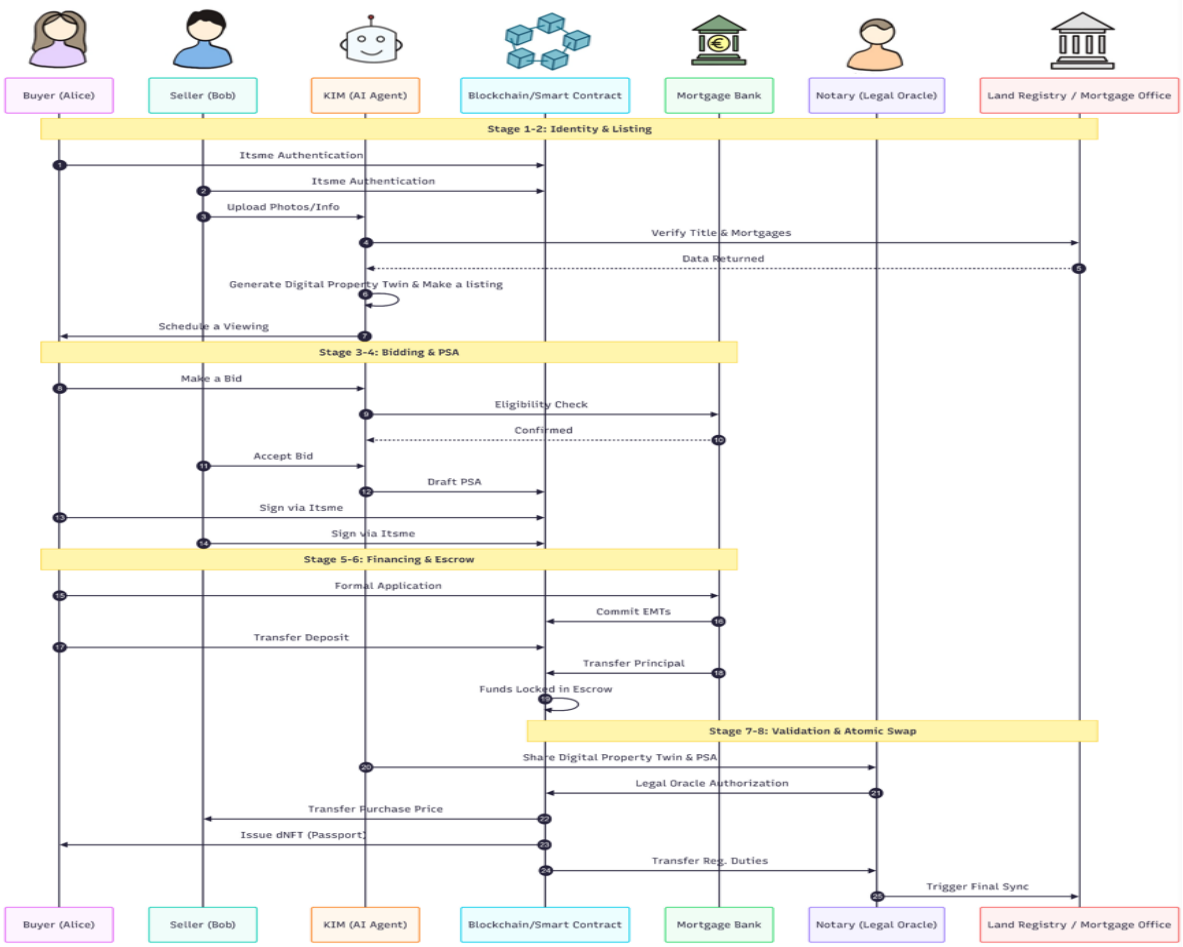

Figure 2: Sequence diagram of proposed property transfer architecture.

Stage 7: notarial validation

The civil law notary receives the "Digital Property Twin" from KIM, stored off-chain via InterPlanetary File System (IPFS). However, the notary remains responsible for verifying the data provided by KIM and performing other mandated checks that require human judgment and institutional authority. Upon completion, the notary issues an on-chain authorisation signal to the smart contract. The oracle problem is addressed through institutional legitimacy.

Stage 8: atomic settlement

Upon notarial authorisation, the smart contract executes an atomic settlement: Bob receives payment, the notary receives the registration fee, and Alice receives a dynamic Non-Fungible Token (dNFT) and a physically signed deed representing ownership. Unlike static hashing, which fails to capture the dynamic nature of a real estate asset, dNFT can be updated and thus functions as a Property Passport. Off-chain data can be erased in compliance with GDPR requirements, while the DLT retains cryptographic proofs. The idea of using dNFTs for real estate assets was mentioned by Bărbuță & Alexandrescu (2024). Simultaneously, the system notifies the official land registry and mortgage office to ensure synchronisation between the blockchain ledger and the off-chain records.

Discussion and conclusion

This study proposed a hybrid framework for blockchain-enabled real estate transactions in Belgium that embeds blockchain technology within existing legal structures rather than disintermediating legally mandated institutions. Existing research shows that blockchain achieves meaningful impact when integrated into legal and governance frameworks rather than disrupting them (De Filippi & Wright, 2018). By assigning operational and informational tasks to algorithms and validation functions to notaries, the framework addresses specific inefficiencies while maintaining legal certainty. In line with Saari et al. (2022), who emphasised that blockchain implementation in land administration will likely take a hybrid form. The framework employs a permissioned consortium blockchain, restricting validation to civil law notaries represented through Fednot, the land registry and mortgage office, and participating banks. This structure ensures that no single private entity controls the ledger while enabling faster transaction processing and controlled governance (Peters & Panayi, 2016).

Drawing on Williamson's (1985) TCE, the framework addresses both ex ante and ex post transaction costs. In Belgium, real estate agent commissions typically range from 2% to 5% of the property's value, and the average settlement period is three to four months. Ex ante, KIM reduces these costs by automating real estate agent functions, including property searches, data retrieval, document preparation, and eligibility coordination. Importantly, KIM does not require the elimination of real estate agents; buyers and sellers who prefer professional mediation can still choose that option. Instead, the platform lowers the barrier for those who cannot afford or decide not to use an agent, thereby reducing transaction costs more significantly. KIM's outputs are strictly decision support: all outputs are subject to notarial verification, as there is a risk of errors and inaccuracies inherent to LLM-based systems. Ex post, smart contracts and atomic settlement eliminate enforcement costs associated with escrow and manual fund transfers (Davidson & Potts, 2022), while consortium consensus reduces fraud risk and balances efficiency with institutional trust (Kowalski et al., 2021).

The framework proposes a trustworthy environment where algorithmic trust is anchored in institutional trust through notarial oversight. Moreover, the architecture uses dNFTs that, in combination with Digital Twins, could enable longitudinal tracking of construction materials, maintenance logs, and energy performance certificates, contributing to circular real estate and circular construction (Naderi & Shojaei, 2024). Crucially, dNFTs represent a data layer rather than actual ownership and do not require legal equivalence to a notarial deed.

The framework has several limitations. First, it has not yet been tested in real-world deployments, and its performance with high-volume transactions remains unverified. Second, the long-term legal interpretation of the use of dNFTs in property law continues to evolve. Third, relying on notarial oversight might limit scalability in other countries with different legal systems. Fourth, KIM introduces risks specific to LLM-based agent systems, such as outputs that depend on the availability and accuracy of government APIs, residual hallucination risks that cannot be fully eliminated, and user over-reliance on AI-generated documents, which could weaken informed consent. Mandatory notarial verification partly addresses these risks but also creates a dependency on notaries' digital literacy, a skills gap that needs targeted professional development as part of the deployment plan.

Future work will validate the framework through prototype development and multi-dimensional evaluation: (1) technical performance, assessing system reliability, latency, and interoperability; (2) transaction cost analysis, comparing ex ante and ex post costs against traditional Belgian workflows; (3) stakeholder evaluation, conducted through semi-structured interviews with key actors in the Belgian real estate ecosystem, using a protocol grounded in the Technology Acceptance Model (TAM), trust assessment constructs, and perceived adoption barriers (Davis, 1989); and (4) circular construction extensibility, exploring how the dNFT model can support multi-stakeholder material provenance tracking and lifecycle management.

In conclusion, this paper offers a legally grounded template for blockchain-enabled real estate transactions that does not compromise institutional integrity. By embedding algorithms with mandated structures rather than replacing them, this framework provides actionable insights for public authorities seeking to combine technological innovation with regulatory compliance in property markets.

AUTOMATED GENERATION OF DISASSEMBLY GRAPHS BASED ON DETAILED 2D SECTION DRAWINGS

Kasimir Forth[1], Mikhael Johanes[1], Elvire de Clermont Tonnerre[1], and Catherine De Wolf[1]
[1]ETH Zurich, Zurich, Switzerland

Abstract

Disassembly and circularity assessments are limited by the lack of structured, machine-readable data on material layers and connections, which are typically represented in expert-readable 2D section drawings. This paper explores how disassembly-relevant information can be automatically derived from such drawings represented as graphs using computer vision for segmentation, vision language models for material labeling, and language-based reasoning for semantic enrichment. The prototype extracts components and their connectivity and material information and generates graph representations capturing assembly hierarchies, enabling automated disassembly reasoning. This work marks a first step toward integrating heterogeneous data sources into unified graph models for circularity assessment.

Introduction

The built environment is one of the largest consumers of raw materials and a major contributor to global waste streams. Within Europe, construction and demolition activities generate close to 40% of all waste (García et al., 2024). Growing urbanization and rising living standards are expected to intensify this demand, particularly for mineral-based construction materials (OECD, 2019). Furthermore, as resource extraction and processing continue to drive greenhouse gas emissions, which are projected to rise to 4.6 Gt CO_2-equivalent annually by 2060 (UN Environment Programme, 2022), the construction sector faces increasing pressure to reduce its environmental footprint.

To address these challenges, the concept of a circular economy has gained prominence in the construction sector. It promotes keeping materials and components in the use stage for as long as possible by designing buildings that can be adapted, dismantled, dis- and reassembled rather than demolished. Achieving such reusability, however, depends on reliable knowledge of how building parts are connected and composed. This information of materials and components in existing contexts is often missing or inconsistently represented in current digital workflows, limiting the ability to evaluate a building's potential for disassembly.

Motivation and research gap

Existing circularity metrics, such as the material circularity indicator (MCI) (Goddin et al., 2019) and disassembly potential (Durmisevic, 2006), require detailed information on material composition, connection types, and assembly hierarchies. In previous studies (Forth and De Wolf, 2025), we showed that representing this disassembly information using knowledge graphs, hereinafter referred to as disassembly graphs, supports circular decision-making. However, the extraction of all relevant data for existing assemblies remains time consuming and dependent on expert knowledge.

Current digital methods for assessing disassembly potential rely on incomplete as-built data or manual modeling, while detailed two-dimensional (2D) section drawings contain rich latent information on assemblies and materials that remains underutilized. Automating the interpretation of such drawings can bridge the gap between design documentation and disassembly-oriented building information, enabling large-scale circularity assessments and disassembly planning and thus the reuse of components and materials.

This study investigates how disassembly graphs can be automatically derived from detailed 2D as-designed section drawings to represent the hierarchical and material relationships of existing building assemblies. We hypothesize that by combining vision-language reasoning techniques, it is possible to infer building component connectivity and semantic relationships sufficient to construct a graph representation that supports circularity assessments that focus on disassembly potential.

Background and related work

This section introduces the two main concepts of representing disassembly-related information using graphs and reasoning techniques for automatically extracting information from 2D architectural drawings.

Graph representations of disassembly information

The representation of disassembly information has evolved from manual heuristic assessments to sophisticated graph-based models that capture the complex interdependencies between building components. Fundamental to this domain is the work of Durmisevic, who established the theoretical groundwork for quantifying disassembly potential (Durmisevic, 2006). She proposed modeling building configurations as relational diagrams of components and their connections to represent physical dependencies. By analyzing these relational structures, Durmisevic demonstrated that the disassembly potential is inversely propor-

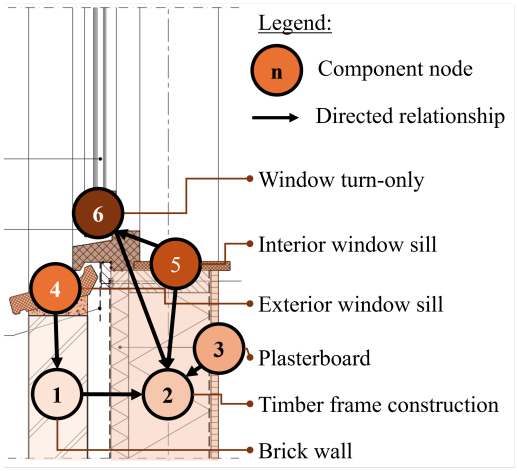

Figure 1: Example of information for disassembly potential of a wall and window according to van Vliet (2018)

tional to the complexity of the dependencies of components (Durmisevic, 2006). Specifically, hierarchical and parallel relational patterns facilitate higher recoverability compared to integrated, sequential dependencies.

Building on these topological foundations, Smith et al. introduced the disassembly sequence structure graph (DSSG), a formalism designed to optimize the disassembly process itself (Smith et al., 2012). Unlike static dependency diagrams, the DSSG models the process by generating a graph in which nodes represent specific parts and edges represent feasible removal sequences. This approach addresses the ”selective disassembly” problem by allowing for the identification of optimal paths to remove specific target components for maintenance or reuse while minimizing the total number of operations.

In more recent applications focusing on circularity assessment, van Vliet operationalized Durmisevic’s relational patterns to evaluate the circular potential of existing whole buildings (van Vliet, 2018). He simplified Durmisevic’s approach by focusing on the most important properties, such as ”type of connection”, ”assembly sequence”, ”accessibility to connection, as well as ”assembly shape”, ”independency”, ”type of relational pattern” or ”method of fabrication” to calculate a disassembly potential score. This method highlights the practical utility of graph representations in translating abstract circularity principles into quantifiable metrics for building elements.

Most recently, the focus has shifted toward using semantic knowledge graphs to manage the data required for these assessments. Bosma investigated the use of linked data to create digital product passports (DPPs) (Bosma, 2024). Instead of purely geometric or process graphs, Bosma utilizes an ontology-based graph structure, where products, materials, and their properties (such as location and warranty) are interlinked nodes. This semantic graph approach ensures that the disassembly information, such as material composition and manufacturer data, remains accessible and able to be queried.

Reasoning of 2D architectural drawings

In the domain of pixel-based analysis, convolutional neural networks (CNNs) and vision transformers (ViTs) have become the standard for tasks requiring visual pattern recognition, such as material detection and drawing classification. For instance, Pizarro et al. reviewed widespread methodologies involving CNNs for extracting walls, doors, and rooms from raster images. They note that these methods often discard essential topological metadata (Pizarro et al., 2022). More specialized applications include the work of Kairlapova et al., who successfully deployed CNN architectures like MobileNetV2 and ResNet50 to detect and classify building materials in 2D drawings to facilitate material passport generation (Kairlapova et al., 2025). Similarly, Carrara et al. compared ViTs against graph-based methods for classifying construction drawings into categories like discipline and project phase. They demonstrated that while pixel-based transformers are effective, they may fall short in capturing complex structural relations (Carrara et al., 2025a).

To address the limitations of raster approaches in capturing geometric and topological relationships, recent research has increasingly focused on vector and graph-based representations. Graph neural networks (GNNs) are gaining prominence for their ability to model drawings as connected entities rather than mere collections of pixels. Ko and Lee proposed a framework that converts architectural detail drawings into graph structures. Their framework utilizes GNNs to improve error detection and drawing classification by learning the interrelationships between drawing elements Ko and Lee (2025). Further advancing this domain, Carrara et al. introduced VectorGraphNet, a method that parses PDF drawings into scalable vector graphics graphs (Carrara et al., 2025b). By applying graph attention transformers, they achieved state-of-the-art results in line-level semantic segmentation, thus validating that structure-aware models can offer superior scalability and accuracy for complex technical drawings compared to conventional computer-vision-based techniques. Complementing these extraction methods, Schönfelder and König addressed the downstream challenge of data interoperability (Schönfelder and König, 2025). They introduced the drawing analysis ontology (DAnO), a framework designed to standardize the output of various computer vision tools into knowledge graphs, thereby enabling automated validation and semantic reasoning to refine the reconstructed building models.

Most approaches focus on segmentation and object detection on the floor plan level. To date, only Ko and Lee have focused on detailed architectural sections (Ko and Lee, 2025). However, they did not take textual input of legend and descriptions into account to further reason quantities, material, and connection information. Consequently, the work presented here extends the field toward multi-modal reasoning of detailed section drawings. It leverages segmentation, legend parsing, and graph-based modeling to infer assembly hierarchies and material relationships from

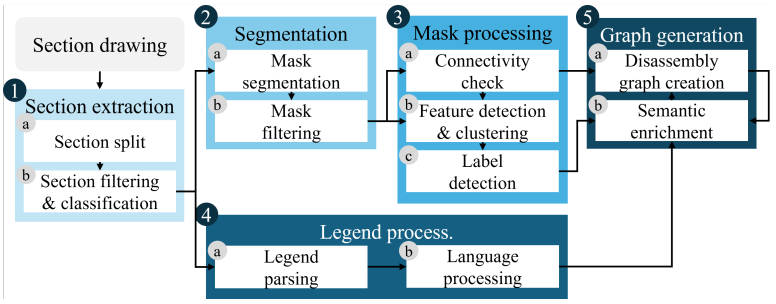

Figure 2: Overview of the proposed framework of deriving disassembly graphs based on 2D section drawings

as-designed documentation.

Method of generating disassembly graphs based on 2D section drawings

This study introduces a novel workflow for the automated generation of disassembly graphs based on 2D section drawings using computer vision, vision language models (VLM), and large language models (LLM) as well as graph-based reasoning techniques. Following Peffers' Design Science Research methodology Peffers et al. (2007), we identified the problem and defined the objective. Next, we designed and developed the overall framework, the steps of which are explained here. Finally, we demonstrated the framework with a case study and evaluated the results.

Overall framework

The overall framework consists of five main steps with several substeps, as shown in Figure 2. First, we split the whole drawing into its individual sections (1.a) and filter or classify them (1.b). Those section images that do not contain color gradients or legend text are further processed for segmentation (2). In the second step, each section is segmented into masks (2.a), and the masks are filtered (2.b): meaningful masks are kept, and almost blank masks are discarded. In the next step (3), the filtered masks from the second step are further processed and combined with the processed legend information. In the first substep (3.a), the connectivity between neighboring masks is identified. Next, features are detected (3.b), and finally, every mask is labeled either according to the detected features or the identified legend association (3.c). The section that was classified as legend is further processed by parsing and correcting the text (4.a) and then restructuring the text according to geometric and semantic information (4.b). In the final step (5), the disassembly graph is generated by, first, creating nodes for each mask and edges for each connection (5.a) and then enriching the results of the labeling and legend information (5.b). Depending on the drawing style, the order of these steps may change, but the general steps can be robustly applied to several drawing styles.

Section extraction

The section extraction-and-filtering pipeline automates the decomposition of sections across the entire drawing. Initial regions of interest are isolated by detecting structural contours within the image, which separates potential layout blocks from the background. Text-only areas are excluded using CLIP-based semantic filtering (Radford et al., 2021). These candidates are then validated using a visual classifier that checks for low color saturation and high edge density. This process effectively distinguishes valid technical sections, which are characterized by dense, monochromatic line work, from non-geometric artifacts, such as logos or photorealistic renderings.

Segmentation

We apply an automatic mask generator based on a Segment Anything Model (SAM) (Kirillov et al., 2023) that densely samples point prompts across the drawing to produce a large set of overlapping candidate segments. These proposals are subsequently post-processed to resolve overlaps and extract a set of disjoint graphical regions corresponding to distinct drawing components. To ensure reproducibility and stabilize color-encoded outputs, each detected mask is assigned a fixed, distinct color generated via a deterministic color scheme. Each cropped mask is evaluated using grayscale statistics, including brightness distribution, proportion of dark pixels, edge variance, and intensity histogram entropy. Segments are retained only if they exhibit (i) sufficient dark content relative to the background, (ii) meaningful edge structure indicative of technical line work or texture, and (iii) adequate intensity diversity throughout the region. Near white or homogeneous fragments that do not meet these criteria are discarded.

Mask processing

Different processing steps are necessary to bridge the gap between the segmented masks and the processed legend in order to generate semantic-rich disassembly graphs. We propose three main processing steps: connectivity check (4.a), feature detection and clustering (4.b), and label detection (4.c).

The first step checks the connectivity between masks representing physical adjacency between them. In technical drawings, lines of masks that should theoretically touch are often separated by tiny gaps of 1–2 pixels due to rasterization (converting vector lines to pixels) or anti-aliasing (smoothing edges). To take this into account, we use a 3x3 kernel dilation, which expands every segment by 3 pixels

in all directions. Now the artificially expanded segment bridges tiny gaps, ensuring that segments which are almost touching are recorded as adjacent. This robust adjacency detection ensures that compound structures (e.g., a wall composed of multiple material layers) are correctly linked as a coherent assembly.

To enable classification of similar materials within each mask, the system extracts a high-dimensional feature vector for each segment. While models like CLIP are powerful for semantic image-text alignment (Radford et al., 2021), we used DINO (self-supervised Distillation with No labels) in our implementation (Siméoni et al., 2025). The decision to use DINO stems from the nature of technical drawings. Architectural component materials are defined by local geometric textures (hatching patterns) rather than the global semantic contexts. The extracted features are subsequently clustered using K-Means algorithm, which groups segments with visually similar hatching patterns into common classes. This visual clustering serves as a fallback mechanism. If a specific segment lacks a direct text label from the next step, then its material properties can be inferred from its cluster neighbors that have been successfully identified.

The final step bridges the gap between the component segment connectivity graph and the parsed legend data. While the previous steps characterize the shape of the segments where they touch, this step identifies what label it contains by detecting numerical callouts. The system employs a VLM, specifically configured with a structured prompting strategy, to scan the original section images and the segments. The model is provided with the cropped section and the bounding box coordinates of the segments. To further facilitate spatial reasoning, the input image is augmented with a visible grid aligned with the image's pixel resolution. This grid provides an explicit, shared spatial reference frame that simplifies the localization and description of leader lines and numerical callouts by the language model. It is then tasked with identifying leader lines and numerical indicators pointing to specific geometries. The output is a structured mapping linking a segment ID to a legend number. This direct assignment allows the system to propagate the rich material metadata extracted from the legend in the next step to the corresponding nodes in the graph, thereby completing the semantic enrichment of the graph in the final step.

Legend parsing

To bridge the gap between abstract geometric segments and their physical properties, we detect and interpret the drawing's legend. Initial attempts to digitize this information relied on conventional optical character recognition (OCR) engines, such as Tesseract. However, these methods proved insufficient for the provided dataset. The low resolution and rasterization artifacts inherent in the technical drawings led to significant character misrecognition, resulting in incoherent text outputs that lacked semantic continuity.

To overcome these limitations, we use a VLM, in our case OpenAI's "GPT-4o-mini" (OpenAI et al., 2024). Unlike standard OCR, which processes characters individually, the VLM analyzes the visual context of the legend table, allowing it to infer meaning even from pixelated text. The model is prompted to extract the legend text and restructure it into a machine-readable dictionary, as shown for one layer in 4.b in Figure 3. This prompting strategy explicitly instructs the model to decompose the raw text descriptions into granular attributes for each layer. The resulting data structure differentiates for every component between material composition and layer thickness and, if available, connection type. We have, to date, implemented this workflow for only one style of legend and need to adapt it to further styles in future.

Graph generation

The final stage of the framework synthesizes the geometric, topological, and semantic data into a unified graph database. This step transforms the isolated segmentation masks into a disassembly graph that can be queried, where the building assembly is represented as a network of interconnected components. We use labeled property graphs since component properties can directly be stored in nodes and connection properties in edges, and implement the disassembly graph using Neo4j.

For every segmentation mask, a distinct component node is instantiated within the graph database. To ensure full traceability and visual consistency between the disassembly graph and the original drawing, each node is populated with a comprehensive set of properties, including a unique segment identifier, the source case study and section reference, and the specific RGB color values of the mask, which allow for manual traceability. Additionally, classification data such as the detected label and the cluster ID from feature analysis are stored as node properties to serve as keys for subsequent semantic mapping.

Following node creation, the physical relationships between components are encoded as edges to model the structural topology of the assembly. Using the adjacency list generated during the connectivity analysis, the system establishes connection relationships between interacting nodes, effectively distinguishing between isolated elements and composite structures.

Finally, the graph is enriched with the detailed metadata parsed from the legend. By querying the label property of each node against the structured legend dictionary, the system infers all available information, such as material composition and layer thickness, into the geometric entities.

Case study and results

To validate the proposed framework, we prototypically implemented the workflow and evaluated the segmentation, connectivity, and label detection step in two case studies to show the accuracy and stability performance at each step.

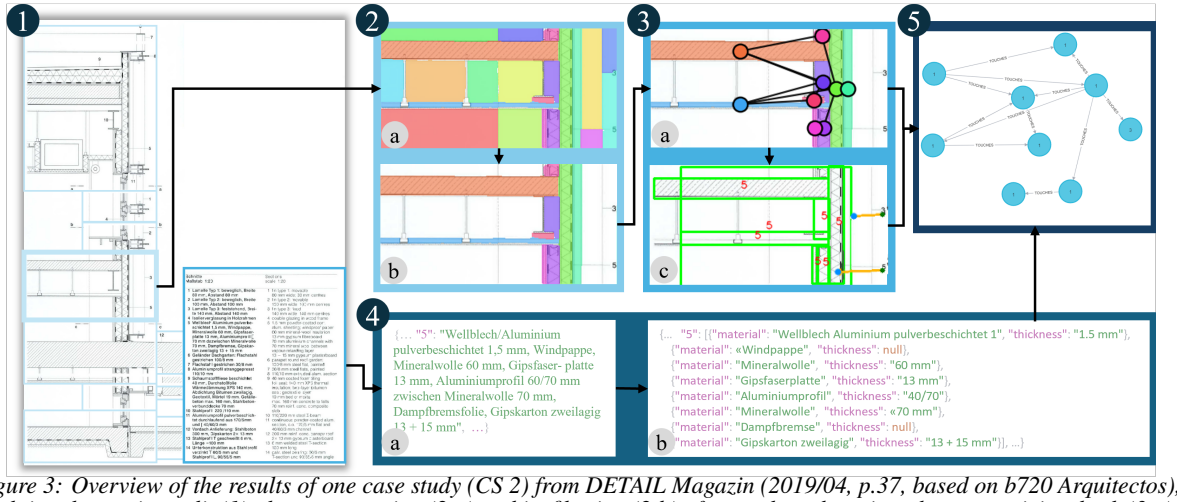

Figure 3: Overview of the results of one case study (CS 2) from DETAIL Magazin (2019/04, p.37, based on b720 Arquitectos), highlighting the section split (1), the segmentation (2.a) and its filtering (2.b) of one selected section, the connectivity check (3.a) and detected labels (3.c), the related legend excerpt (4), and the resulting disassembly graph of this section (5).

Case studies

We selected two exemplary detailed section pages from the architecture trade magazine *DETAIL*, one containing six sections and the second four sections. These reflect a standardized style of detailed section drawings and contain a legend in German. Figure 3 shows one exemplary section with the results of each step. The case studies show multi-layered facades, challenging the segmentation, connectivity, and labeling algorithm to distinguish repetitive geometries, continuous layers, and air gaps.

Results and discussion

In the following subsections, we evaluate three main steps of the overall workflow, focusing on the segmentation, the resulting connectivities, and the identification of labels for the relevant segments. We ran the implementation five times for both case studies to quantitatively validate accuracy and stability for the three selected steps, as well as analyzing error patterns qualitatively selecting one example section.

Segmentation

The segmentation performance was evaluated by comparing predicted instance masks against manually annotated ground truth across all ten section drawings from both case studies. Instance-level evaluation was performed using greedy matching at an IoU threshold of 0.5, resulting in a precision of 52.4%, a recall of 61.5%, and an F1-score of 56.6%. These results indicate limited agreement at the instance level.

Further analysis shows that the instance-level scores are primarily affected by systematic over- and under-segmentation rather than poor spatial localization. When instance boundaries are ignored and evaluation is performed on pixel-wise overlap between the unions of ground truth and predicted masks, the measured agreement is substantially higher, with a precision of 73.7%, a recall of 93.2%, and an F1-score of 82.3%. This discrepancy indicates that most relevant regions are spatially detected but not consistently partitioned into the correct instances.

Qualitative inspection, shown in Figure 4, confirms this behavior. The overlay view (top) shows good geometric alignment between predictions (colored fill) and ground truth (gray outlines), indicating that errors are primarily due to incorrect mask extent rather than mislocalization. The middle view highlights under-segmentation, where multiple adjacent components are merged into a single predicted instance, producing overly large masks that introduce false-positive regions. The bottom view illustrates over-segmentation, where elements with large hatched regions are split into multiple predicted instances, particularly across internal boundaries introduced by hatch patterns.

These results highlight the need for more domain-specific instance segmentation approaches for architectural and construction drawings. Although the use of SAM-based segmentation is promising, the model is not well adapted to the abstraction level and graphical conventions of section drawings, leading to systematic under- and over-segmentation. In particular, thin, contiguous, and hierarchically composed elements are not consistently grouped into coherent instances despite being geometrically well localized. This limitation suggests that generic image-driven segmentation models require additional architectural priors, drawing-aware constraints, or task-specific fine-tuning to reliably support instance-level reasoning in this domain.

Connectivity results

The performance of the connectivity algorithm was quantitatively assessed by comparing the automatically generated connectivity graphs against a manually annotated ground truth across ten detailed 2D architectural sections. Missing connections lead to false negatives (red), and wrong connections lead to false positives (orange), as

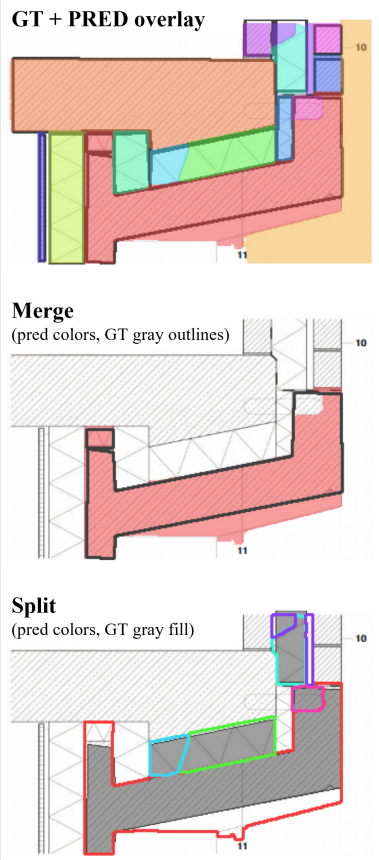

Figure 4: A qualitative comparison of ground truth and predicted segmentation for a representative section drawing shows generally sufficient alignment but inconsistent instance boundaries due to over- and under-segmentation.

shown exemplarily in Figure 5. The system achieved balanced and stable performance in all five iterations, yielding a precision of 82.52%, a recall of 87.41%, and a resulting F1 score of 84.89%. These metrics indicate that the framework is highly reliable for identifying standard physical adjacencies, effectively translating segmented mask data into a functional connectivity graph. The near parity between precision and recall suggests that the model does not suffer from a systemic bias toward over-prediction or under-prediction, providing a stable baseline for automated disassembly reasoning.

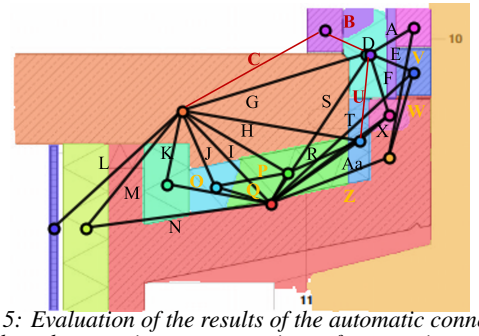

Figure 5: Evaluation of the results of the automatic connectivity check based on previous segmentations of one section example

A critical challenge identified during the evaluation is missed connections due to insufficient proximity between masks. In several instances, as illustrated in Figure 5, the human expert identified essential structural connections that the algorithm failed to detect because the masks were separated by small gaps. These gaps, often only a few pixels wide, frequently result from anti-aliasing artifacts during segmentation or the presence of thin architectural membranes that do not register as overlapping pixels. Because the current logic relies on strict pixel-to-pixel contact (extending by 3 pixels), these semantically connected components are treated as isolated entities. This limitation is particularly evident in complex joints where multiple materials converge but do not perfectly intersect in the digital representation.

Furthermore, the accuracy of the connectivity graph is heavily dependent on the upstream success of the computer vision segmentation phase. As highlighted in Figure 5, the absence of specific material masks directly results in a cascade of missing connections. These missing segments or over-segmented masks, such as unidentified insulation layers (light blue and green) in Figure 5, represent most of the recorded false positive connections. When the segmentation model fails to identify a mask for a specific material layer, the graph generator cannot establish any adjacency for that component, leading to incomplete assembly hierarchies. This underscores that the robustness of the final disassembly graph is intrinsically linked to the recall of the initial segmentation and labeling processes.

Segment label identification

Table 1 shows the average results of precision, recall, and F1 score as well as their standard deviations (σ) of all five iterations for each case study and overall (mean).

Table 1: Performance metrics for label identification across five iterations and the overall average

Average	**Precision**	**Recall**	**F1 Score**
CS 1	50.47%	86.00%	61.04%
CS 2	27.83%	100.00%	43.52%
Mean	37.68%	90.75%	52.91%
Std. Dev.	**Precision**	**Recall**	**F1 Score**
CS 1	9.58%	21.91%	2.39%
CS 2	1.82%	0.00%	2.23%
Mean	1.41%	14.58%	2.37%

The results show that case study 1 achieved a balanced performance, with an average F1 score of 61.04%, characterized by a recall of 86.00% and precision of 50.47%. However, it exhibited significant instability in detection rates. This was indicated by a high standard deviation in recall ($\sigma = 21.91\%$). Conversely, case study 2 demonstrated

perfect retrieval stability (recall 100.00%, $\sigma = 0.00\%$) but significantly lower precision (27.83%), resulting in a lower F1 score of 43.52%. This comparison highlights that while the system reliably detects all labels in complex configurations (CS 2), it is prone to assign labels too broadly compared to the more balanced but variable results of standard details (CS 1).

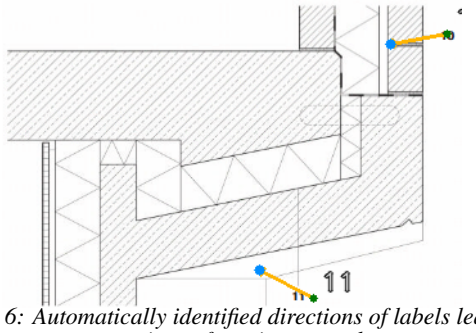

Figure 6: Automatically identified directions of labels leading to sections of one ion example.

The sources of inaccuracy were further investigated by visually inspecting and describing one exemplary section using the intermediate and final outputs. Figure 6 illustrates the system's interpretation of the leading lines. The green start point identifies the numeric label text, indicated by a green start point, and the blue end point the identified end point at the target segment, connected by a yellow leader line. While the leading line of label "10" accurately follows the initial direction, the leading line of label "11" deviates significantly, causing wrong labeling.

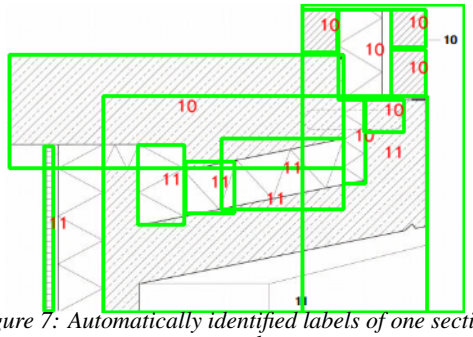

Figure 7: Automatically identified labels of one section example.

Figure 7 presents the resulting label assignments, revealing distinct success and failure modes. The system demonstrates robust performance in standard conditions, as evidenced by the correct labeling of the four top right segments. However, errors primarily arise from geometric inconsistencies in vector interpretation. A notable example occurs in the bottom-left region, where a segment is incorrectly labeled as "11" because the interpreted leading line vector deviates from its intended termination point and intersects a neighboring mask, as shown in Figure 6 . Additionally, the system exhibits a tendency to assign false positives in ambiguous zones. Two empty segments are incorrectly assigned label "10" despite the absence of explicit vector connectivity, suggesting an over-reliance on spatial proximity when graphical signals are weak.

In summary, the results indicate that while the VLM-based extraction is highly effective at retrieving semantic data (high recall), the geometric mapping mechanism requires refinement. The prevalence of false positives highlights the need for stricter vector constraints and collision detection algorithms to resolve ambiguities in dense or complex drawing regions. Thereby, we are aligning the module's precision with its high retrieval capability. In practice, better performance is observed in sections with larger components, while smaller or finer elements tend to generate more ambiguous mappings.

Limitations

The primary limitation pertains to the validated case studies. The current workflow is optimized using high-quality, standardized architectural detail drawings from a DETAIL magazine. Consequently, the system's robustness against the heterogeneity of broader architectural drawings, such as archival drawings, varying hatching standards, or hand-drawn sketches, remains unverified. The pipeline's adaptability to unstructured annotations or non-standardized material indications has not yet been evaluated.

Methodologically, quantitative benchmarking was restricted to the geometric processing modules. More specifically, it confirm only the accuracy of segmentation, connectivity detection, and label identification. Performance of legend processing and visual feature extraction have not yet been validated. Finally, the resulting disassembly potential calculations for every section have yet to be validated against a manual ground truth.

Technically, the prototype utilizes a specific configuration of models (SAM, DINOv3, GPT-4o) without comparative analysis. Ablation studies benchmarking these choices against alternative architectures, e.g., CLIP for feature extraction or open-source LLMs for parsing, were not conducted. Therefore, the current implementation may not represent the optimal balance between computational cost and inference accuracy.

Conclusion and outlook

This study proposes a novel computational framework for the automated generation of knowledge graphs interpreting disassembly-related data from 2D architectural section drawings. By integrating geometric segmentation (SAM), visual feature encoding (DINOv3), and semantic parsing (VLM), the pipeline successfully converts detailed section drawings with dense domain knowledge into disassembly graphs that can be queried. This transformation bridges a critical gap in the built environment: It enables the systematic assessment of reusability of components and materials and assembly hierarchies from legacy data sources that were previously inaccessible to digital circularity tools.

Future research will focus on validating the end-to-end fidelity of the generated disassembly graphs by comparing disassembly potential calculation results against manually curated ground truth. Next, the pipeline's robustness

will be tested on heterogeneous datasets that extend beyond standardized details to include diverse archival and hand-drawn documentation. Additionally, systematic ablation studies will benchmark alternative architectures. We will compare different models for computer vision, VLM, and LLM to optimize the trade-off between computational cost and inference accuracy, and focus on connection type properties. Finally, we aim to research how to link and fuse data with other data sources such as point clouds and BIM models (Forth and De Wolf, 2025) to enable a data-driven workflow for holistic circularity assessments.

TOWARDS STANDARDISED ENVIRONMENTAL PRODUCT DATA INTEGRATION IN IFC

Martina Jakubowska[1], and Kristoffer Negendahl[1]
[1]Technical University of Denmark, Denmark

Abstract

Whole Building Life Cycle Assessments are currently hindered by manual, labour-intensive workflows and fragmented BIM and LCA data, making iterative use impractical. Existing automated workflows often lack adherence to standards, undermine data quality, or introduce data migration burdens. This study investigates integrating WBLCA data within IFC, focusing on the Danish context, by formalising Danish LCA requirements on bSDD. We propose a data model for implementing EPDs as PDTs, according to ISO 22057, in IFC using the `IfcProjectLibrary` exchange format defined in ISO 17549-2 and ISO 16757-5. A prototype implementation of PDT-to-IFC conversion tool demonstrates and evaluates the data model's feasibility.

Introduction

Life Cycle Assessment

Life Cycle Assessment (LCA), standardised through the ISO 14000 series, is the established methodology for quantifying the environmental impacts. It evaluates multiple environmental indicators across the life cycle, from raw material extraction to end of life, and is essential for avoiding burden shifting from one environmental problem to another. LCA applied to buildings is referred to as Whole Building Life Cycle Assessment (WBLCA). A WBLCA aggregates the impacts of construction products and combines them with impacts from the operational phase.

Product-level results in building LCAs are typically communicated through Environmental Product Declarations (EPDs), defined by ISO 14025 and harmonised in the construction sector through the Product Category Rules (PCRs) standard EN 15804. Product LCA data may be product-specific or generic, e.g. the ÖKOBAUDAT, which is based on representative assumptions rather than individual products. At building level, EN 15978 provides the assessment framework.

While EPDs are still mainly published as PDFs, machine-readable formats are gaining importance. In Europe, ILCD+EPD is widely used, alongside newer approaches like ISO 22057, which defines EPDs as product data templates (PDTs) for direct integration into BIM workflows.

Current WBLCA Workflow

Today, performing a WBLCA is complex and labour-intensive, relying heavily on manual processes such as extracting quantities from models, mapping materials to appropriate EPDs, and coordinating inputs across disciplines. Interdisciplinary communication relies on disconnected tools, while required environmental data is frequently incomplete or unavailable in digital formats. These steps introduce additional workloads, are error-prone, and limit the feasibility of iterative assessments.

Long-term data storage is a further challenge. Although buildings last for decades, LCA results and their underlying assumptions are often difficult to access or reuse after only a few years, reducing transparency and leading to information loss.

Existing automated workflows offer some improvements, but often lack alignment with standards, compromise data quality, or depend on data transfers between systems that require additional mapping and validation. There is clear potential to improve WBLCA by reducing manual effort, enabling earlier and more iterative assessments. Such workflows should align with data standards, maintain scientific rigour, and ensure that models remain transparent and self-documenting over time.

Background

Strategies for Storing and Sharing EPD Data

Addressing these issues requires tighter integration of LCA data into BIM-based workflows (Klumbyte et al. (2023), Bari et al. (2019), Safari and AzariJafari (2021)), with a focus on open standards, such as IFC, and vendor-neutral, collaborative processes like openBIM, to ensure interoperability and long-term data accessibility.

Initial attempts to integrate LCA data into IFC rely on the property sets `PSet_EnvironmentalImpactIndicators` and `PSet_EnvironmentalImpactValues`. These property sets store environmental indicators per functional unit and calculate scaled results based on element quantities. However, their practical use is currently limited. The main limitation is the inability to represent multiple lifecycle modules for a single element. The `LifeCyclePhase` attribute allows only one phase to be assigned, which prevents full "cradle to grave" representation. In addition, the supported indicators are not fully aligned with EN 15804, agreement on

indicator definitions is incomplete, and LCA data cannot be consistently defined at material level or aggregated at building level.

ILCD+EPD and ISO 22057

The ILCD+EPD format, a subset of European Commission's ILCD framework, was an early and significant step in digitising EPDs, using XML to make environmental data machine-readable. Initially developed to meet German governmental requirements, it has since 2022 become the mandatory format for all new European EPDs.
Despite this progress, ILCD+EPD remains limited in its applicability within BIM workflows, particularly for representing construction objects. This limitation motivated the development of ISO 22057, which aims to better integrate EPDs into BIM workflows and support fully machine-interpretable EPDs in the future.
A significant benefit of ISO 22057 lies in its integration within systems already familiar to manufacturers, who will predominantly be responsible for maintaining and publishing EPDs moving forward. The task of digitising EPDs should not fall on architects or LCA practitioners. Additionally, the implementation of EPDs as PDTs presents opportunities for integration with existing systems such as SMART CE, ETIM, and GTIN/GS1. A JSON-based representation of ISO 22057, called DT JSON (Erlandsson et al. (2024)), is also mentioned in the EU Taxonomy and as the potential base-format for Digital Product Passports.

ISO 17549-2 and CODview2

The standard ISO 17549-2 defines an MVD of the IFC schema, named Construction Object Data View 2 - CODview2 for short. The purpose of CODview2 is to store and exchange configurable construction objects and their requirements using the `IfcProjectLibrary` mechanism of IFC. The MVD can be used to exchange both empty PDTs and filled product data sheets (PDSs). CODview2 does not support geometrical representations, but allows for exchanging geometric properties, focusing on complex, dynamic requirement constraints, and product specifications using embedded JavaScript functions. ISO 17549-2 does not define any construction-specific semantic entities or IFC element classes. Instead, it recommends using `IfcBuildingElementProxy` to represent all object types and defines classification through external data dictionaries based on ISO 12006-3:2022, such as the buildingSMART Data Dictionary (bSDD), as the sole sources of construction semantics.

ISO 16757-5 and IFC Catalogues

ISO 16757-5:2025 - *"Data structures for electronic product catalogues for building services - Product catalogue exchange format"* builds on the structure defined in ISO 17549-2 by, among others, introducing means of representing parametric geometry and generation of IFC geometries for selected product variants. The result is an IFC-based product catalogue, dubbed IFC catalogue, bridging the gap between manufacturer's catalogues and BIM project models. ISO 16757-5 keeps the strong connection to data dictionaries, relying on them for definitions of product classes and related properties.

Existing Research on LCA and BIM Integrations

Research on BIM–LCA integration is extensive (Bolognesi et al. (2025), Parekh and Trabucco (2024), Potrč Obrecht et al. (2020)). Wastiels and Decuypere (2019) identified five levels of integration. These range from exporting Bills of Quantities (BoQs) and processing them in spreadsheets or dedicated LCA tools, to importing BIM models directly into LCA software, and performing real-time estimations using LCA plug-ins within native BIM software. A further level, relatively new in the LCA context, involves using manufacturer-specific BIM objects enriched with environmental data.
Most research and software implementations do not place IFC or openBIM at the core of the workflow. Studies that do focus on IFC or openBIM, are comparatively few. The main contributions in this area are summarised in Table 1. All of the approaches rely on creating custom IFC property sets. Some avoid embedding EPD data in the model, instead referencing external datasets via unique identifiers (UUIDs). While this reduces model size, it introduces risks related to data persistence, responsibility, and broken links.
The buildingSMART Sustainability Group's "Industry Report on Environmental Impact Indicators" (Schmid et al. (2022)) is the only approach identified that integrates ISO 22057 data into IFC and links to a DD. It defines LCA and EPD modules in the bSDD and maps them into IFC using existing entities such as `IfcTask` and `IfcResource`. However, the resulting structure is highly complex, relying on deep nesting and repurposing IFC concepts beyond their original intent to represent even simple EPD data. This limits software support and may reduce clarity for users. The approach also lacks scenario handling, diverges from ISO 22057 in several respects, is incompatible with the CODview2 MVD, and does not support easy reuse or exchange of EPD data across projects or BIM objects.
Notably, Kremer et al. (2025) recently demonstrated an implementation of IFC product catalogues with dynamic requirements, defined in ISO 16757-5, using a heat pump as

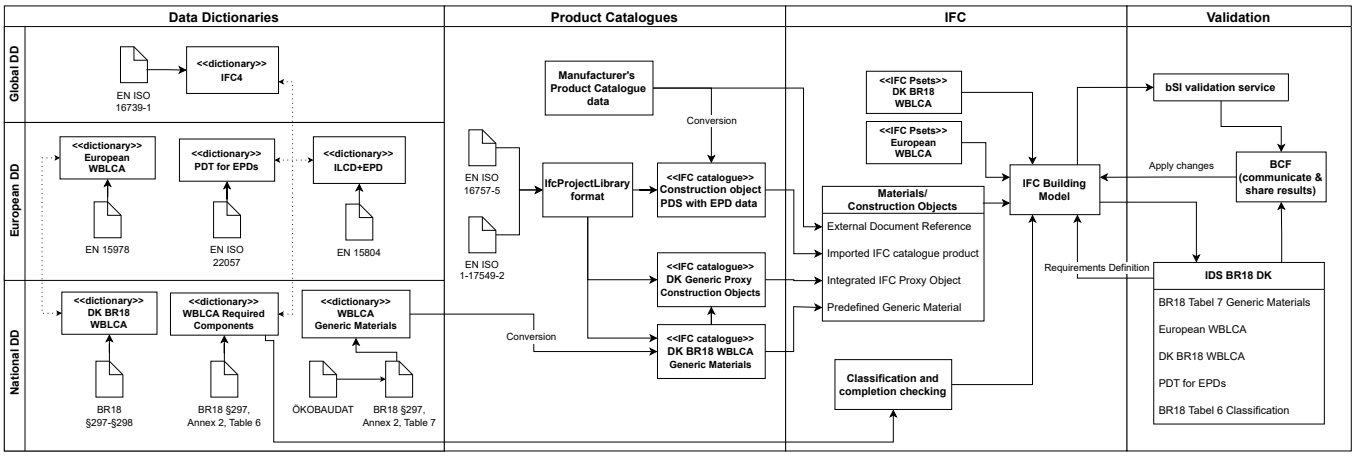

Figure 1: Data flow diagram of storing LCA information in an IFC context.

a case study.

None of the identified research investigates the implementation and enrichment of IFC catalogues, based on ISO 17549-2 and ISO 16757-5, with EPD data aligned with ISO 22057 as a means to enable transparent environmental data exchange and support automated WBLCA. Addressing this gap constitutes the primary focus and contribution of this study.

Danish Regulatory Context

In 2023, Denmark introduced new energy and climate regulations (§297–298), requiring WBLCAs. All new buildings, except unheated constructions under 50 m², need to comply with Global Warming Potential (GWP) limits ranging from 4 to 8 kg CO_2-eq/m²/year depending on function and size.

To define a consistent and practicable LCA scope, Annex 2, Table 6 of BR18 §297 specifies which building elements must be included and which may be excluded. Rather than requiring full material coverage, Table 6 focuses on elements that account for most of a building's climate impact, balancing analytical accuracy with feasibility and ensuring comparability across projects.

According to BR18, the environmental impact of included elements must be calculated using either product-specific EPDs or generic data defined in Annex 2, Table 7. Table 7 provides standardised generic values based on average data from the ÖKOBAUDAT database. No other generic datasets may be used, and any more detailed assessments must rely on third-party verified EPDs.

Methodology

This study proposes a method for integrating data needed to support a WBLCA process in a BIM context, with a specific focus on the Danish regulatory framework. The main objective is to enable practical integration of product-level EPD data into IFC models, with minimal manual input, clear data traceability, and long-term usability. Building-level LCA integration is addressed at a conceptual level.

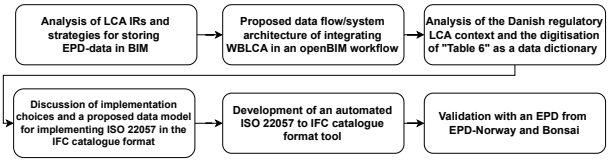

Figure 2: Summary of the methodological approach.

Figure 2 summarises the methodological approach. Firstly, existing approaches for storing, sharing, and reusing product data in IFC-based BIM workflows are then reviewed, alongside relevant sources and schemas for machine-readable, product-level LCA information.

Based on this analysis, an openBIM data model and workflow for WBLCA integration is proposed, linking IFC models with products stored in IFC catalogues, data dictionaries (DD), and national information requirements specified using Information Delivery Specification (IDS). Potential DD architectures are explored to support building-level, product-level, and Danish national requirements. As part of this work, BR18 §297, Annex 2, Table 6, is formalised, mapped to IFC classes, and digitised as a DD in the bSDD.

Implementation choices are then discussed and a data model for implementing ISO 22057 in the IFC catalogue format is proposed. This includes the handling of information modules, alternative scenarios and sub-scenarios, and the representation of EPDs at different modelling levels. Finally, a proof-of-concept automated conversion tool from ISO 22057 to the IFC catalogue format is developed using the IfcOpenShell library and validated with a real EPD from EPD-Norway using the Bonsai software.

Proposed Data Flow of LCA-IFC Integration

Figure 1 presents the proposed data model and its associated data flow. It illustrates the DDs required to support WBLCAs, structured across three levels: global, European, and national. In practice, an additional layer may be introduced for company- or project-specific data. Each dictionary is linked to the relevant standards that define its content. An implementation of ISO 22057 as a DD (shown as "PDT for EPDs") can build on existing initiatives, such as the buildingSMART Sustainability Group's "LCA In-

dicators and Modules" dictionary (Schmid et al. (2022)) discussed earlier.

Manufacturer's product catalogues provide input to construction objects shared through an IFC catalogue in the `IfcProjectLibrary` format, as defined in ISO 16757-5 and ISO 17549-2. The Danish context is represented through national data dictionaries and potential generic construction objects and materials in accordance with BR18 §297, Annex 2, Table 7.

An IDS tailored to Danish LCA requirements is used both to define information requirements and to validate the completed model. Final verification is carried out using the buildingSMART validation service, with results communicated via the BIM Collaboration Format (BCF), either externally or returned to the model for correction.

Implementation Analysis and Discussion

BR18 §298, Annex2, Table 6 as a Data Dictionary

A key part of the presented WBLCA workflow in the Danish context, is ensuring that it includes the required building components (part of inventory scope) defined in Table 6, Annex 2 of BR18 §298. Table 6 is provided by BR18 as an Excel sheet with nested categories of building elements, boolean specifying inclusion or omission, comments, and examples. To minimise oversights, support the integrated modelling process and be able to use the BIM model as a single source of truth (SSoT) in reporting and long-term archiving, Table 6 was formalised as a classification system to be used in IFC.

Using properties or classification systems defined in the bSDD has become one of the main recommended ways of extending IFC by buildingSMART. With the provision to avoid duplication of existing definitions, this approach presents a semi-standardised alternative to the many national and project-specific property sets that otherwise characterise the BIM landscape. Many BIM software today also provide direct integration with the bSDD API.

In line with this philosophy, we implemented the required elements from Table 6 as classification system on the bSDD[1]. Firstly, we made an English translation and numerical categories to organise the hierarchy. All required elements were then mapped to a corresponding IFC class. While this mapping should not be seen as a mandatory assignment to specific IFC classes, it serves as guidance for BIM practitioners during modelling and could be used in BIM software to recommend a classification assignment to the user. Figure 3 shows how an `IfcWallType` would be classified as a masonry wall ("Opmurede vægge") through nested `IfcClassificationReference` entities when using Table 6 as a DD.

Implementation of ISO 22057 in IFC

In this paper we present an integration of the ISO 22057 standard and its Annex A Excel workbook into the IFC schema using the IFC catalogue format defined in ISO

[1] A preview version of the Table 6 DD can be found here.

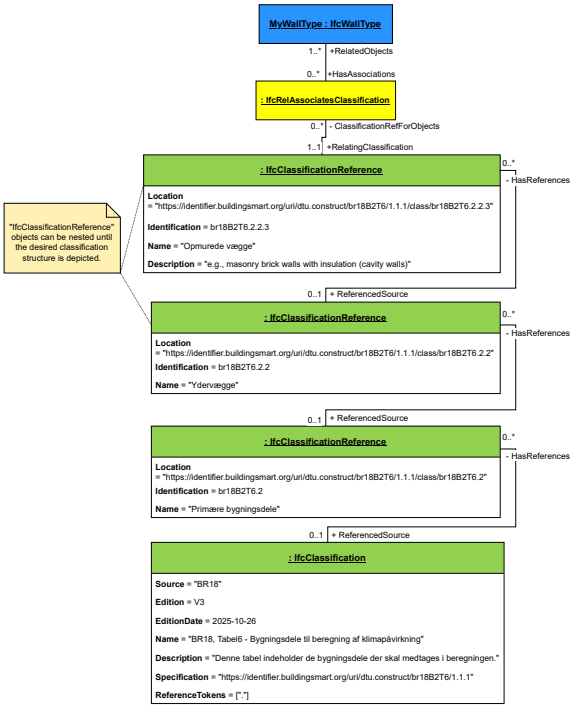

Figure 3: Example object diagram of association of BR18 Table 6 — "Masonry Walls" on the bSDD as a classification in IFC.

16757-5 and ISO 17549-2. In general, the IFC implementation adheres as closely to the standard as possible, preserving property names, descriptions, units, and other salient details unchanged.

Minor, IFC-specific implementation choices include; converting property names into PascalCase to align with the IFC naming conventions, prefacing property sets with `LCAPset_` to differentiate custom property sets from official `IfcPropertySets` beginning with "`Pset_`", mapping "Data type" fields to the appropriate `IfcValue` type. In case of enumerations, the property type was sat to `IfcPropertyEnumeration` and individual enumeration values were assigned to appropriate data types as indicated in the standard. More substantial modifications, or implementation choices, are described in the following sections.

Omitting Enumerations with Boolean Values

ISO 22057 defines several properties with "yes" and "no" enumerations, seen defined in Tables 9 and 10 in the standard. Representing these binary states as enumerations is redundant where a boolean data type such as `IfcBoolean` is available. Using `IfcBoolean` directly simplifies the data model and reduces unnecessary complexity.

Flattening the Nested Structure

ISO 22057 defines a deeply nested data template, organised into property groups with three levels of nesting in some cases (Figure 4). Annex D of the standard ("EPD in Smart CE Marking Declarations") describes how this structure is mapped to the smart CE XML format, which supports only two levels of nesting; "Property Level 1"

groupings and “Property Level 2” individual properties. ISO 22057 introduces additional tags (e.g. <EPDGeneralInformation>) to represent higher-level categories (shown in blue on Figure 4).

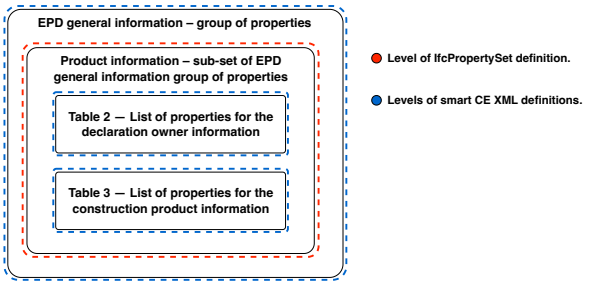

Figure 4: EN ISO 22057 nested structure adjusted for IFC and smart CE XML.

As IFC supports only a single level of property grouping, the intermediate groupings are implemented as `IfcPropertySets`. For example, the grouping highlighted in red in Figure 4 is represented as the property set `"LCAPset_ProductInformation"`. This balances the trade-off between restricting the number of properties in a single property set and minimising the overall number of property sets.

Implementing Information Modules and Scenarios

Representing EPD results for a single indicator, such as GWP limited to modules A1–A3, as commonly found in EPDs aligned with EN 15804+A1, is relatively simple and can be achieved with a single property (e.g. “`GWP_A1toA3`”). However, comprehensive assessment requires support for multiple indicators and life cycle modules, which substantially increases data model complexity. In ISO 22057, life cycle phases are defined through the “information module” property in the EPD methodological framework (Table 9, ISO 22057). This property links environmental indicators, waste categories, and output flows to specific modules. Complexity is further increased by the use of scenarios, which allow multiple declared values for the same indicator under different assumptions.

Several alternative approaches were considered for representing life cycle modules and scenarios in IFC, including dependent properties, repeated property sets following the ISO 22057 Smart CE XML implementation from Annex D, `IfcPropertyTableValue` properties, and the use of `IfcTask` and `IfcResource` entities (Schmid et al. (2022)). These approaches were rejected due to excessive property duplication, reliance on naming conventions, poor alignment with CODview2, increased model complexity, or limited software support.

The chosen approach represents environmental indicator results using `IfcTable`, referenced from a property via `IfcPropertyReferenceValue`. This enables a compact and structured representation closely aligned with the tabular format commonly used in EPDs, with indicators listed as rows and life cycle modules as columns. Unlike `IfcPropertyTableValue`, `IfcTable` allows an arbitrary number of columns and richer column definitions, supporting clearer semantics and better scalability as the number of indicators and modules increases. Units can be assigned at column level, improving machine interpretability while avoiding the repetition of properties for each module or scenario.

The `IfcTable` is composed of `IfcTableRow` and `IfcTableColumn` objects, with the former containing a list of values in their respective data types. `IfcTableColumn` enables the specification of an “identifier” attribute, allowing it to be referenced across multiple tables. It also supports the definition of “description”, “unit”, and a “reference path” that links to the object and attribute targeted by the column’s data via the `IfcReference` entity. The nesting capability of `IfcReference` entities further allows for direct linkage of an `IfcTableColumn` to a particular property within a property set of a specific object.

Given that `IfcTableColumns` can define units while `IfcTableRows` cannot, an alternative approach involves transposing the table, positioning indicators as columns and modules as rows. Unlike modules, indicators require unit definitions, and assigning them proper IFC units enhances computational interpretability, compared to listing them as IfcLabels in an additional column. However, this approach would complicate the direct referencing of modules to their defining property sets, and it may be more user-friendly to adhere to the conventional table format familiar from PDF EPDs.

A potential drawback of this approach is that the `IfcExternalReferenceRelationship`, utilised for linking properties to external definitions such as those in the bSDD, is not applicable to `IfcTableRows`. This constraint implies that while individual indicators would be able to be directly linked to their definitions in a DD, the overarching property could reference a compiled list of indicators.

While current support for visualising `IfcTable` is limited in some software, the data structure itself is robust, extensible, and well suited to automated processing.

Implementation of Alternative Scenarios

ISO 22057 allows two interpretations for handling alternative scenarios; either by defining separate data sheets for each scenario or by consolidating multiple scenarios within a single data sheet (as presented in Annex D).

Both approaches were examined in an IFC context, in the first of which, each scenario is modelled as a separate object definition (for example, alternative `IfcWallTypes`), each containing a complete set of environmental indicator results. Emission values are organised in a table linked to the `EN15804+A2CoreLCIAIndicators` property, under a new property set, `LCAPset_EnvironmentalIndicators`, housing all relevant indicator values (Table 2). Since `IfcTableColumns` can be referenced by multiple tables, the `ReferencePath` attribute, alongside an `IfcReference` object, points to the specific

Table 2: Implementation of modules using IfcPropertyReferenceValue and IfcTable

Pset.Name:	LCAPset_EnvironmentalIndicators					
Property Name	PropertyReference					
EN15804+A2CoreIndicators	Table.Name: EN15804+A2CoreLCIIndicatorsResults					
	Indicator	Unit	A1	A2	A3	...
	GWP_Total	kg CO2-eq				
	GWP_FossilFuels	kg CO2-eq				
	GWP_Biogenic	kg CO2-eq				
	...	...				

property set that corresponds to the module scenario, as outlined for modules A4 to D in the standard. This approach defines only a single scenario per module, suggesting that for alternative scenarios, the entire structure would be duplicated, rather than duplicating individual properties or property sets.

An alternative is to encode multiple scenarios within the same object definition by introducing additional properties and property sets for alternative scenarios and linking them to a base scenario. While this can be advantageous in early design phases, where rapid comparison of alternative assumptions is valuable, it relies on project-specific naming conventions and increases internal object complexity. It also departs from the main-text guidance of ISO 22057 and complicates standardisation through data dictionaries, as only the base scenario can be predefined.

Overall, modelling alternative scenarios as separate construction objects provides a straightforward and schematically clearer method. This approach is particularly suitable for the later stages of design, where the building LCA's primary goals is documentation and long-term storage of product information. However, if LCAs were reimagined as not merely calculations yielding a single numeric results but as comprehensive uncertainty analyses in and of itself resulting in a range of potential outcomes, the second approach could become relevant even in final LCAs. Figure 6 shows the implementation of alternative scenarios as separate construction objects.

Implementation of Sub-scenarios

Sub-scenarios, such as waste handling or transport, introduced in section 8.4.1 of ISO 22057, consist of an intricate data model with nested property dependencies. This complexity, as shown in Annex D for the smart CE XML, could be simplified by repeating all properties relevant to a module scenario. The IFC framework does, however, offer a mechanism for defining nested property sets through `IfcComplexProperty`, which allows grouping several properties under a single entry within an `IfcPropertySet`. Figure 6 details how sub-scenarios can be actualised within the IFC model using `IfcComplexProperty` and `IfcPropertyDependencyRelationship` to establish property dependencies. However, due to inconsistent implementation in BIM software, this mechanism is considered optional, with direct repetition of sub-scenario properties per scenario representing a valid solution.

Representing EPDs at Different Modelling Levels

Construction objects carrying EPD information may exist at different levels of detail and should therefore be definable at multiple levels within a BIM model. Where an EPD represents a complete building element, such as a prefabricated wall or a door, it can be assigned at the element type level. The element type defines LCIA indicator values per declared unit, while the corresponding element instance, with quantities defined through an `IfcQuantitySet`, represents the scaled results. These scaled values may be explicitly stored, for example in `IfcTables` for communication or visualisation, or derived implicitly by storing only a scaling factor and a reference to the type. This approach is exemplified in Figure 5 where an `IfcWallType` specifies $1m^2$ of a prefabricated wall, and the `IfcWall` instance represents the scaled results for $320m^2$ of the wall.

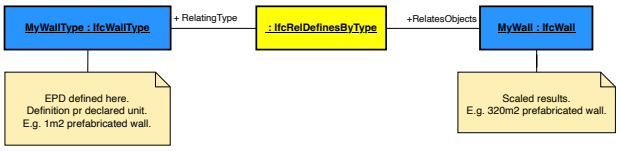

Figure 5: Construction object EPD definition on element level.

However in some cases, EPDs may describe smaller components or raw materials rather than complete building elements. Here, EPDs can be assigned at the material level, such as to an `IfcMaterialLayer` within a larger assembly, as exemplified on Figure 7. Defining EPDs at the type or material level avoids redundant property sets on individual instances, reducing file size and improving model quality. For materials requiring scaling, typically declared per mass or volume, ISO 22057 introduces reference quantities and scaling factors. In IFC, these can be implemented using attributes such as `LayerThickness` together with user-defined scaling properties, allowing EPDs to be defined once at the `IfcMaterial` level and consistently applied across different material set definitions.

PDT-to-IFC Implementation

The data model presented in the previous sections was evaluated by an implementation in the IFC STEP Physical File format (SPF-IFC), using a custom conversion tool developed with the IfcOpenShell library. The implemen-

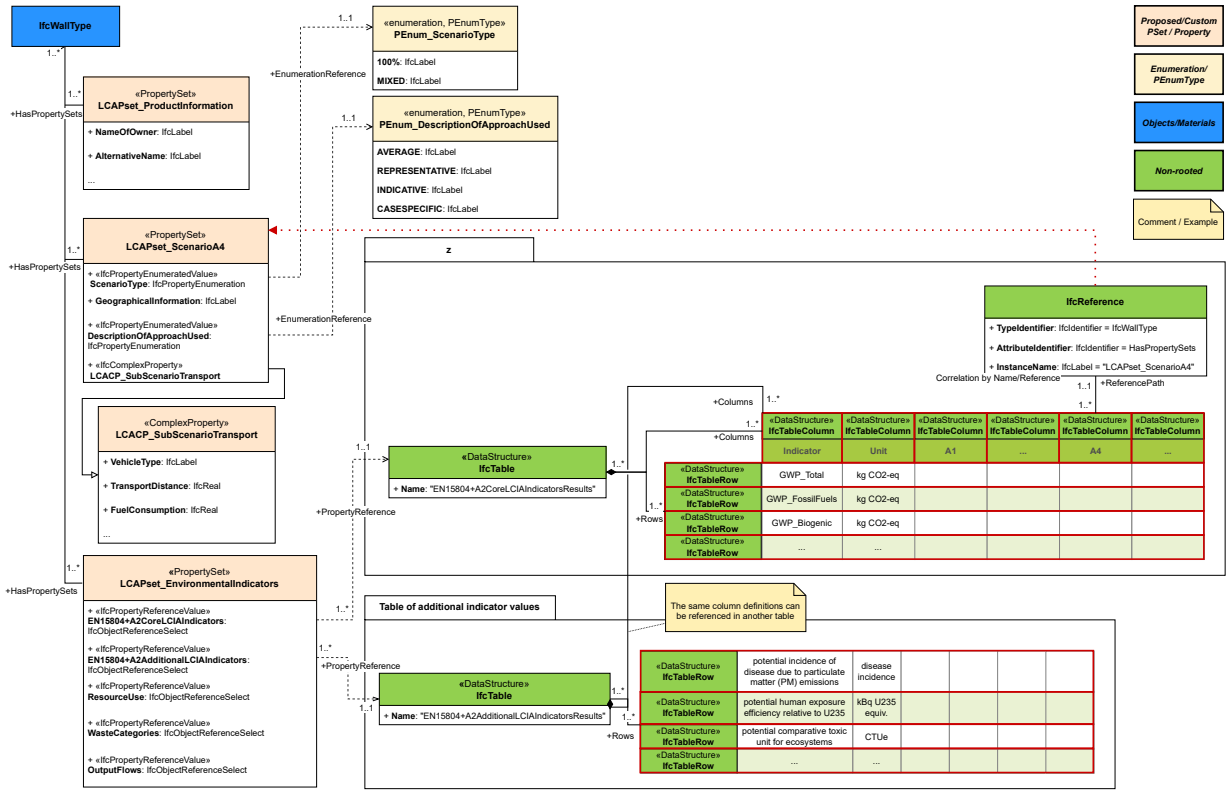

Figure 6: Alternative scenarios defined in different construction objects - with sub-scenarios.

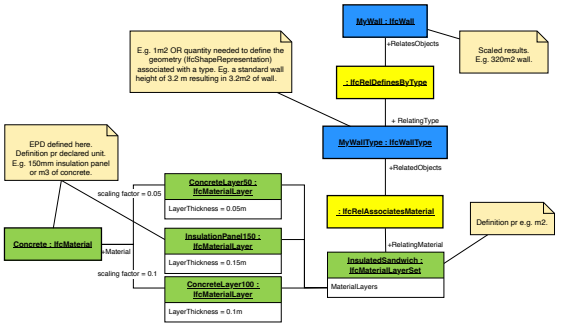

Figure 7: Construction object EPD definition on material level.

tation is based on the CODview2 MVD and the accompanying example IFC files.

The workflow begins with the creation of a `IfcProjectLibrary` model, including reference libraries. A user-defined element type is then introduced as the anchor for all subsequent LCA data. Property sets with simple or complex properties are created, including the dedicated `LCAPset_EnvironmentalIndicators`, which stores LCIA indicator results using `IfcTable`. All properties are linked to bSDD definitions via the `Specification` attribute of `IfcProperty`.

The ISO 22057 product catalogue implementation was demonstrated using a real EPD from EPD-Norway. The pilot project "EPD in ISO 22057 format", which provides a JSON-based representation of the standard, was used as input for the conversion. As an example, the EPD for "Massiv betongelement - Vegg, lavkarbonbetong" was selected, with Listing 1 showing a subset of properties from the `LCAPset_ProductInformation` property set.

As the available EPDs did not include scenario data, an extended version with proxy data was created to demonstrate the full implementation, including `IfcPropertyEnumeration`, `IfcPropertyEnumeratedValue`, and `IfcComplexProperty`. The resulting IFC files were validated using the Bonsai add-on. The full source code, generated IFC files, and supporting spreadsheets are available online.

Conclusions

This study contributes to the integration of product-level LCA data into IFC-based openBIM workflows. It reviews existing methods for storing, sharing, and reusing product data in BIM, together with available schemas for machine-readable LCA data. ISO 22057 is identified as the most suitable standard for product-level LCA

information, while the IFC catalogue format based on `IfcProjectLibrary`, as defined in ISO 17549-2 and ISO 16757-5, is selected as the main mechanism for integrating this data into IFC.

We propose an openBIM workflow for WBLCA that improves data longevity, traceability, documentation, and regulatory compliance, while reducing manual work for LCA practitioners. The approach relies on coordinated data dictionaries at national, European, and global levels. As a concrete implementation, BR18 §297, Annex 2, Table 6 is formalised, mapped to IFC classes, and digitised as a data dictionary in the bSDD.

A detailed IFC data model for integrating ISO 22057 into the IFC catalogue format is developed. Key modelling choices are discussed, including the handling of information modules, alternative scenarios, sub-scenarios, and different levels of EPD representation. These concepts are tested through a proof-of-concept tool that converts EPDs from the ISO 22057 JSON format to IFC-SPF. The approach is demonstrated using a real EPD from EPD-Norway and validated with Bonsai.

The proposed solution also has some limitations. Although it can be implemented in IFC-SPF today, many of the more advanced IFC features used, such as complex property structures beyond `IfcPropertySingleValue`, are not yet supported by most BIM software. This is a tooling limitation rather than a conceptual one and should be addressable if demand increases.

In addition, while ISO 22057 represents a significant step towards machine-interpretable EPDs, recent work has highlighted the remaining challenges that require further refinement of the standard Aragón et al. (2025).

This study focuses on product-level LCA data. Future research should extend the approach to building-level information, including a systematic analysis of information requirements and their implementation within IFC-based workflows.

GRAPH-BASED INSTANCE TRACEABILITY FOR BUILDING PRODUCT REUSE

Silvia Vangelova[1], Clara P. Blum[1], Kasimir Forth[1], Jens J. Hunhevicz[1,2], Pritha Jacob[1] and Catherine De Wolf[1]
[1]ETH Zurich, Zurich, Switzerland
[2]Empa, Dübendorf, Switzerland

Abstract

Tracing information related to the life cycle of building products supports decision-making for circular construction. However, current digital tools and standards in construction primarily address product identification at the type rather than instance level, resulting in information loss that hinders reuse. To trace products across projects at the instance level, we propose a graph-based workflow that maps globally unique identifiers (GUIDs) of element instances. While information continuity can be established manually, preliminary workflow evaluation in a case study reveals that manual GUID verification is impractical. We conclude that realising a digital reuse supply chain requires software automation for instance-level identification.

Introduction

Reuse in construction, one of the most resource-intensive industries, plays a key role in achieving a sustainable built environment (Lima et al., 2021; Eurostat, 2024). Reuse, in general, can be understood as a process that enables multiple use cycles of products (Alcayaga et al., 2019). Capturing and updating product life-cycle information at each use cycle and storing it throughout the product's lifetime is an important capability for enabling product reuse (Wan and Jiang, 2025). However, for construction products, this capability remains a challenge due to the long, multi-phased life cycle of buildings. Novel information management solutions are required to ensure long-term data availability and maintainability (Hunhevicz and De Wolf, 2023).

Current element-based information management solutions for building product reuse build on existing digital tools but remain only prototypical. To achieve instance-level traceability for reuse, potential solutions extend these tools by integrating globally recognised supply chain standards (Hradil et al., 2023). Specifically, the GS1 framework enables product instance identification using Serialised Global Trade Item Numbers (SGTIN) (GS1, 2024). By assigning a unique SGTIN to a physical product, this system distinguishes individual instances from otherwise identical products of the same type. Yet, maintaining instance-level traceability over a product's lifecycle remains challenging; critical data disconnects occur between phases even within a single project (Borrmann et al., 2018), let alone across multiple projects separated by years or decades.

In reuse scenarios, preserving instance-level traceability can be crucial, as secondary products often require individual structural validation or condition assessment. Type-level identification can lead to the loss of instance-specific information, such as material condition or load history, that often differs across reused elements of the same type (Blum et al., 2026). Although identification at the instance level is technically more challenging and often abandoned in favour of simpler type-level tracking, it remains valuable for reuse decisions (Byers and De Wolf, 2023).

While linking type- and instance-based identifiers via semantic models can help mitigate this information loss (Kebede et al., 2022), traditional building information modelling (BIM) software lacks the built-in functionality to implement such semantic models (Pauwels et al., 2017). This disconnect is compounded because BIM tools are primarily designed for construction using new products (Pocobelli et al., 2018), abstracting elements into replicable object-oriented types rather than tracing unique physical instances. By referencing a single parent definition to instantiate multiple elements of the same type (Costin et al., 2022), these applications prioritise computational efficiency at the expense of historical data continuity. Consequently, incorporating reused products into a design results in the instantiation of new elements with new application-generated identifiers, which can effectively overwrite their previous instance-level identity. Consequently, traditional software offers limited support for instance-level identification for product reuse.

Despite limited cross-project instance traceability, BIM authoring tools handle type-to-instance mapping within single projects very well by using relational data schemas internally, which can be translated into Industry Foundation Classes (IFC) for interoperable data exchange. The problem is that these data structures are enclosed within single project files, and there is no established mechanism to query highly granular, instance-level information across separate models. To overcome these native software limitations and explicitly define semantic relationships, BIM models can be linked to a graph in which elements are represented as nodes and their spatial relationships as edges. This approach decouples information from BIM models by enabling storage in graph databases (Cao et al., 2022) and can optimise life-cycle data management by linking project specifications to external product databases (Forth and De Wolf, 2025), facilitating disassembly sequencing (Sanchez et al., 2021) and tracing incremental changes

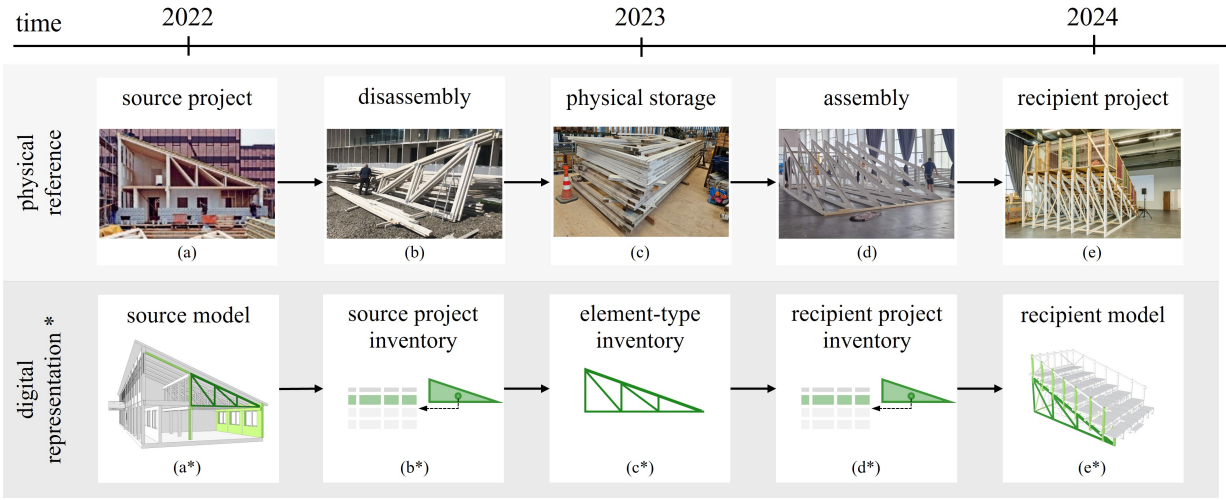

Figure 1: Physical and digital mapping of element instances across projects exemplified by the reuse of the Huber Pavilions. (*) Alignment in time is only approximate. Photo and model credit is provided in the Acknowledgements section

across project phases (Esser et al., 2023).

To address the gap in instance-level element identification, this study proposes a graph-based workflow for tracing product instances across different use cycles. The proposed workflow uses element-based graphs to map globally unique identifiers (GUIDs) from a source project to a recipient project, thereby preserving instance-level identification that is often lost during software exchanges. Following preliminary validation through a case study and a custom visualisation tool, we argue that establishing a digital reuse supply chain requires automated instance mapping that extends the capabilities of current design tools.

Point of Departure

Bridging physical and digital traceability

Reusing elements across multiple projects is a key strategy for enabling a circular economy in construction. However, the information needed to reuse an element is often lost at project handover or becomes outdated during operation and must be reacquired at the end of a building's life cycle (Honic et al., 2021). This acquisition process typically involves a building audit, during which a digital inventory of its constituent elements is created (Honic et al., 2019). To manage this inventory, identifiers such as quick response (QR) codes or near-field communication (NFC) chips can serve as a ''phygital'' link connecting a physical building element to its digital representation (Byers et al., 2025). Unlike the consumer goods industry, where traceability is optimised through linear distribution networks and statistically predictable behaviour, typically without the need for a digital model, construction operates on a project-by-project basis at a higher level of complexity. It involves longer time spans and various stakeholder groups that transfer multidisciplinary data between project phases. Consequently, construction requires coordinating products across two parallel timelines: the physical supply chain and the digital project-related information supply chain (Byers et al., 2025). This interdependency between the physical and digital sides of the construction supply chain makes it challenging to maintain consistent identifiers across both dimensions during reuse.

Type vs. instance traceability

Creating a building model for a project requires distinguishing between element types, which are defined by the shared properties of a product, and element instances, which identify each unique physical occurrence of that product and its specific positioning within the building. This distinction is well established in BIM, where buildings and products are represented in an object-oriented structure with classes and properties organised in a nested hierarchy. Specifically, the IFC schema models type-to-instance relationships in an object-oriented manner by separating universal specifications of a given product (IfcTypeObject) from the unique physical occurrences of this product (IfcObject) within a project (buildingSMART International, 2016). The IfcRelDefinesByType relationship maps each instance to its type, allowing element instances to inherit type-level properties from a single element type definition.

The IFC schema provides standardised property set definitions, such as the Tag property of IfcElement (buildingSMART, 2020), to distinguish specific element instances using serial numbers or application identifiers, such as GUIDs. The IFC Tag was originally intended for standardised global identifiers, such as those defined by GS1. This tag is often used to store element GUIDs, unique codes generated automatically by the authoring software to identify element instances. While these GUIDs are useful for tracking product changes, they are often unreliable for tracing at the instance level across different project phases because BIM authoring workflows often lead to generating inconsistent element identifiers (Esser et al., 2022).

The challenge of instance-level traceability

While there have been developments towards integrating GS1 identifiers into the buildingSMART Data Dictionary (bSDD) for IFC (GS1, 2025), current implementations for tracing across projects are more feasible for product types than for individual instances. One solution for tracing element information at the instance level is provided by Speckle. Speckle uses application IDs, the equivalent of element GUIDs, to maintain a link between an element and its authoring software, and hierarchical graphs to store project information. In these tree-like structures, elements contain other elements and references to elements stored outside the authoring application ecosystem. A suitable way to record these relationships is to store GUID key value pairs in a graph database. In the case of reusing elements from a source project in a recipient project, this requires mapping the original instance GUID from the source project to a product type ID (instance-to-type), and subsequently linking that type ID to the new instance-level GUIDs generated in the recipient project (type-to-instance). However, this process of instance and type mapping is where instance-level traceability breaks down due to information loss when models are transferred across different authoring software (Blum et al., 2026).

Scope and methodology of this study

Given the need to consistently trace product instances of the same type, along with their digital representations, across multiple use cycles in different projects, this study aims to develop a workflow for tracing the history of life-cycle-related information of reused building products across projects.

To answer the research question of how reused building elements of the same type can be digitally represented and identified at the instance level across projects, we analysed a reuse project at ETH Zurich to trace the flows of type- and instance-level information. Based on this analysis, we identified a cycle of instance-to-type mapping that repeats throughout the reuse process. This study therefore suggests that the digital side of the reuse supply chain should follow a cyclic pattern of recurring steps traversed using a graph-based workflow. Following this workflow, we propose that element GUIDs be mapped from source to recipient projects using a graph-based structure that enables the tracing of instance-level changes across product use cycles in line with the recurring steps.

Analysing Instance-to-Type Information Flow

Case study: the Huber Pavilions and Mehrwerk

As a case study, we trace the digital representation of several timber frames of the same type sourced from the deconstructed Huber Pavilions at the ETH Zurich Hönggerberg campus and their subsequent reintegration in Mehrwerk, an installation at the Kunsthalle Zürich (De Wolf, 2025). Specifically, we trace this single element type from its original function in supporting the pavilions' roof structure to its new function in supporting the seating platform of Mehrwerk, demonstrating how instance-level identification can be maintained throughout this transition.

We analyse the case study in five steps, tracing the physical reuse supply chain alongside its parallel digital representation (see Figure 1). Tracing begins with the source project (a), one of the Huber Pavilions (Knecht, 2022), for which a BIM model (a*) was created based on an audit conducted prior to disassembly. During the disassembly (b) of the building, a digital inventory of its constituent elements (b*) was created. The disassembled elements were then relocated to a physical storage location (c), where elements of the same type were physically grouped and represented digitally as a consolidated element-type inventory (c*). During the assembly (d) of the recipient project, Mehrwerk, a new inventory (d*) was created that specified the required elements. After completion of the recipient project (e), its final as-built model (e*) was created.

Identified instance-to-type mapping cycle for reuse

We observed a cycle of mapping instance and type relationships of building elements. We use the term ''cycle'' to encapsulate the pattern of recurring events in product use cycles, distinguishing these events from the physical ''circular'' flow of resources. This terminology emphasises that in reuse scenarios, a building project has one life cycle, whereas building products have multiple use cycles across different projects.

On the sourcing side, buildings at their end-of-life phase typically lack digital documentation. To facilitate reuse and environmental assessments, a digital model is created through a building audit. In this model, the geometry of each physical element is represented as a unique instance with a GUID automatically assigned by the software used to create the model. As the building is deconstructed, these elements lose their original context. When the elements are relocated to a storage facility, individual instance data is condensed into a digital inventory of elements grouped by type. In the recipient project, the steps for element GUID association are repeated by reusing the same elements in a new context. When a designer selects an element type from the inventory, they instantiate it within a new project model. This action generates new instance identifiers, effectively mirroring the initial flow of information by transitioning from the consolidated type-based inventory to element instances in the recipient project.

While current digital tools are built for project life cycles, e.g., managing a single building across specific project phases, they are not built for product use cycles. One example is managing a beam that is sourced from the end-of-life phase of one project to the initial design phase of another. Currently, there is no functionality that allows product information to be retained after the project's end-of-life phase for future use cycles. This is especially important during the early design phases, where implementing circular solutions has the greatest impact (Heisel and McGranahan, 2024).

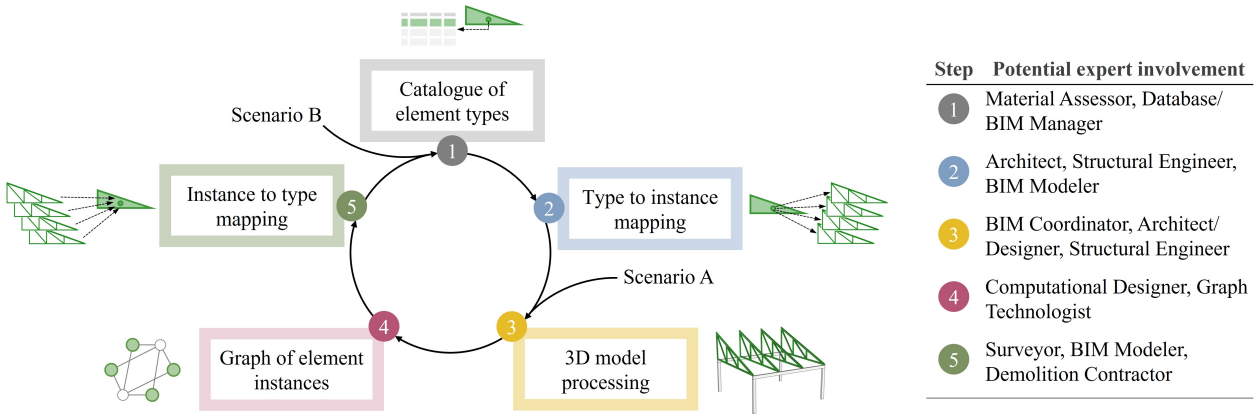

Figure 2: Graph-based workflow for product life-cycle information tracing. Potential expert involvement for each step is proposed. Scenario A starts with an inventory of reused products. Scenario B starts with the reuse of a building constructed with new products.

Workflow for Life-Cycle Information Tracing

In this section, we describe our proposed workflow for tracing information about multiple instances of a single element type in five steps, as illustrated in Figure 2.

In this workflow, we use four types of element instance and type representations (see Figure 3). Type a is a three-dimensional geometric representation, which can be a BIM or CAD model within the authoring software or an IFC export of it. Type b is the graph representation of the model, capturing the connectivities between different elements, where each node represents an element instance, and each edge is a spatial connection between two elements. Type c is an instance-to-type mapping, a key value-pair dictionary, where the keys are the element type IDs and the values are the instance GUIDs. Type d is a tabular dataset, which we refer to as a ‘‘catalogue’’, and can be either a digital inventory of physically stored elements or a specification table of the products to be used in a new design.

To better illustrate the graph-based workflow, we present two scenarios for initiating the reuse cycle. The first scenario (A) is when a building has no catalogue of the products used, it is built with new products, and is inventoried through disassembly for reuse. The second scenario (B) is designing using a given set of element types from an inventory of reused building products.

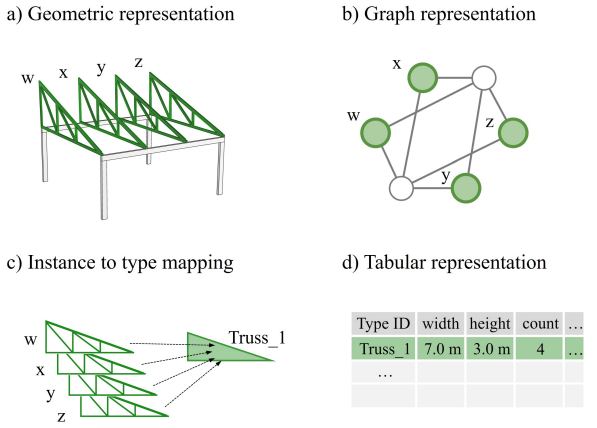

Figure 3: Element instance and type representations used in the graph-based workflow

In the following subsections, we describe our workflow based on scenario B, which consecutively loops through all steps in the circular loop (see Figure 2). The workflow begins with a catalogue of element types (1), which may include both reused and new products. During the design phase, these types are instantiated, establishing a type-to-instance mapping (2) where unique identifiers (GUIDs) are generated for the geometry of each element instance.

Once the design is finalised, 3D model processing (3) standardises the data via IFC export. This geometric data is then used to compute a graph of element instances (4), storing their geometric connectivity, with elements represented as nodes in the graph and linked via their GUIDs. Finally, the workflow concludes during the disassembly or end-of-use phase with instance-to-type mapping (5). In this step, specific element instances are remapped to new element types to repopulate an inventory for future projects, effectively starting a new use cycle.

Alternatively, for scenario A, the cycle can start with the model-processing step (3), as shown in Figure 2. This is how we applied the workflow to the case study since we do not have the original project specifications that catalogue all products used in the building. Additionally, the source building was constructed with new products rather than an inventory of reused ones.

Step 1: Catalogue of element types

Whether creating a model for new construction or reuse projects, the workflow starts with a catalogue of element types. In projects that reuse building elements, this catalogue is usually derived from an inventory, a finite set of reusable elements stored in a physical location, most of which come from a previous building. In new construction projects, this catalogue functions similarly to a bill of materials, specifying the product types that will be assigned to the element instances in the model. In this study, we define the catalogue of element types as a unified tabular

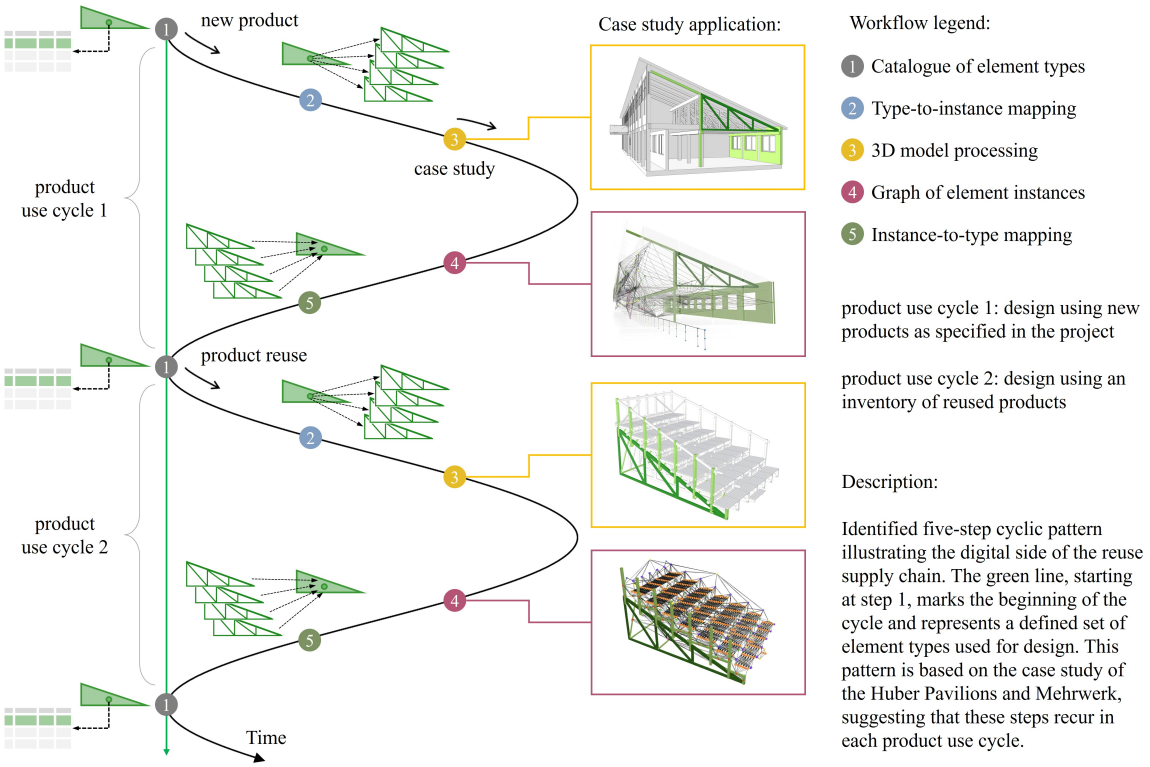

Figure 4: Identified instance-to-type mapping cycle for reuse and its application in the case study

dataset, regardless of whether they are reusable elements or new products. Defined by attributes such as type ID, dimensions, and available quantity, this catalogue serves as a predefined set of element types and is used in the next step of the workflow, where elements are instantiated in the authoring software.

Step 2: Type-to-instance mapping

Type-to-instance mapping occurs implicitly as geometry is created within the authoring software during the design process. The designer assigns an element type ID, which is stored as both a column in the inventory data table and a specific property of the element instance in the model. This linkage is critical for the subsequent model processing in Step 3 because it maintains traceability between the element type and the instance GUID generated by the authoring software in later steps.

Step 3: 3D model processing

To extract and retain relevant life-cycle-related information, we use two distinct processes, depending on the authoring software type of the source file, which are applicable for both scenario A and B. Both processes are based on the IFC schema because it is an open data exchange format and supports product identification through geometric representation and unique identifiers, namely, the tag property of IFC building elements. We differentiate between the two processing workflows:

1. BIM-based processing (e.g., Revit, Archicad): We export these models from native authoring software directly into IFC4, ensuring base quantities and geometry are included in the export configuration.
2. CAD-based processing (e.g., Rhino, AutoCAD): We first ensure the geometry of element instances is assigned to corresponding element-type layers. The model is exported in STEP format, attaching layer information to the geometric representation of each element. We then use IfcOpenShell to convert the STEP file to IFC4, and pythonOCC, a Python wrapper of OpenCASCADE, to generate the geometric representation and compute base quantities.

Step 4: Graph of element instances

Using the IFC file generated in the previous step, we compute a geometric connectivity graph to store how the elements are connected. For this step, we further developed an existing IFC viewer (Forth and Emenegger, 2025) to compute the graph in the back end and edit IFC properties in the front end (see Figure 5). The graph computation is performed using an additionally developed Python back end for the IFC-graph editor, where geometry is extracted using IfcOpenShell and OpenCascade. To optimise performance, we estimate the number of connected pairs based on the distance between oriented bounding boxes. For each candidate pair, we then analyse the actual geometry; if the distance between elements is less than 1 cm, then they are considered to be connected. We justify this assumption because a tolerance of 1 cm to 2 cm falls within standard allowable deviations for building construction (DIN, 2019). Using the final list of pairs, we con-

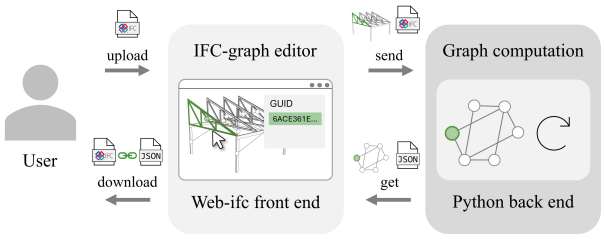

Figure 5: User interaction for assigning a GUID to an element and linking the geometric connectivity graph to the IFC file

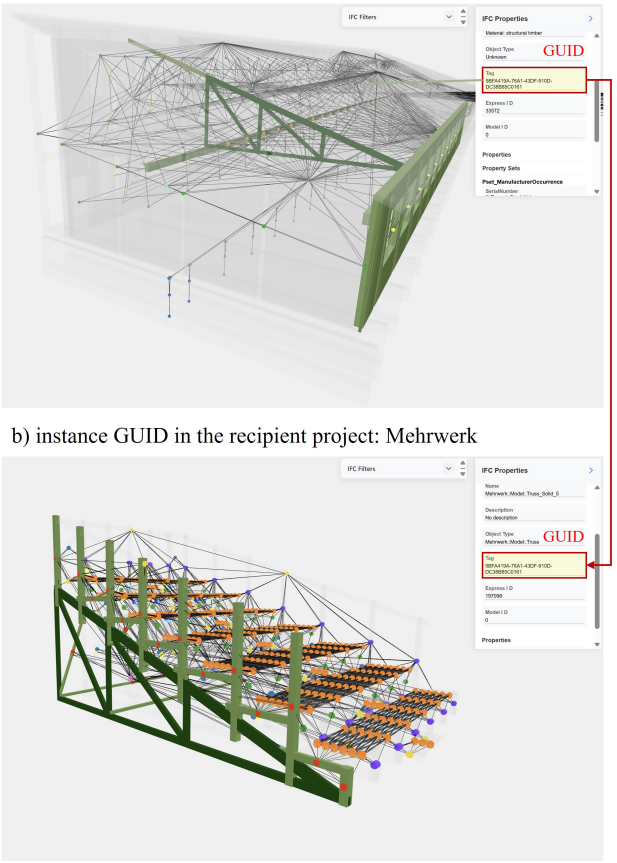
struct a graph with NetworkX, attaching the corresponding GUID to each node and convert it to JSON.

Through this graph, for each node of an element, a list of connected elements can be retrieved. The resulting graph is stored as a NetworkX-based JSON. This approach was chosen because JSON is supported by the application programming interfaces (APIs) of commonly used BIM software, allowing the graph and GUIDs to be linked to their respective elements in the authoring software. For example, by using plugins to serialise and deserialise the JSON of the graph. To preserve the link between the graph and the IFC, we assign a unique identifier to the graph itself and store it within a custom IfcPropertySet as an ifcText.

Step 5: Instance-to-type mapping



Unlike in Step 2, where mapping occurs in the authoring application, in Step 5, we use the IFC-graph editor to update the mapping between specific instance GUIDs and type IDs. This step is necessary because the as-built model often diverges from the initial design model yet requires the original type IDs to be relinked with the final element GUIDs.

The front end of the IFC-graph editor is used to visualise the IFC files and the graph computed in Step 4. The viewer comprises a TypeScript front end based on web-ifc from That Open Company and the previously mentioned Python back end (see Figure 5). Through this interface, we manually verify and map GUIDs to type IDs for the selected elements to be reused. The application then exports an updated IFC with the correct GUIDs and type IDs and a linked JSON graph, where key value pairs of element GUIDs preserve the semantic link between the elements and their connected neighbours for the next use cycle.

Preliminary Evaluation and Future Work

For initial validation, we applied the graph-based workflow to the case study of the Huber Pavilions and Mehrwerk (see Figure 4) by tracing the reuse of timber frames from the source project (Huber Pavilions) to the recipient project (Mehrwerk). Originally, while the frames were geometrically identical, the transfer between software applications during the design of Mehrwerk resulted in a loss of instance-level traceability. Furthermore, the columns connected to the frames in the source project were modified in the recipient project, creating a distinct set of connections that required a new inventory version. Using our workflow,

a) instance GUID in the source project: Huber Pavilions

b) instance GUID in the recipient project: Mehrwerk

Figure 6: Manual GUID assignment of selected elements using the IFC-graph editor. This action modifies the original IFC model and links it to a graph through the assigned GUIDs.

we re-link the timber frames in both models.

The workflow begins with the source project. We exported the Huber Pavilion model from Archicad as IFC4 (Step 3). Then, using the IFC-graph editor, we computed the element connectivity graph (Step 4). We then mapped the type-to-instance relationships by assigning a specific Type ID property to the elements (Step 5). To link the frames from the source to the recipient project, we initiated the workflow by storing their element type IDs in a table (Step 1). We then assigned these types to the corresponding geometry in the Mehrwerk model (Step 2) before exporting it from Rhino and converting it to IFC4 (Step 3). Using the IFC-graph editor, we computed the graph for this new context (Step 4). Finally, we assigned the original GUIDs from the Huber model to the new frame instances (Step 5). This way, we were able to re-link the element instances across both models (see Figure 6).

Challenges and limitations

A limitation in the case study is the inability to verify the instance-level GUID assignment. While we successfully mapped element GUIDs across the source and recipient models, we retrospectively lacked ground-truth data to confirm which timber frame from the source project cor-

responded to which instance in the recipient project. Furthermore, in the case study, no instance-level differentiation has been implemented. This disconnect highlights a broader issue: collecting and maintaining instance-level data across the reuse supply chain is currently not realised. Even though the instance-to-type mapping solution in the IFC schema allows for the preservation of instance-level variables, manually verifying that every element has a correct GUID corresponding to a physical product requires significant effort, particularly during early design iterations, when geometry is rapidly changing. The labour of manual verification is also due to long project life cycles, during which information is lost across different software.

Although GS1 standards specify the general requirements for instance-level identification through SGTINs, current construction software lacks the capability to integrate these standards efficiently. In particular, tracing building products composed of multiple sub-components or layers is challenging to integrate, as these can be disassembled and reassembled into different elements. To enable instance traceability without the overburden of manual tagging, algorithms need to be developed to automatically detect when a digital element instance in a new design contextually represents a physical element in the inventory, and maintain this link throughout further project phases. On the physical side, a potential solution to these efforts is to use extended reality for the identification of as-built elements. On the digital side, algorithms for measuring geometric similarity between elements can help identify matching pairs (Collins et al., 2024).

Regarding the IFC-graph editor developed for this study, user feasibility testing is needed to validate better graph visualisation approaches and determine whether the front-end graph visualisation actually supports instance-level identification or should be kept in the back end. Future research will focus on formalising the graph-based representation and connecting the viewer to a graph database, thereby enabling the integration of dynamic digital passports that evolve throughout product use cycles.

Conclusion

In this study, we developed a graph-based workflow for tracing product use cycles across projects. We demonstrated the workflow using an IFC-graph editor to map element GUIDs across two projects, using the Huber Pavilions and Mehrwerk as a case study. The workflow shows that preserving element identification outside the original authoring software is a viable strategy to reduce vendor lock-in and facilitate product data transfer across use cycles. However, data provenance remains to be addressed, as individual product data can be isolated from project databases with varying levels of access.

Making instance mapping more efficient by linking digital passports to graph databases of building projects will facilitate reuse. If realised, this functionality would serve two purposes: it would allow building owners and reuse partners to trace the life-cycle history of building products effectively while simultaneously supporting designers to integrate reused products into new designs. Applying the learnings from the case study of the Huber Pavilions and Mehrwerk to active projects will be the next step in advancing the graph-based reuse workflow.

[3]University of Ottawa, Ottawa, Canada

Abstract

BIM-based cost estimation often depends on proprietary tools and ad-hoc mappings to external cost databases, limiting interoperability and auditability. This paper presents an openBIM workflow that enriches material definitions with standardized Canadian-specific cost items and automatically generates element-level quantity takeoff and capital cost breakdowns. A case study demonstrates automated extraction of material, labor, and equipment costs, as well as structured inputs for maintenance-and-replacement-oriented life-cycle cost analysis. In the current implementation, automated computations focus on construction-phase capital costs, while LCC support is limited to structured inputs for external RSMeans-based estimators.

Introduction

Accurate cost estimation remains a continuous challenge in construction projects, where early decisions are made under uncertainty and information is fragmented across stakeholders and tools (Lee et al., 2012). Building Information Modeling (BIM) has enabled automated quantity takeoff (QTO) and facilitated 5D BIM workflows, yet many BIM-based cost estimation pipelines remain tightly coupled to specific authoring platforms or proprietary estimating systems (Fazeli et al., 2021). These constraints impede reproducibility, limit integration with alternative cost databases, and complicate longitudinal use of cost information across the asset life cycle (Ramaji et al., 2020).

OpenBIM addresses these limitations by promoting vendor-neutral data exchange through the Industry Foundation Classes (IFC) schema (Hosseini Gourabpasi et al., 2025; Laakso & Kiviniemi, 2012). IFC is standardized as ISO 16739 and is widely used for interoperable model exchange. However, the representation of cost information in open standard formats is still uneven in practice: cost data are frequently exported as spreadsheets, maintained in separate systems, or stored as project-specific properties without consistent semantics (Khudhair et al., 2023, Hosseini Gourabpasi et al., 2025).

This study develops and evaluates an openBIM-based framework for automated QTO and costing in which cost items are explicitly linked to IFC material definitions and then propagated to building elements for computation. In addition, the framework extracts a defined set of building attributes to support LCC inputs focused on preventive maintenance and replacement planning (ISO 15686-5). The paper also addresses whether embedding detailed cost parameters within the BIM/IFC model is preferable to keeping them in linked external containers. Accordingly, a balanced assessment and approach relative to BIM-Cost-Container frameworks (e.g., DIN 18290-3) is proposed that packages cost determinations externally while maintaining links to model objects. According to ISO 15686-5, life-cycle costing covers acquisition, operation, maintenance, and end-of-life costs over the asset's service life. In this study, the term LCC is used in a narrower, implementation-specific sense: the proposed workflow automates construction-phase capital cost estimation based on IFC quantities and RSMeans unit rates and extracts structured model attributes (e.g., building area, number of floors, perimeter) needed by RSMeans' online LCC estimators for maintenance and replacement planning. Operational energy costs, water and utility charges, and explicit end-of-life scenarios are outside the current prototype's scope and are identified as targets for future work.

Literature Review

BIM-driven cost estimation has been studied for the past two decades and remains an active area of research, including ontology-based approaches for measurement rules and standardized cost semantics (Abanda et al., 2017; Lee et al., 2014, Fazeli et al., 2024), and automated QTO methods for compound and interior elements (Khosakitchalert et al., 2019; Kim et al., 2019, Fazeli et al., 2022). Several studies integrate BIM with cost databases to automate estimation or to support 5D BIM workflows (Elbeltagi et al., 2014; Banihashemi et al., 2022). Previous studies have also explored Industry Foundation Classes (IFC)-based cost estimation pipelines and extensions for construction-related data exchange (Ma et al., 2013; Cassandro et al., 2024; Zhang et al., 2024).

Despite this progress, two gaps are highlighted. First, many implementations rely on exports from proprietary BIM tools and do not preserve a consistent, reusable linkage between model objects and cost items in an open schema. Second, the term life-cycle costing (LCC) is used inconsistently: some studies address full whole-life costing across construction, operation, and end-of-life,

while others focus primarily on construction-phase capital costs or limited maintenance scenarios (Rad et al., 2021). This paper explicitly distinguishes capital cost estimation based on quantities and unit rates and a maintenance-and-replacement-oriented LCC view enabled through structured data extraction and mapping to an external LCC estimator that is precisely used in Canadian context. In parallel, European standardization efforts have advanced the concept of linked containers for multimodal exchange. DIN 18290-2 (2023) defines a BIM-LV container for linking models with bills of quantities, and DIN 18290-3 (2023) defines a BIM cost container for structured exchange of model-based cost determinations linked to IFC reference objects. These container approaches externalize cost documents while maintaining traceable links to the BIM model, offering an alternative to embedding detailed cost parameters directly within the model.

Methodology

This study provides an openBIM-based approach to cost estimation and preparing the model for a high-level LCC. Figure 1 shows the overall design of the current study, which began with quantitative inputs to establish an OpenBIM-based cost-estimation framework. Quantitative inputs include both IFC External database and IFC Internal database. In the IFC External database, cost specification database (RSMeans) will be connected to the IFC Materials of the model. This database includes all Canadian-specific cost information for materials, equipment, labour, and total cost, along with their corresponding Overhead & profit costs. In addition, each item taken from the RSMeans dataset includes ID, Name, Unit, and Crew, which specify the type of material, unit, and workers used in the cost estimation process. This information provides full cost estimates for every element in the IFC model. IFC Internal database also includes all information about quantities of elements, including Area, Volume, and Length and Layer Thickness. The entire process of cost estimation, including the connection between cost information and model quantity, as well as its corresponding calculations, is in the simulation stages, where it evaluates the causes and impacts on various variables and potential reactions in various scenarios (Privé and Errico, 2016).

The proposed methodology comprises four steps. The first step is to develop an IFC model. The next step is to connect cost database into IFC materials. The authors developed a new framework to automatically import all cost data into IFC materials. Following this, the user must enrich elements inside the IFC Model with RSMeans database and new developed IFCMaterials. Finally, the cost estimation process has been conducted using the IFC geometric information and IFC materials inside the model. The implementation uses IfcOpenShell to read and write IFC, create and attach property sets, and compute quantities from IFC physical quantity definitions.

1) Develop an IFC model: 3D modelling capability is regarded as one of the most important benefits of OpenBIM application. 3D modelling can help visualize both elements and data within elements, enabling project practitioners to manage and control time and cost effectively and other data within the project. Accordingly, the whole list of cost items can be stored in a material list of elements in the 3D modelling as inputs for cost estimation.
   i) Required IFC model and Level of Information Need: The proposed workflow presumes an IFC model with necessary data to support quantity takeoff and material-based costing. Concretely, the following minimum Level of Information Need (LOIN) is required for reliable operation:
      a. Geometry: Explicit solid or layered representations for main elements (IfcWall, IfcSlab, IfcCovering, IfcWindow, IfcDoor) with consistent units, enabling derivation of length, area, and volume from IFC physical quantities and material layer sets.
      b. Materials: Each cost-relevant assembly must be associated with one or more IfcMaterials or IfcMaterialLayers that can be enriched with RSMeans-linked properties (cost item ID, unit, formula, unit rates).
      c. Quantities: Either IfcElementQuantity sets or material layer quantities must be present or derivable (e.g., base quantities for walls, slabs, ceilings), as the prototype relies on these definitions for automated QTO
      d. Identification: Stable global identifiers for elements and materials (GlobalId, consistent naming conventions) to support repeatable mapping between IFC objects and cost items.

   In cases where these conditions are not met—for example, models lacking material assignments or relying solely on symbolic representations the workflow may still operate but will require additional pre-processing, manual material mapping, or default quantity assumptions.
2) Develop new IFC Materials with cost specifications: In this step of the process, a list of the most important cost items is retrieved from the RSMeans database. The ID, name, and unit shows the identity of material and units. Crew specify the type of workers needed for the cost estimation process. Then, all other information are the cost information in RSMEANS database. The formula also specifies which geometric information of elements is needed for the cost estimation process. A new framework is developed to import all RSmeans database inside IFC Materials of the project using IFCOpenShell.
3) Equip IFC Elements with new IFC Materials: In this step, project managers can either replace Materials inside elements with IFCMaterials or create new elements with new IFC Materials.
4) OpenBIM-based Cost estimation: In this step, Quantities are retrieved from IFC physical quantities,

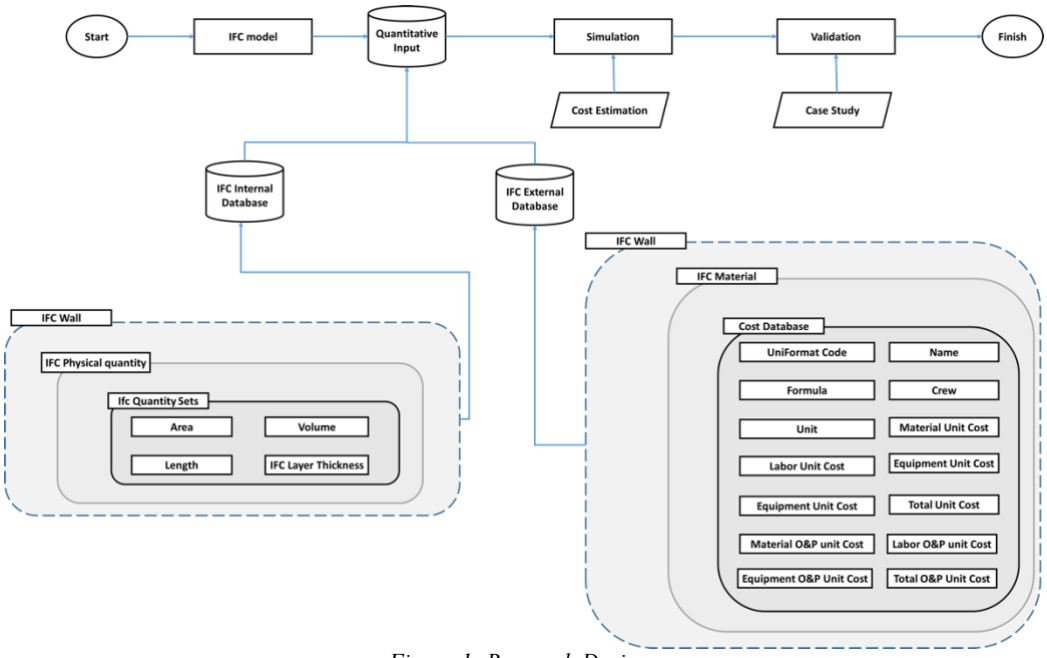

Figure 1: Research Design

evaluated against the cost formula, and multiplied by unit rates to produce element-level cost components. Results are stored back into the IFC as element properties to enable downstream queries, auditing, and visualization. The formula is used to change all units to SI units using a coefficient. Figure 2 shows the overview of the calculation made for cost estimation.

This workflow is most beneficial from late schematic design through detailed design and pre-construction, when key assemblies and material systems have been defined but design iterations and cost feedback are still frequent. At these stages, the IFC model typically contains sufficient geometry and material assignments to support reliable quantity takeoff while remaining flexible enough for design changes, enabling rapid re-estimation as materials, assemblies, or quantities evolve. During early conceptual design, the approach may be used with simplified template assemblies and approximate quantities, whereas in later construction phases it can support auditing and change impact analysis provided that as-built models and updated cost data are available.

Figure 3 shows how IFC structure for wall elements was used to implement the cost estimation of current study. As shown in the figure, the prototype first finds the elements inside the IFC Model. The IFC has standard structure to reach elements of the IFC model. In order to reach elements, firstly, IFCbuidingproduct will be found from IFCRoot. Inside IFC product, there are many elements including IFCWall, IFCSlab, IFCCovering, IFCDoor, and IFCWindows. The next step is to find IFCMaterials of elements inside the element. IFCRelAssociatesMaterials will be used to reach IFCMaterials of elements. Then, all RSMEANS information will be extracted from IFCMaterials through IFCMaterialProperties. The quantities of elements will be extracted through both IFCQuantitySets and IFCMaterialLayerSets. Finally, both quantities and RSMEANS data will be used to

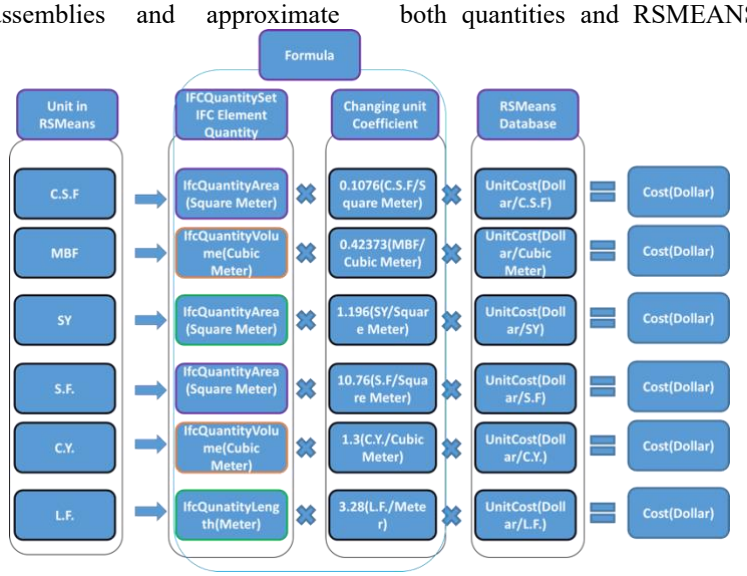

Figure 1: Cost estimation process

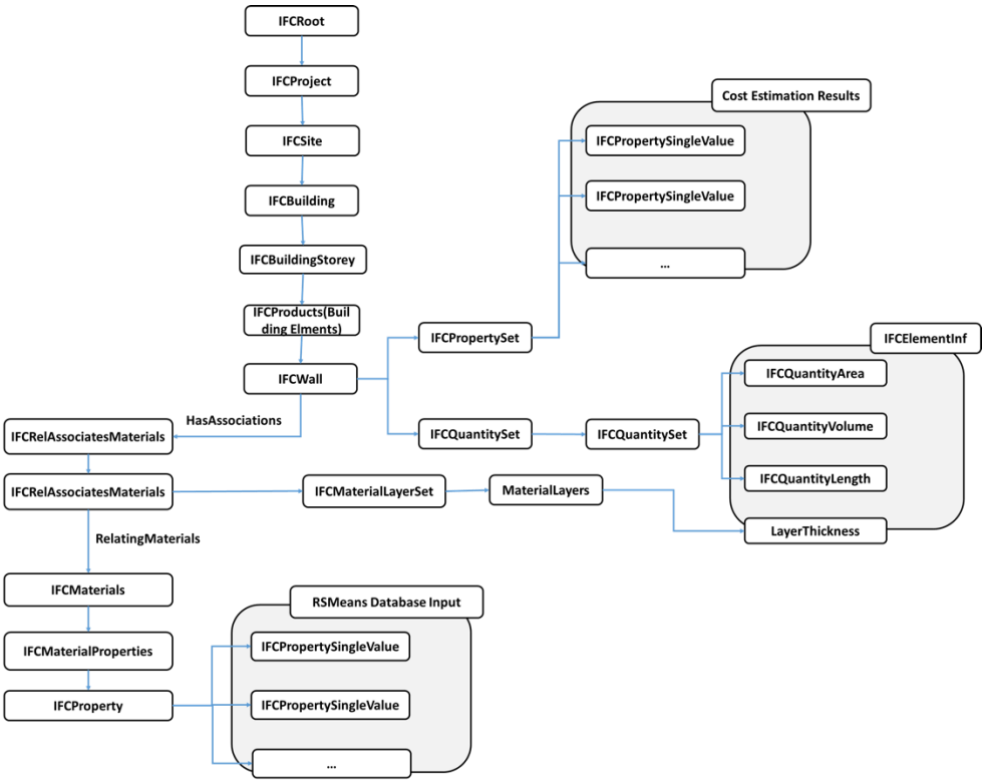

Figure 2: IFC-linked cost data architecture used for estimation

estimate the cost of project. The results of cost estimation will be imported through new developed property inside IFCPropertySet of elements.

The RSMeans website can estimate LCC costs of IFC project using some specific information from IFC project. The process of getting this information from IFC project is very challenging and time consuming. A new framework is needed to retrieve this information from IFC project. The LCC component of the workflow does not compute a full whole-life cost model inside IFC. Instead, it automates extraction of RSMeans-required input parameters (gross area, floor count, floor heights, perimeter) from the IFC model and delegates detailed maintenance and replacement costing to RSMeans' external LCC engine. As a result, the current prototype effectively covers construction-phase capital costs internally, while mid-life maintenance and replacement are handled externally; operational energy performance and end-of-life stages will require coupling with BIM-to-BEM methods and deconstruction/disposal datasets in future extensions. Therefore, In this step of the study, a framework has been developed to retrieve LCC information from IFC project to estimate LCC cost using RSMeans database. This framework can retrieve information, including the number of floors, the total floor area, the floor heights, and the total perimeter of the project. This information can be the primary input on the RSMeans website for LCC estimation. After entering this information on the RSMeans website, the total lifecycle cost is estimated.

Figure 4 shows the overview of the process. The first step is to retrieve LCC information from IFC model. A new prototype is developed to automatically extract all LCC information from IFC model. Then, the information should be imported in the next step and finally, LCC would be estimated from RSMeans. Using the current prototype saves a lot of time and prevents errors.

In this study, a platform has been developed to estimate the cost of construction project. Figure 5 shows the overall view of new developed framework. The first part is element part which has three types of elements including Wall, Floor, and ceiling. The main purpose of element part is to implement quantity take off from all parameters inside IFC model. The second part is edit part. The first button in edit part is the import RSMeans data. This button aims to import all RSMeans database inside

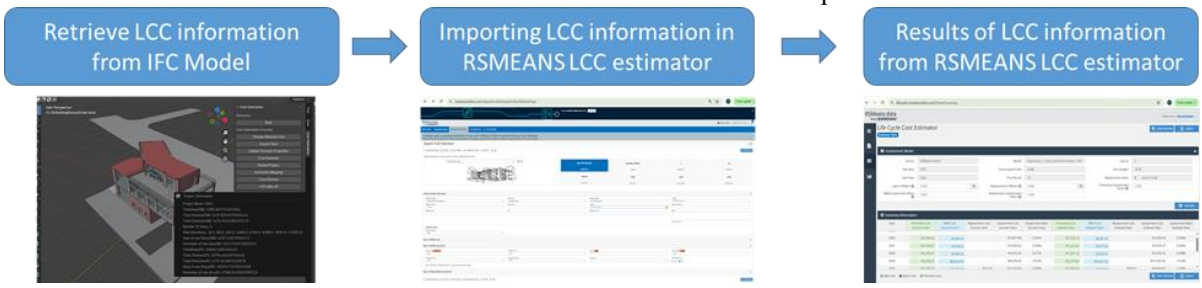

Figure 3: LCC estimation process

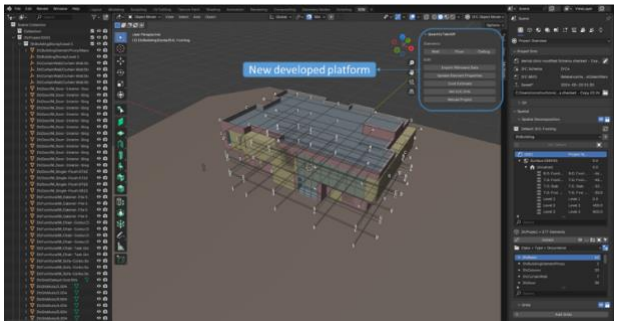

Figure 5 . Overview of the proposed OpenBIM costing workflow

materials of elements in the IFC project. The main purpose of second button (Update Element Properties) is to develop cost parameters in the elements of the project. The third button implement cost estimation from IFC project and update cost parameters in the IFC project.

The proposed framework is designed to align cost properties with shared semantics rather than ad-hoc custom fields. The buildingSMART Data Dictionary (bSDD) can host definitions for cost-related properties and classifications, enabling software-agnostic referencing of property meaning. Thus, Information Delivery Specifications (IDS) can be authored to formally specify which cost properties must be present for a given exchange (e.g., required cost code, unit, currency, and date), enabling automated compliance checking of IFC submissions before estimation. While full operationalization of bSDD- and IDS-driven governance is left as future work, these standards provide a practical path to scale the approach to other cost databases, regional cost indices, and organizational taxonomies without changing the underlying IFC computation logic.

Case Study and Results

The proposed framework was tested on a two-story office building in Toronto as a representative case. This building has a total gross area of 1005.35 m^2 and a net area of 781.91 m^2. The two-story office building model used in this study corresponds to a design-development level of detail, which aligns with the intended primary use-phase of the proposed workflow.

The model includes layered wall, floor, and ceiling assemblies with explicit material assignments. RSMeans unit rates were mapped to the enriched IFC material library, and quantities were extracted from the IFC physical quantities. Table 1 shows the results of cost estimation by the developed framework. The current methodology can estimate three main costs within the project: Material Cost, Equipment Cost, and Labour Cost, for both construction costs and Overhead and Profit costs.

The next step is to estimate the LCC cost of the office building from IFC format using RSMeans website. Figure 6 shows the LCC information required for LCC cost estimation, based on RSMeans requirements.

Discussion

The main contribution in this study is to propose an explicit and reusable linkage and between openBIM (in IFC data exchange format for objects like materials and assemblies) and standardized cost items, implemented without dependence on a specific BIM authoring tool or estimating platform. By storing both the mapping (cost code, unit, and formula) and the computed results in the IFC, the workflow improves auditability and supports downstream uses such as element-level cost visualization, change impact analysis, and exchange to other systems via non-proprietary solutions.

Table 1: Cost estimation results

	Material Cost	Equipment Cost	Labor Cost	Total Cost	Material Cost O&P	Equipment Cost o&P	Labor Cost O&P	Total Cost O&P
Wall	42262.75	116528.25	20268.5	179059.5	52407.58832	144276.34	25277.82167	221961.75
Floor	8494.8	17802	5580.94	31877.74	9650.463307	20395.04301	6358.093684	36403.6
Ceiling	1765.8	3801	1071	6637.8	2021.340613	4351.067884	1225.991503	7598.4

As specified in the ISO 15686-5, LCC can cover acquisition through operation and disposal. In the current implementation, automated computation focuses on construction-phase capital costs, and the LCC results are restricted to generating structured inputs for maintenance and replacement planning using RSMeans life-cycle cost estimators based on the Canadian-specific datasets. Operational energy costs and performance-driven OPEX (e.g., energy, water, and carbon-related costs) are not calculated in the current workflow; integrating BIM-to-BEM pipelines and measured operational data is in progress and will be covered in future work.

Cost becomes a time-dependent attribute when it is linked to design revisions, procurement decisions, and construction progress or asset condition. The presented openBIM cost layer can act as a foundational dataset for a cost-focused digital twin by providing a traceable mapping between physical components and cost parameters, enabling systematic updates when quantities, rates, or asset states change.

Embedding cost parameters directly in IFC provides a self-contained, portable package that supports offline review, element-level traceability, and automated computation. However, it introduces governance and maintenance burdens. For instance, cost data can become outdated, licensed cost datasets may not be distributable inside models, and large models may not operate properly with detailed pricing information. Container-based approaches such as DIN 18290-3 (BIM cost container) and DIN 18290-2 (BIM-LV container) mitigate these issues by externalizing cost determinations and bills of quantities while preserving explicit links to IFC reference objects. For projects that require strict control over cost document versions, procurement workflows, or licensing constraints, a linked container may be preferable. For early-stage design, alternative analysis, and internal collaboration, in-model cost embedding can be effective when paired with clear update rules and access controls.

To scale across databases and contexts, the openBIM approach should rely on stable semantics for properties and exchange requirements. bSDD offered by buildingSMART can support standardized property definitions, and IDS can specify information requirements and validation rules for exchanges, reducing ambiguity in cost mappings across tools and stakeholders in various life cycle stages. In practice, bSDD and IDS can be used to formalize the Level of Information Need for model-based estimation by specifying which cost-related properties, material assignments, and quantity sets must be present at each project stage. In fact, it enables automated compliance checking of IFC submissions before running the estimation workflow.

Conclusions

Traditional cost estimation methods were often reliant on manual processes and licensed tools. This creates many inefficiencies and inaccuracies in the process. The integration of BIM has revolutionized this process by enabling digitalized, automated cost estimation. However, there are still challenges in the process due to the use of different BIM tools and data formats, leading to interoperability issues and data loss during data transformation between them. This study aimed to develop an OpenBIM-based approach to cost estimation. IFC facilitates seamless data exchange between different BIM authoring tools, ensuring consistency and accuracy across platforms. Furthermore, incorporating standardized classification systems (e.g. UniFormat) and reliable cost databases, such as RSMeans, enhances the precision and reliability of cost estimates.

Despite the advantages of the current study, it has some limitations. There is a lack of robust software to handle IFC for large projects. The Blender software used in the current study cannot open large IFC projects, so the authors are limited to medium-sized projects in the validation phase. On the other hand, this study focuses on only three categories of elements. To enhance the precision and accuracy of cost estimation, it is necessary to estimate the costs of all other project elements. A notable limitation of the current implementation is its reliance on explicitly modelled elements for quantity takeoff and costing. Thin finishing layers (e.g., paint, screeds), multi-component façade systems, lightweight partitions (e.g., timber or gypsumboard walls), and temporary works (e.g., scaffolding, cranes, site logistics elements) are often omitted or represented only implicitly in design-stage models, which means their costs are not directly captured by the automated workflow. In practice, practitioners could address these categories using: i)Parametric allowances (e.g., applying finish factors or percentage-based mark-ups tied to gross area or perimeter). ii) Assembly templates that aggregate typical finishing and sub-components into a single modelled proxy with an associated composite cost item. iii) Linked cost containers or external BoQs that include non-modelled items but remain traceable to the model context. In fact, Systematic integration of such non-modelled or partially modelled cost drivers especially temporary works and construction logistics remains an open research direction and is not fully supported by the current prototype. Furthermore, life-cycle cost data were sourced exclusively from the RSMeans. This reliance may limit the model's adaptability across different regional contexts or project types. Future study is in progress to independently estimate the life cycle cost of the project and consider all other factors in the life cycle cost process. Finally, While the present case study and implementation rely on Canadian-specific RSMeans datasets, the core workflow is not tied to a specific vendor or region. Because cost logic is encoded as generic IFC material properties (cost code, unit, formula, unit rates) and the linkage semantics can be governed via bSDD and IDS, the same pattern can be applied to other regional or international cost databases (e.g., national price books, company-specific cost libraries) by changing the external dataset and property definitions without modifying the underlying IFC computation engine. Future work will focus on validating the approach with alternative cost sources and regional

indices and on defining reusable IDS templates for cross-context deployment.

Acknowledgement

This study has been supported by the Construction Sector Digitalization and Productivity (CSDP) program under the project "OpenBIM integrated framework to standardize life cycle environmental and economical benchmarking of building projects" at National Research Council Canada. The authors would like to extend their sincere gratitude to all the stakeholders who participated in this research and contributed to the findings presented in this paper.

Abstract

CityRetrofit integrates publicly available datasets with building archetypes to create urban building energy models (UBEMs). The tool integrates geospatial data, occupancy schedules, construction assemblies, and HVAC/energy system characteristics for both baseline and potential retrofit scenarios to support retrofit strategy development at the urban scale. This paper summarizes the development of this workflow in a mandatory building energy disclosure context (Montreal) and its extension to a jurisdiction without such disclosure (Toronto). The resultant case study demonstrates the workflow. The results show CityRetrofit's adaptability across jurisdictions to inform urban decarbonization policy.

Introduction

Global cities face mounting pressure to reduce CO_2 emissions but the sheer scale of retrofits is overwhelming, particularly given the paucity of building energy disclosure in many jurisdictions, existing building heterogeneity, and the lack of appropriate simulation tools.

Previous work has explored various approaches to urban building energy modeling (UBEM) , most notably single- and multi-zone bottom up simulation and top-down energy mapping. While the latter was enabled with mandatory building energy disclosure (MBED) laws, the ability to simulate building system performance was necessary to model and evaluate potential retrofit pathways. In this context, bottom-up models play a critical role.

Urban Building Energy Modeling (UBEM) tools have been developed to analyze city-scale energy flows, with a strong focus on building stocks and their interactions within the urban context, such as shading, thermal exchanges, urban heat island effects, and vegetation (Allegrini et al. 2015).Over time, a wide range of tools have emerged, using different modeling approaches—from reduced-order and resistance–capacitance models to detailed dynamic simulations—and varying in scope, input formats, and integrated features like transportation, life-cycle analysis, or cost–benefit assessment .

Despite these advances, the literature shows that existing Urban Building Energy Modeling (UBEM) tools have progressively improved the representation of urban energy flows—particularly building stocks and their interactions—using a wide range of modeling approaches and simulation engines (Monien et al. 2017). However, most tools remain strongly conditioned by the specific use cases for which they were originally developed, leading to limited modularity, scalability, data flexibility, cross-sector integration, and automation, as well as difficulties in clearly communicating results.

To address these gaps, recent research argues for moving away from tool-specific, ad hoc solutions toward an open-source, flexible framework built around a central urban data model capable of handling heterogeneous data sources and interfacing with multiple simulation tools at different levels of detail. This approach aims to support diverse urban sustainability and building retrofit use cases by integrating different processes and software within a unified, adaptable structure rather than relying on a single modeling engine, following (Gavaldà-Torrellas et al. 2025).

To populate such workflows, archetype development has been a topic of significant research globally. In the North American context, two sets of archetype libraries were available: 'reference models' for older (pre-2001) buildings, and 'prototypical' code-minimum models aligning with each version of the ASHRAE 90.1 energy efficiency standard, which was released codified on a three-year basis. This has been adapted regionally, for example the Canadian Building Technology Assessment Platform (BTAP) (CanMet Energy, 2023) that adapt these to local codes. The latter was a reasonable approximation for newer building stock, since this standard has been codified into regional codes across North America.

The former reference models (US DOE, 2012), however, categorize older buildings into two broad vintages: pre-1980 and 1980-2004, regardless of building type or form. This simplification fails to capture critical differences in construction practices, materials, and code requirements within each period. As a result, these archetypes often misrepresent the performance of older buildings, leading to inaccurate energy predictions (Li & Feng, 2025). The development and integration of more granular characterizations was thus critical to capture these differences.

Within Europe, there has been substantial archetype development, using both bottom-up and top-down aggregation methods; see (Mata, Kalagasidis, & Johnsson, 2014) for a comprehensive review. Across

multi-country studies, the use of code minimum performance has been shown to consistently estimate building stock performance with low (<5%) error (Mata et al., 2014).

This paper presents the development of the CityRetrofit tool for Montreal, its supporting workflows, and its extension to incorporate bottom-up approaches allowing its mapping to new jurisdictions with significantly limited public data. A case study for Toronto, a cold climate (ASHRAE Climate Zone 5 (CZ5)) dense urban context was presented to demonstrate and validate this process. The resultant tool supports its adaptation and replication, providing a scalable digital twin suitable for decarbonization policy and district energy planning across global urban contexts.

The paper was structured as-follows. First, the methodology guiding the development of CityRetrofit was presented, including geometric data processing, energy model input mapping, and the detailed development of refined inputs (to address the above oversimplification limitations) to provide more accurate baseline and retrofit pathway building-level models for UBEM integration. Next, the resultant inputs were summarized, and the platform integration was presented. Finally, the extension to other jurisdictions was discussed and the future research trajectory to address current limitations was presented.

Methodology

The CityRetrofit platform was developed through four overlapping phases: (1) workflow development; (2) ingestion of building geometry; (3) building archetype refinement; (4) retrofit design and analysis; and (5) integration and testing using a second urban area (Toronto) as a use case.

Workflow development

Existing UBEMs rely on use-case–specific architectures and back-end simulation engines, which constrains modularity and limits their computational scalability when extended to large building stocks, multiple cities, or cross-sectoral applications, as evidenced by their typically small-scale deployments in prior studies. In line with previous benchmarking research, the limited automation of data ingestion and preprocessing remains a key bottleneck, increasing human effort, reducing reproducibility, and hindering systematic comparison across tools and case studies. Moreover, the trade-off between reduced-order and detailed dynamic simulation approaches restricts their suitability for different decision contexts, ranging from rapid policy screening to high-resolution retrofit analysis. The proposed CityRetrofit platform addresses these gaps through an open-source, centralized data model that automates data handling, enables transparent benchmarking across simulation engines, and supports scalable, decision-relevant outputs tailored to policymakers, urban planners, and researchers. From a detailed perspective, the CityRetrofit platform integrates empirical data, archetype-based modeling, simulation, and comparative assessment to support scalable, portfolio-level retrofit decision-making through five main stages: (1) Building energy demand calculations, including geometric data acquisition and preprocessing, construction and usage archetype assignment, and weather file selection; (2) HVAC system assignment and energy disaggregation; (3) Retrofit identification and characterization; (4) Retrofit assessment; and (5) Visualization (Fig. 1). This modular structure enables scalability and adaptation to different building stocks and jurisdictions.

Building-level data availability determines the modeling approach adopted. For bottom-up analyses, geometric information is required and can be extracted from CityGML, 3DS, or GeoJSON files at varying levels of detail (LOD1/LOD2), all of which were processed through a unified geometry factory. When detailed geometry is unavailable, predefined geometrical archetypes enriched with building attributes were employed instead. These archetypes were developed by clustering extensive geometric and monthly energy datasets from data-rich cities, resulting in a set of transferable, high-resolution building representations integrated into the tool.

Building geometry ingestion

The first step for building modeling was the creation of a 3D city model. This model can be generated from multiple

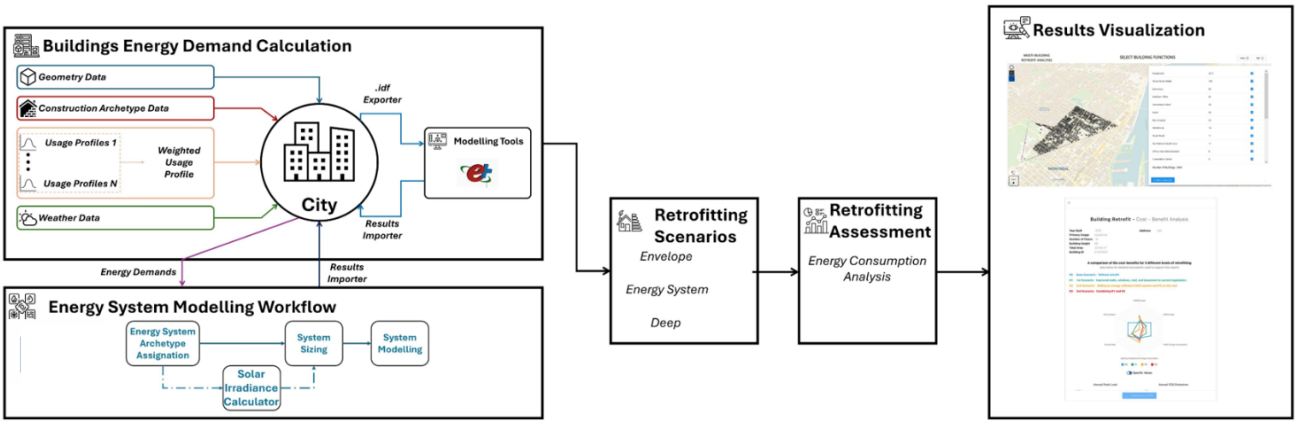

Figure 1: CityRetrofit workflow

formats, including GeoJSON, obj, 3ds and CityGML. Automated processes to validate and integrate different data sources was developed. For Québec cities, the input data was created by combining several open-source datasets including LiDAR aerial data (Montréal 2026a), property assessments (Montreal 2026a), Building Footprints (Canada 2026), and Layer 2 cadastral data for disaggregated building use types (Université Laval 2026). A validation and cleaning process, comparing the results with sources of ground truth (utility data for 2019-2021 divided by building function and Forward Sortation Area) was developed and helps validate the process of merging initial low-quality datasets, which was a usual situation in large scale city data. The comparison between simulated and measured energy use showed good agreement, with deviations generally within 15–20%, consistent with previous validation studies of the proposed UBEM workflow (Gavaldà-Torrellas, Monsalvete, Ranjbar, & Eicker, 2025).

Required building inputs include year of construction, building function, and height. The process begins by creating an instance of the *City* class, which was then populated with city object information extracted from the input file through a dedicated importer. This importer enriches the city model by integrating both geometric and attribute data. Once the city objects were extruded to form a 3D representation, the internal zoning of buildings was defined. At present, each building is modeled as a single thermal zone, although several multi-zoning approaches are currently under development. An important aspect of the approach taken was the capacity of ingesting different levels of detail of data (presently LOD1 and LOD2) depending on the quality of the original data sources.

Archetype development

Non-geometric building attributes were captured using archetypal constructions, systems, and scheduled, to map to the geometric archetypes. Existing reference and prototypical building models – e.g. DOE/ASHRAE and BTAP reference and prototype models – were used to provide the starting point for archetype development, providing reference geometry, construction assemblies, HVAC system definitions, and building schedules by period and type. A review of these archetypes against the existing building stock indicated a need for more granular construction and HVAC system characterization for the pre-2001 commercial (office) and multi-unit residential (MURB) building typologies while smaller buildings were more consistent with respect to both construction and HVAC systems. In all cases, occupancy schedules follow ASHRAE 90.1 as these were typical across the building stock.

Archetype development in a mandatory building energy disclosure context

Because Montreal had publicly available building energy use, that data was used to validate and refine inputs from the literature and allowed building clustering similar to what was achieved for the geometry.

Construction archetypes

Construction assemblies were re-evaluated through recalculation of U-values using explicit material properties and consistent assumptions regarding layer composition and air gaps. This process led to improved representation of post-2000 lightweight cladding systems, correction of legacy U-values where discrepancies were identified, and harmonized treatment of air gaps in accordance with building physics best practices. In parallel, the material library was expanded to include underrepresented but commonly used materials, such as stucco finishes and explicit air-gap layers, improving transparency and physical realism. Terminology was standardized across archetypes to ensure consistency with BTAP, NECB, and ASHRAE conventions, facilitating interoperability and collaboration.

To enable a robust and comparable assessment of building energy performance, this study applies a set of statistical diagnostic methods to both measured utility data and simulated baseline consumption. The primary analytical framework was the PRISM (PRInceton Scorekeeping Method), which characterizes the relationship between energy use and outdoor air temperature through segmented linear regression, yielding key indicators such as heating sensitivity (Fig 2).

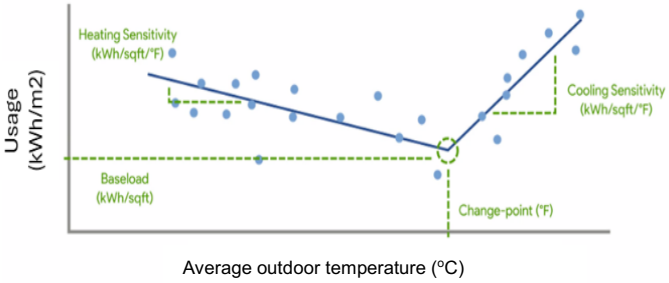

Figure 2: PRISM methodology

At the portfolio scale, kernel density estimation (KDE) was used to identify a reference centroid representing typical thermal performance within the building stock, allowing individual buildings to be benchmarked relative to representative baselines rather than absolute thresholds.

HVAC/Energy system archetypes and data model

In addition to construction and usage archetypes, each building must have the HVAC system assigned, which permits energy disaggregation. This process was done automatically where the assignation criteria can be defined based on: (1) Regional statistics; (2) Current building codes (for retrofit performance requirements); and (3) Scientific literature.

Process automation was enabled through the development of a generic object-oriented energy system data model where all the energy system-related data needed in simulation and optimization were structured in a parametric, generic, and extensible way. This provides a structured, object-oriented representation of building energy systems that explicitly separates data representation from simulation and optimization logic.

All system components – namely generation, storage, distribution, and emitters – were described through standardized classes with well-defined attributes, relationships, performance curves, and cost functions.

This separation enables the same data structures to be reused consistently across feasibility screening, hourly simulation, life-cycle costing, and multi-objective optimization, without rewriting model logic for each application. The object-oriented design supports modularity and extensibility: new technologies or manufacturer-specific components can be introduced by adding data entries or subclasses, without modifying the computational workflow. As a result, the data model serves as a robust computational backbone that enables scalable automation, cross-climate comparability, and relevant system analysis, while remaining compatible with semantic annotation or ontological layers if broader interoperability was required in future extensions. The appropriate energy system archetype was assigned. The system component parameters were retrieved from the energy system data and passed on to the simulation model. System retrofit analysis is implemented by changing the energy system archetype from that of the base case.

Extension to the low data availability context

Because of the lack of publicly available building energy data in Toronto, a more empirical approach was necessary to refine archetypes. Buildings types for CZ5 were characterized and clustered according to construction assemblies and HVAC systems to enrich existing building archetypes to reflect the full range of variations in form, use, and system configurations. This was done in three key phases: (1) historical analysis; (2) relevant code review; and (3) validation.

The construction historical analysis was based on an architectural study, which characterized the various forms, window-wall-ratios (WWRs), and constructions associated with each of the 20th century architectural movements. These movements were broadly used to define building styles and tend to be international in scope, providing a broadly-applicable method for building classification. Each architectural movement period was mapped to identify periods where multiple distinct styles were present within a single period. This approach allowed the archetypes to capture the diversity of common building types across typologies and identify the defining characteristics for each. The HVAC historical analysis similarly looked at the invention and period of adoption for various equipment and system types, grounded in industry documentation and previous historical studies (Carrier 2012, US DOE 2015).

While the historical analysis provided insight on typical equipment and construction types, these did not provide sufficient detail to model the performance of the HVAC /energy systems and construction assemblies. For this, a detailed code review was undertaken, where the various iterations of relevant building and energy codes were reviewed and prescribed performance was documented at each point. Once this was complete, periods with different code mandated-performance were used to subdivide the building sets and required RSI/U-values for construction and efficiency/COP for HVAC were documented for each. For HVAC systems, the resultant characterization sets were then cross-referenced with the typical systems and efficiencies identified in the reference models (US DOE 2012), building code requirements (NRCan 1997, NRCan 2011a) and guidance documents (NRCan 2011b).

To validate the characterizations, the Delphi technique, a procedural research method involving repeated rounds of input by experts until consensus was reached (Linstone 1985, Barrett and Heale 2020) was used. This approach was widely used to develop best practice guidance in the absence of available data (Barkhordari Ahmadi, et al. 2023) and is increasingly adopted in the energy modeling context (Phichetkunbodee, et al., 2023). Two leading building science firms, each with substantial (200+) energy model databases of past project in both pre- and post-retrofit conditions supported this process, referring to their libraries of energy models to confirm or clarify the proposed characterizations. The code minimum construction thermal performance and construction assumptions were documented in a set of tables circulated to both consultant teams at this stage. Because of the limited service lives of HVAC equipment, likely replacement periods for each building set and the replacement equipment – whether like-for-like or an anticipated new type (e.g. oil boilers replaced with natural gas boilers) were also included in the HVAC system review table.

Two rounds of review were used, along with an in-person meeting after consensus was reached to present the final archetype inputs and provide a venue to identify any further issues warranting consideration or inclusion in the model. Finally, cluster analysis was undertaken to identify constructions and HVAC/energy systems with similar characteristics. For construction assemblies, clustering used effective conductivity ($\mathrm{Cond}_{\mathrm{eff}}$; Eq. 1) vs effective solar heat gain coefficient ($SHGC'_{\mathrm{eff}}$; Eq. 2) and both Euclidean and Mahanobilis distances were used with 2 to 15 tested.

$$\mathrm{Cond}_{\mathrm{eff}} = \mathrm{U}_{\mathrm{wall}} * (1 - WWR) + \mathrm{U}_{\mathrm{window}} * WWR \quad (1)$$

$$SHGC_{\mathrm{eff}} = SHGC_{\mathrm{window}} * WWR \quad (2)$$

The resultant construction and HVAC system inputs by period were then translated into EnergyPlus input files.

Retrofit development and prioritization

Retrofit scenarios were generated for each building archetype through a three-stage process for each of construction and HVAC system retrofits. In the first stage, the research team reviewed each of the base building combinations and identified the full spectrum of possible retrofits based on hygrothermal, thermodynamic, or practical considerations. For example, for building construction upgrades, insulation strategies that risked moving the freeze point into a porous cladding such as brick were avoided. Similarly, local/terminal equipment requiring high temperatures limited fuel switching to those capable of providing the appropriate temperature

range. For practical reasons, retrofits requiring a complete replacement of all HVAC devices in a building or requiring the installation of significantly larger equipment were not considered as they were cost prohibitive.

In the second stage, the building consultants were again engaged through a Delphi technique where the researchers identified potential upgrades feasible for each a) construction and b) HVAC system type and created tables for each base condition to summarize these options. Notes regarding excluded retrofit options were also shared. These tables were circulated to the consultants for their review against their project databases and comments were received regarding any unconsidered technical challenges preventing listed retrofit measures, the frequency of such retrofits, and performance characteristics (i.e. revised U-value or COP). After another two rounds of review, consensus was reached, informing a range of retrofits representing different levels of ambition (Level 1 Most Typical (Short Payback) vs Level 2 Deep Retrofit) and for HVAC, retrofits enabled by the presence of a thermal energy network or ground-source heat pump system (Level 3). Again, an in-person meeting with all parties was held after retrofit finalization to present the results and provide an additional opportunity for clarification or refinement. The finalized retrofit inputs for both construction and HVAC systems were then characterized and translated into EnergyPlus input files. The final workflow is shown in Figure 3.

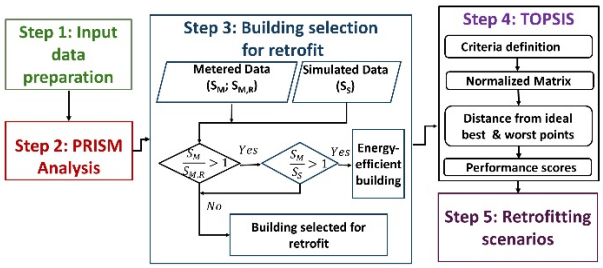

Figure 3. Building portfolio retrofit prioritization workflow

To further support transparent and data-driven retrofit prioritization, the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) was employed as a multi-criterion ranking method. Buildings were evaluated using a combination of measured and simulated indicators, including heating sensitivity slope, energy use intensity, total annual energy consumption, and volume-to-area ratio. After normalization, each building's distance to ideal and negative-ideal solutions was computed to derive a composite performance score. By integrating operational performance metrics with physical characteristics, this approach enables a balanced and justifiable ranking of retrofit candidates, ensuring that investment decisions reflect multiple dimensions of energy impact and align with broader energy and policy objectives.

Integration

Once the structural components of the model were defined, their composition was formalized through workflows, whose primary function was to manage the flow of data from external sources to one or more models, execute those models, and collect and distribute the resulting outputs. Regardless of the specific model being managed, each workflow follows a common sequence of fundamental steps: importing heterogeneous input data from proprietary formats, filling data gaps using archetypal data for construction, usage and energy systems and converting them into a shared central data model; optionally pre-processing these data through cleaning, calibration, pruning, or compression; optionally constructing or adapting model structures based on input characteristics such as building geometry; running the selected models one or multiple times using appropriate data exporters and model-specific input formats; retrieving and standardizing model outputs back into the central data model; and finally delivering the results through files, visual interfaces, or availability for subsequent workflows and external applications. This standardized workflow structure ensures interoperability, extensibility, and consistent data handling across diverse models, use cases, and urban-scale analyses. The re-running of the cases was crucial to obtain retrofit results once the model was validated.

District energy network optimization

To evaluate the impact of building retrofits on a district system, a 5th generation (heat recovery) thermal energy network (TEN) assessment/feasibility tool was developed in MATLAB to identify thermally balanced micro-TENs within urban blocks. The tool reads hourly building heating/cooling time series from building-specific EnergyPlus simulations results in Excel format and assembles a matrix in which each column represents one building's 8,760-hour profiles. After the building with the highest net heat rejection was selected as an anchor, the remaining buildings within the block were considered in n={1,2,3} sets to support adding building pairs with complementary net heating and cooling loads. Building profiles were aggregated along with the thermal storage state (charge/ discharge) to compute the outstanding mismatch, which then informs inclusion/exclusion decisions for the remaining candidate buildings. An objective function (Eq. 3) was used with forward selection to minimize the total energy imbalance, $Q_{net.}$

$$minimize\ \mathrm{Q_{net}}(t) = \Delta Q(t) + \mathrm{Q_s}(t) \qquad (3)$$

where: ΔQ was the instantaneous imbalance of connected buildings, and Q_s was the energy stored or used from storage. stored energy available. This method was applicable for both baseline and retrofit cases, along with future development scenarios.

Building energy simulations were performed using the EnergyPlus engine, with all archetypes translated into IDF input files and simulated at hourly resolution. Model calibration and validation were conducted using measured utility data where available. In the Montreal case, statistical calibration was performed using the PRISM method, enabling the derivation of heating sensitivity and base load parameters, which were compared against simulated outputs. At the portfolio level, kernel density

estimation (KDE) was used to define representative performance benchmarks. The resulting simulated energy use intensity (EUI) values were found to be consistent with measured datasets, with deviations generally within typical UBEM uncertainty ranges reported in the literature (<10–20%). In data-scarce contexts such as Toronto, archetypes were validated through expert-based Delphi processes informed by large databases of calibrated energy models (>400 cases).

Results

Construction characterization

Figure 4 shows the evolution of building codes (left) along with representative architectural styles (right) across periods. The overlapping of styles across multiple instances of the building code, along with differing residential vs non-residential code requirements led to an initial 23 archetypes, validated using Delphi technique.

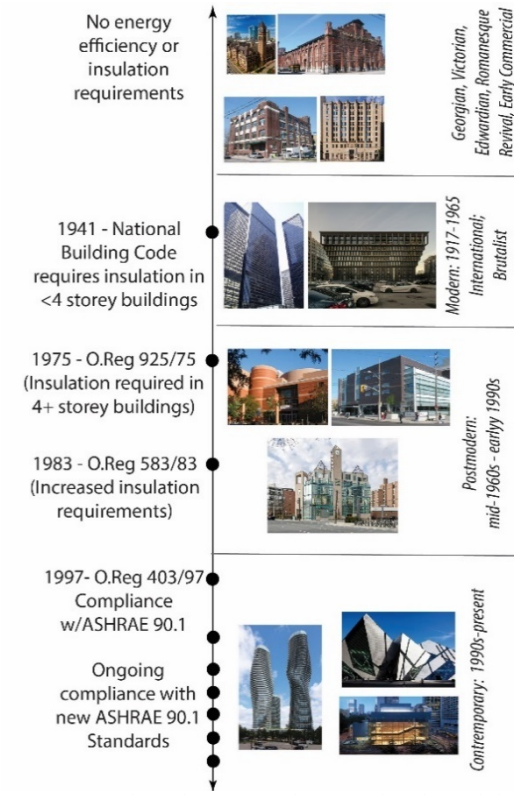

Figure 4: Timeline showing Architectural Styles Subdivided by Evolving Building Code Thermal Performance Requirements

Cluster analysis (Figure 6) was then used to identify buildings with highly similar thermal performance – both with respect to conductivity (area-weighted U-value/RSI) and radiation (area-weighted solar heat gain coefficient (set to 0 for opaque walls) – reducing the set to nine distinct construction characteristics.

The clustering exercise identified eight clusters and while the resultant areas and cluster identification orders were different, the cluster assignments themselves were identical for both approaches. The resultant construction assembly clusters are: {1975-2004 low-rise (brick), mid-high rise (concrete), and high-rise (steel) structures; 1975 -2004 Mid/High rise office (spandrel panel Postmodernist); 1975-2004 MURBS (all); 1941 1975 Mid/High rise office (curtain wall international); 1941-1975 mid/high rise offices (brick); All pre-1940 buildings + 1941-1975 low-rise MURBs; 1941-1975 low-rise office (brick) and mid-high rise MURBs (brick); 1941-1975 mid/high rise office & MURBs (concrete)}. These were uploaded into the CityRetrofit tool and mapped by address to each of the buildings based on year of construction and type. The input data for all clusters is published online at: https://github.com/DanaAlJadaa/Pre-2004-Canadian-CZ5-Envelope-focused-IDF-models.

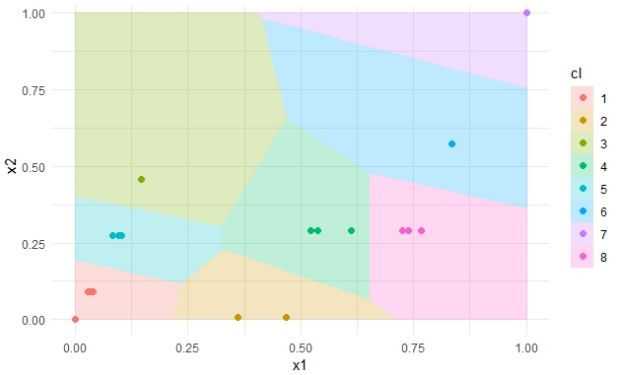

Figure 5: Construction Clustering using Euclidean Distances

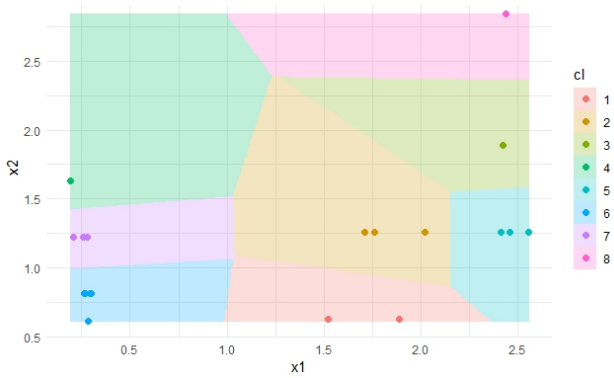

Figure 6: Construction Clustering using Mahanobilis Distances

HVAC system characterization

The HVAC system characterization identified nine representative HVAC systems across commercial offices and MURBs of various sizes, increasing the number of systems from DOE by two and providing more insight on shifts in fuel type (oil vs natural gas) and distribution (constant vs variable air volume) than the latter. These, with both baseline and the three levels of retrofit, were provided at https://github.com/jakjak42069/Baseline-E-Models-Canada-CZ5A. All other typologies were found to be consistent with DOE reference models, thus requiring no modification. Again, these were uploaded into the CityRetrofit library and mapped to buildings by type and period of construction.

District energy network optimization

The "Golden Mile" was an area within Toronto with significant planned densification (28,000 new residential

units to be added (Fig 7, blue buildings) was used as a demonstration case, consisting of 35 buildings including a large grocery store used as the anchor. Results were shown after each iteration in Fig. 8.

Figure 7: Demonstration Area

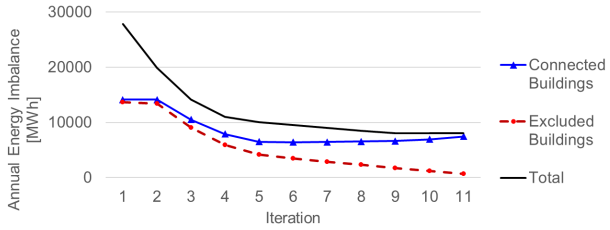

Figure 8: District interaction results

With this existing building set, 26 out of the total 35 buildings were identified for connection to the optimal TEN. This allowed 77% of the total heating and cooling loads to be met using heat recovery and seasonal storage, reducing the total heating and cooling energy required from by 77%, from 32,065 MWh/year to 7,449 MWh/year. The remaining load must be met from other sources, whether central (for the TEN) or at the building-level. Compared with individual building heat recovery using ground-source heat pumps with seasonal storage, the optimal TEN reduces net energy demand by 70%.

Platform integration and performance

In addition to the Golden Mile used for district interaction, the complete Toronto 2030 district (a 16km^2 area with over 30 million m^2 of built space across 7000+ buildings) has been integrated CityRetrofit tool (Fig. 10). The tool simulate up to 1,000 buildings in less than 1 hour using a single Intel® Xeon® E-2400 processor, with up to 8 cores at 95W, allowing the full district to be modeled in just over 7 hours, at which point the values were saved for future recall.

To use the tool, the building set of interest is identified, either through the GUI or by uploading a new set of buildings with archetype mappings as a .csv. Sample visualizations selected for implementation of the tool ae shown in Figure 10 alongside baseline energy consumption data.

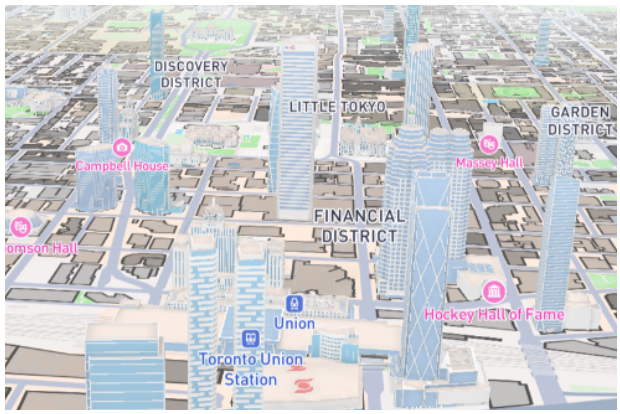

Figure 9: Toronto 2030 district (cropped)

Discussion and conclusions

The CityRetrofit platform presents a cost-effective way to create UBEMs suitable for retrofit pathway analysis at the portfolio, district, or city scale. Extending the tool to a new jurisdiction requires any new envelope constructions and HVAC/energy systems not already in the library to be added, which can be done by appending csv files.

Compared to existing UBEM platforms such as CitySim, UMI, or UrbanOPT, which are typically built around specific simulation engines or predefined workflows, CityRetrofit adopts a modular, data-centric architecture that decouples data models from simulation engines. This enables interoperability across tools, automated data ingestion from heterogeneous sources, and scalable application across jurisdictions with varying data availability. Additionally, the integration of empirical calibration methods (PRISM) and expert-informed

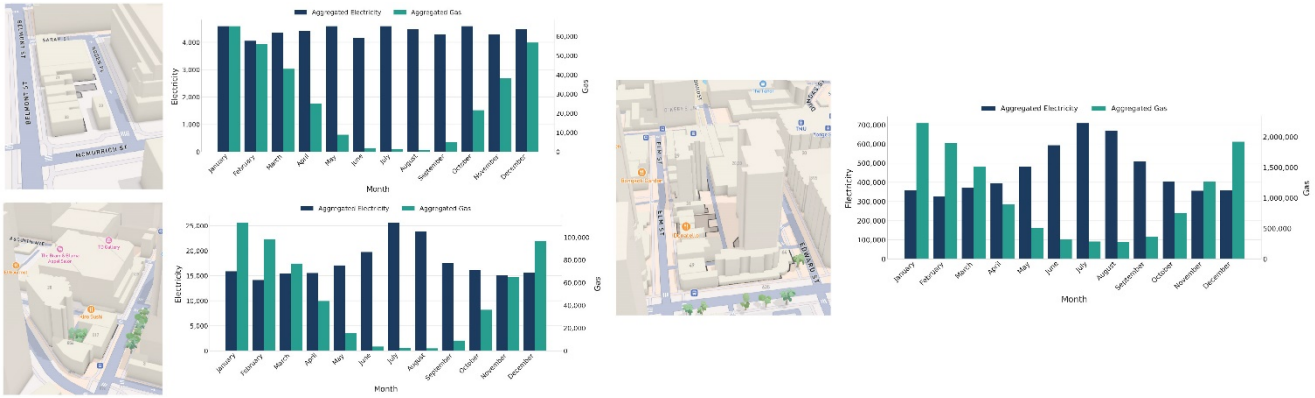

Figure 10: CityRetrofit sample visualizations (baseline condition)

archetype refinement provides improved adaptability in both data-rich and data-scarce contexts.

There were some limitations of this work. First, the lack of publicly available building energy data has made it impossible to validate the archetypes using utility so the Delphi study, informed by over 400 calibrated energy models, was used to confirm archetype inputs. Negotiations are ongoing to obtain access utility data for archetype calibration purposes and thus confirm the accuracy of these inputs. Second, the current modeling is single-zone only; multi-zone (by storey) is currently being tested for integration into the tool. Third, only forward-selection has been integrated for TEN optimization; future research will incorporate Backward Elimination and a binary Genetic Algorithm using tournament selection and uniform crossover, enforcing anchor buildings to remain included in all chromosomes. Finally, while the archetypes developed have been fully integrated into the back end of the platform and the district energy models are running, the full Toronto 3D model has not been loaded into a web-hosted platform and thus the Montreal GUI has not yet been implemented for the Toronto case. This is anticipated to be completed by August 2026.

Data Availability Statement

The full set of archetypal construction and HVAC system baseline and construction retrofit inputs were available in EnergyPlus format on GitHub as noted in the manuscript. The repository for the tool presented is available at https://ngci.encs.concordia.ca/gitea/CERC/hub.

Acknowledgments

This research was funded by Volt-Age (CFREF) through the CityRetrofit project.

BREAKPOINTS IN DATA CONTINUITY ACROSS CONSTRUCTION REUSE PROJECTS

Abstract

This study investigates where and why material identification and digital representation fail to persist across reuse life cycles. Digital material tracking in circular construction is commonly organized through separate data pipelines for logistics and design, resulting in discontinuities as building elements move between projects. A unified analytical framework is proposed and used to define six recurring classes of breakpoints in data continuity. These breakpoints are empirically identified and analyzed across eight construction reuse case studies. The findings establish a systematic breakpoint typology and provide recommendations for continuity-oriented data infrastructures that support traceable material reuse in construction.

Introduction

Material reuse is increasingly promoted as a key strategy for advancing circular construction (De Wolf et al., 2024), yet its practical implementation remains limited. While reclaimed materials are often physically available, their integration into new projects is constrained by insufficient or unreliable data (Wijewickrama et al., 2021). In many reuse scenarios, design decisions are hindered not by material scarcity but by uncertainty regarding material identity, condition, and provenance.

Across multiple reuse projects, data continuity was repeatedly observed to break as building elements move through typical reuse stages, including deconstruction, transport, planning and material storage, and construction. These process stages are illustrated in Figure 1 through the example of the Huber Pavilions, former student workshop pavilions at ETH Zurich, which were disassembled in 2022 and served as a source project for several recipient projects on and off the university campus (Knecht, 2022; De Wolf, 2025).

Each construction project establishes its own physical and digital infrastructures, including modeling environments, documentation practices, physical identification and labeling methods on building elements (Byers et al., 2024c). These infrastructures are typically optimized for a single project and its immediate life cycle (Whyte and Hartmann, 2017; Papadonikolaki et al., 2020). When elements are transferred between projects, their associated physical and digital systems are rarely maintained or preserved. Each of these infrastructural components, shown in Figure 2, namely the physical storage, physical element, physical data carrier, user interface, ID, digital model, and digital storage, exist at each process step depicted in Figure 1 but may change or be lost between these steps and along the reuse process.

Based on these recurring observations, this study argues that material data discontinuities in reuse projects emerge in part because information is handled through two established yet poorly connected data pipelines: supply chain logistics and design. Logistics-oriented approaches in practice commonly focus on tracking, aggregation, and inventory management and rely on standardized identification and data exchange systems, such as GS1, which define globally unique identifiers, hierarchical packaging structures, and event-based tracking across supply chains (GS1, 2025). In research, emerging track-and-trace frameworks extend these logistical principles to construction materials, and even reuse (Byers et al., 2024a). Design-oriented workflows generally rely on digital representations as the primary means of organizing and managing project information. In contemporary construction practice, this role is most commonly fulfilled by Building Information Modeling (BIM) environments, which use internally defined element identifiers, object hierarchies, and project-specific data structures to support design, coordination, and fabrication (ISO, 2018).

As illustrated in Figure 2, both logistics- and design-oriented pipelines address identification and representation, but operate according to different data structures: logistics emphasize persistent identifiers across inventories and transactions, while design environments prioritize context-dependent model elements and project-bound semantics. When these two structures are not aligned, material identities are frequently reduced, duplicated, or detached from physical elements altogether.

Despite growing interest in digital integration and reuse, there remains limited empirical documentation of how and where these logistic and design data pipelines break down in practice as materials move between projects. Therefore, this study investigates where and why material data continuity breaks down between logistics and design in reuse-oriented construction life cycles.

Research design

Through direct involvement in multiple reuse projects, recurring overlap and misalignment between logistic and design-related data flows were observed, particularly for identification and digital representations of elements. Based on these observations, a combined analytical framework was formulated that integrates logistics and design perspectives across digital infrastructures corresponding to physical components, namely data carriers, user interfaces, IDs, digital models, and digital storage (Figure 2). Upon establishing this framework, potential breakpoints in persistence of data across reuse cycles were identified.

In line with the framework, a set of past reuse projects were analyzed to determine where and why these breakpoints occur. The analysis focused on how material data is structured, transferred, and transformed, with emphasis on its implications for material tracking and tracing. The analysis follows a comparative multiple-case study design (Yin, 2018) to identify recurring patterns and systemic gaps and to synthesize identified breakpoints in current digital infrastructures.

Data collection combines document analysis, including digital models, databases, and material documentation, with process reconstruction of data handovers between life cycle stages. Where available, expert insights are used to contextualize observed data practices.

The goal is to improve understanding of how existing digital systems support, constrain, or disrupt persistence of data in reuse-oriented construction processes.

Proposed framework for data continuity

The integration of infrastructures present in both logistics and design results in the combined infrastructure shown in Figure 2. Rather than treating logistics and design as separate data domains, material identity should be established, accessed, and maintained across both perspectives. The **physical element** is commonly considered only on the logistical side, being transported and stored in a **physical storage** or installed within a building, whilst in design it is abstracted as a geometric and semantic entity and exists only in the form of the digital model. The framework requires the physical element to remain linked to all digital representations, which is facilitated through a physical data carrier, the user interface, and an identifier (ID). **Physical data carriers** (e.g. direct product marking (DPM), Quick Response (QR) codes, barcodes, and near-field communication (NFC)) provide the primary interface between the physical element and digital systems. By scanning the physical data carriers, **user interfaces** mediate access to element data in logistics. In design, the user interface functions as an access point to the digital model. While these two forms of user interfaces are often implemented separately, the framework highlights their shared function: resolving an identifier into actionable information. The **ID** acts as the key link across all layers. In logistical systems, IDs are often assigned based on type or batch, whilst in design systems, IDs are typically instance-based and embedded in digital models. The framework positions the ID as a shared anchor that must persist across systems and representations to enable continuity, rather than being redefined at each stage. **Digital models** primarily emerge from the design perspective, where elements are represented geometrically and semantically. In the combined framework, the digital model is linked via the shared IDs, which allows material data originating in logistics to be associated with specific modeled elements. The digital infrastructures require **digital storage**. While these are often separated in practice, the framework considers linked or interoperable storage structures to prevent duplication and manual synchronization. Digital storage is thus understood as a shared backend that supports both inventory tracking and design integration. In line with the functionality of the identifiers, this considers both the storage of the digital model and the IDs and how these correspond.

Identified breakpoints

By aligning the combined stack in a single framework, overlaps, gaps and misalignment become apparent. Beyond illustrating the system as a whole, six breakpoints (A–F) were identified and are shown in Figure 2.

Breakpoint A addresses the interface between the physical construction element and the physical data carrier, which is commonly attached, engraved, or imprinted. Since construction and reuse processes typically involve transformations of the element, such as cutting it to the dimensions required for a subsequent project, the connection between the data carrier and the physical element may be disrupted. This can lead to loss of access to the element's identity and the associated stored data.

Breakpoint B highlights discrepancies that arise when

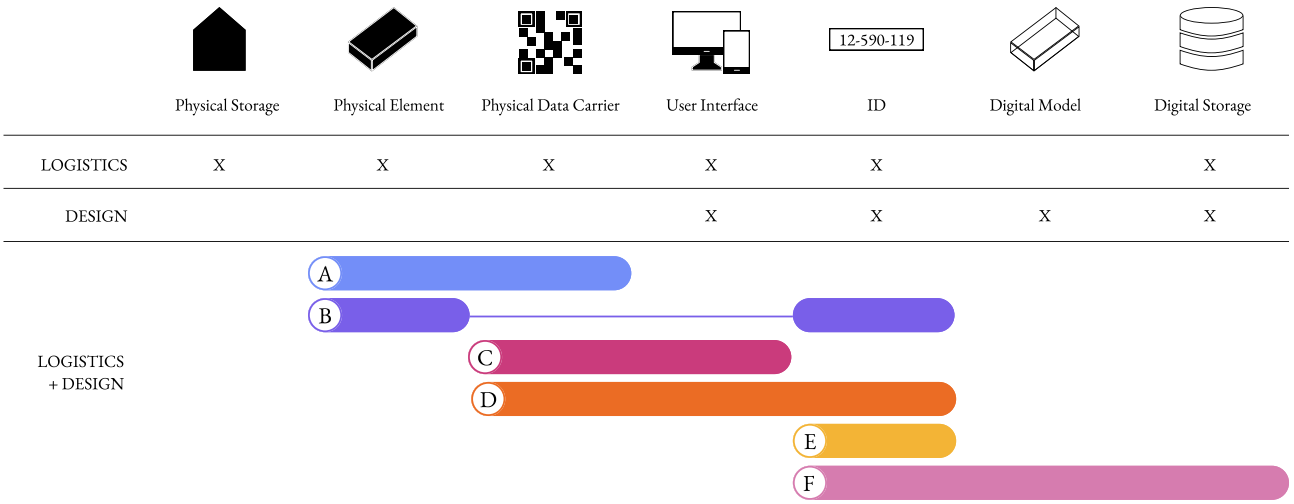

Figure 2: Infrastructure integrating logistics and design and tabular presence of digital infrastructures for identification and representation of construction elements separated between logistics and design. Breakpoints in the separated data pipeline are highlighted and in order: Physical–Digital Interface Loss (A), ID Granularity Mismatch (B), Data Carrier Degradation (C), Static Carrier Limitation (D), Cross-System ID Inconsistency (E), Unlinked Data Repositories (F)(Bottom)

groups of elements are recorded not by instance-specific IDs but by generalized identifiers, such as type-based classifications.

Breakpoint C refers to the physical data carrier and its accessibility via the user interface. In particular, the readability of the data carrier is influenced by its durability, which directly affects long-term data access.

Breakpoint D points to the link between the physical data carrier, the user interface, and the ID. It specifically addresses whether the data carrier is static or dynamic, and thus its capacity for adaptability over time.

Breakpoint E emphasizes inconsistencies in the definition and use of IDs across logistics and design systems, where the ID assigned to a physical element in logistics may not correspond to the ID used in the digital design model.

Breakpoint F addresses data storage, particularly the separation of ID storage and model storage. When these are not linked, duplicate information arises, requiring manual updates on both sides whenever modifications occur.

Breakpoints across case studies

Based on the identified breakpoints, eight case studies conducted at the Chair of Circular Engineering for Architecture at ETH Zurich between 2020 and 2025 were analyzed. Figure 3 synthesizes these case studies by illustrating the flow of digital infrastructures across reuse processes. Source projects are labeled with Roman numerals and recipient projects with Arabic numerals, with the project legend shown in the top-right corner. Instances of identified breakpoints are annotated by breakpoint class (A–F) and project number (1–8). Where multiple materials were used within a single project (e.g., case study 8), an additional index is appended. Figure 3 also includes keywords indicating the specific infrastructural components involved (e.g., QR codes or DPM for physical data carriers and Rhino for digital models). Detailed descriptions are provided in the following text, which should be read together with the figure for full interpretation. Breakpoint instances are bolded in the text to facilitate efficient cross-referencing between the descriptive analysis and the synthesized overview in Figure 3.

Timber from an automobile warehouse in Geneva, Switzerland (I), was used for the construction of Dome 1 (1), a geodesic dome that was later disassembled and reconstructed as Dome 1.2 (2) and Dome 1.3. For the construction of Dome 1, QR codes were engraved on the timber elements (Byers et al., 2022; Byers and De Wolf, 2023), and assembly logic was recorded directly on the elements using DPM. During the reconstruction of Dome 1 as Dome 1.2, the DPM information was no longer present (**A.2**), while the engraved QR codes remained readable. During reconstruction, elements were temporarily misplaced due to out-of-sequence staging and inaccessible labels. These elements were subsequently identified using the remaining QR codes (Byers and De Wolf, 2023). In case studies 1 and 2, all elements originated from the same source and were reconstructed using identical procedures. Within this context, no functional difference was observed between instance-specific IDs and categorical IDs (**E.2**). QR code content was limited to material properties and nomenclature, while higher-level project information such as assembly and disassembly instructions was not accessible through the system (**F.2**). Following the construction of Dome 1.2, the online material passport was no longer actively maintained (**D.2**).

Dome 2 (3) was built with a similar design as Dome 1, and Dome 1.2, with timber reclaimed from the deconstruction of a music pavilion in Oetwil am See, Switzerland (II). In Dome 2, the technical database did not include mechanisms for privacy or controlled accessibility, allowing unrestricted editing and deletion of material data (**D.3**) (Byers and De Wolf, 2023).

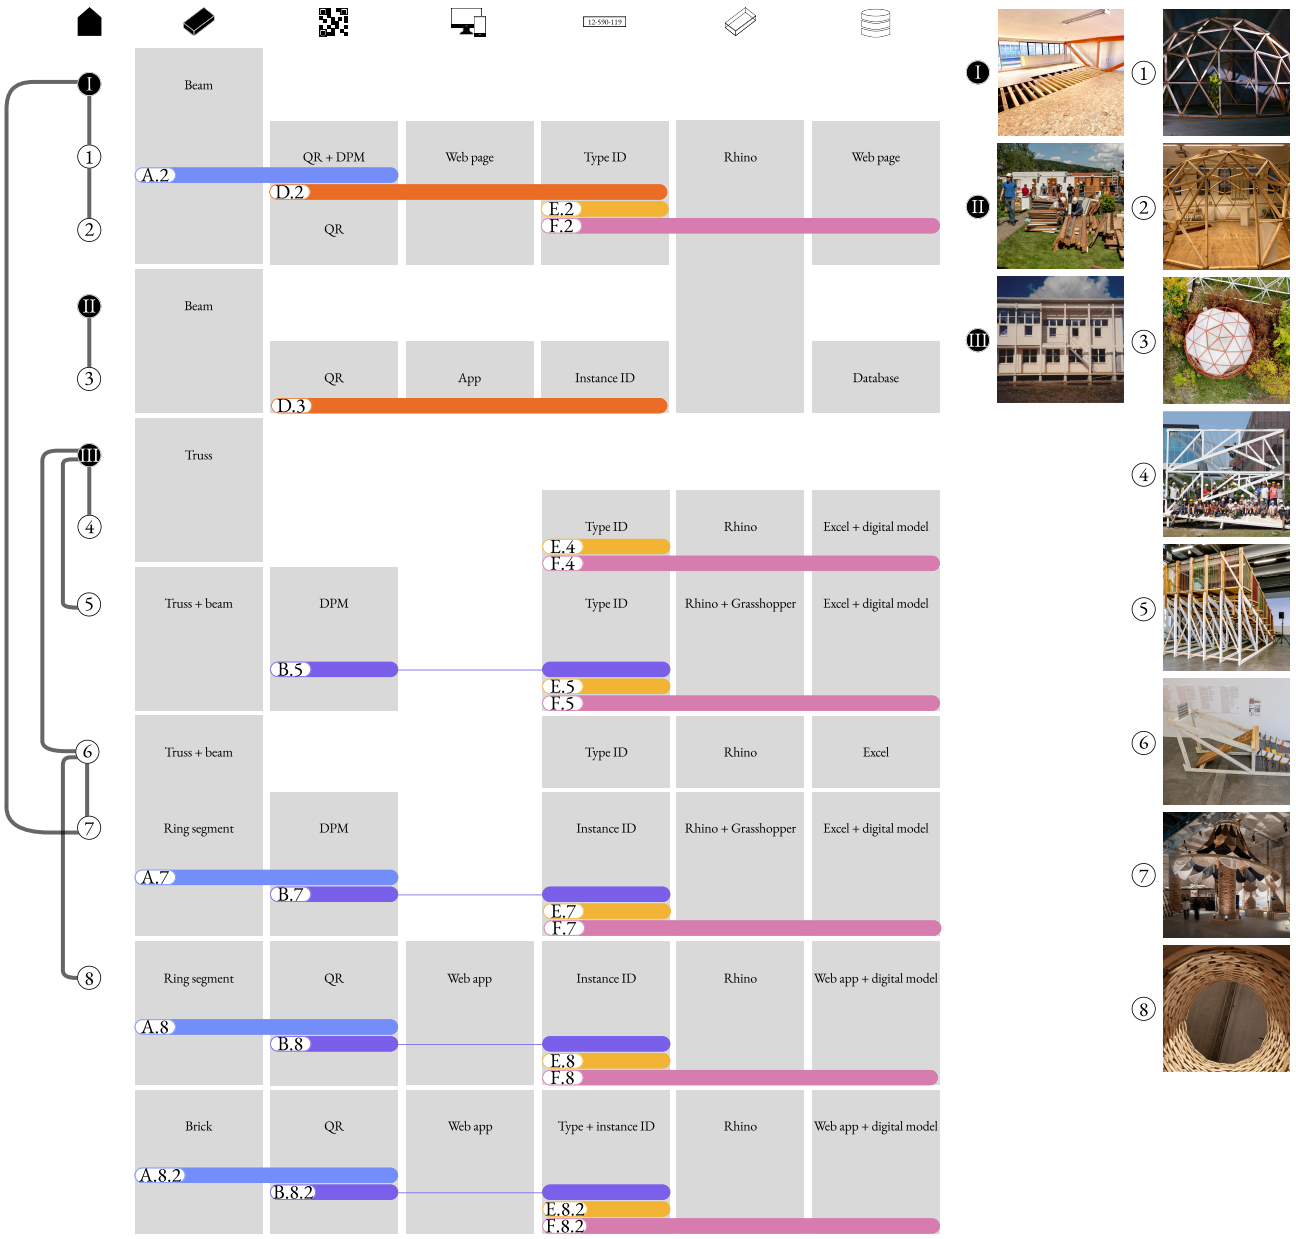

Figure 3: Flow of digital infrastructures across reuse case studies. Breakpoint instances are annotated by class (A–F) and project number (1–8), with additional indices indicating multiple material instances per project. Source projects are labeled with Roman numerals and recipient projects with Arabic numerals (see project legend on the right) in order: automobile warehouse in Geneva, Switzerland (I); music pavilion in Oetwil am See, Switzerland (II); Huber Pavilions (III); Dome 1 (1); Dome 1.2 (2); Dome 2 (3); CircÛbi (4); Mehrwerk (5); playground structures (6); VAMO (7); Insieme (8). Photo and model credit is provided in the Acknowledgments section.

Subsequently, the Huber Pavilions (III) were deconstructed, providing material for further projects, including CircÛbi (4), Mehrwerk (5), and a set of playground structures (6). In case study 4, IDs were not documented for the wooden trusses used, resulting in missing element identification for subsequent reuse (**E.4**). In addition, discrepancies between Excel-based documentation and the digital model resulted in unlinked ID storage locations (**F.4**).

Case study 5 showed the same patterns of missing or inconsistent element IDs (**E.5**) and unlinked data storage between documentation and digital models (**F.5**). Beam IDs were documented only by type, quantity, and dimensions without instance-specific identifiers (**B.5**). Only type-based DPMs were present on the physical elements, while beam condition varied.

Following the deconstruction of the playground structures (6), part of the reclaimed material was reused in two additional projects: VAMO (7) and Insieme (8). Insieme also included reclaimed bricks from several sources. Case study 7 sourced material from both source project I and case study 5. Wooden beams from case study 6 were transformed into cold-bent laminated ring segments. The original DPM markings were not transferred or documented for the new elements, resulting in the loss of the phys-

ical element–data carrier connection (**A.7**). Floorboards sourced from project I were used in a similar transformation process but did not carry documentation of their prior life cycle. Because they had no DPM, they are disregarded here. In this context, beam IDs were documented only by type, quantity, and dimensions and not by instance (**B.7**). Instance-specific IDs were also not assigned during recycling (**E.7**), and beams were treated as generically available material, while projects 7 and 8 ran in parallel using the same inventory. Beam IDs were documented in an Excel file by type but were neither referenced in the digital model nor assigned to model elements intended for the ring segments (**F.7**).

In case study 8, similar transformation-related losses occurred: beams were cut and cold-bent laminated without transferring or documenting DPM information for the new elements and their QR codes (**A.8**). Prior to this project, beam IDs had been documented only by type, quantity, and dimensions (**B.8**). Instance-specific IDs were again disregarded during recycling (**E.8**). A resulting cold-bent lintel was assigned an instance ID stored as a JSON file in a web application; this ID was not linked to the corresponding element in the digital model (**F.8**). Case study 8 also incorporated reclaimed bricks from multiple sources. The data and identification infrastructure for the bricks followed the same structure as that for the wooden elements, corresponding to observations (**A.8.2**), (**B.8.2**), (**E.8.2**), and (**F.8.2**). In contrast to the timber elements, some bricks were assigned instance-specific IDs due to documented damage and repair histories.

Results

Physical–digital interface loss (Breakpoint A)

Repeated loss of physical data carriers (**A.2, A.7, A.8, A.8.2**), namely DPM, during disassembly and element transformation indicates that data carrier strategies tied to original geometries are vulnerable in fabrication-intensive reuse workflows. To maintain the connection between physical elements and their data, and thus their identity, data carriers must persist through material transformation. Other approaches may be to use different data carriers during certain process stages to ensure the presence of data carriers (Dervishaj et al., 2023) or to enforce protocols for reattaching data carriers and recording provenance and transformation events in respective models (Guillem et al., 2025). Such protocols should include unique element identifiers, timestamps and actors involved in transformation, descriptions of geometric and material changes, and links to updated digital representations (e.g., BIM elements or graph nodes), enabling traceability across transformations within a shared data infrastructure.

ID granularity mismatch (Breakpoint B)

The reliance on type-based IDs (**B.5, B.7, B.8, B.8.2**) obscures instance-specific differences between elements, which become relevant when material condition or history varies within the same type. As each project is different and neither the future use of materials nor the respective requirements of data granularity can be predicted, one approach might be to use a multi-level ID schema. This would mean defining both a type ID and an instance ID with structured metadata, enabling differentiation by condition and role through semantic data models and otologies (Kebede, 2024; Forth et al., 2025). The brick reuse in case study 8 demonstrates that combining type-based and instance-specific IDs can mitigate several of the challenges observed in breakpoints **B**, **E**, and **F**, when element-specific histories are relevant. Nevertheless, the added value of maintaining instance-specific identifiers depends on their relevance for the recipient project: while tracking large numbers of interchangeable elements of the same type (e.g., bricks) may provide limited benefit, instance-level identification becomes essential when element-specific properties or regulatory requirements, such as fire safety labels on doors, must be individually verified. Complementary work builds on these observations by proposing instance-level tracing methods that address limitations of type-based identification in reuse scenarios (Vangelova et al., 2026). In practice, such multi-level ID systems could be implemented using graph-based data structures, where type nodes define shared properties and instance nodes capture condition, provenance, and transformation history, enabling flexible queries depending on project requirements.

Data carrier degradation (Breakpoint C)

Breakpoint C was not directly represented and observed in the analyzed used cases. Beyond the analyzed cases, Byers and De Wolf (2023) highlight that insufficient durability and readability of physical data carriers can undermine long-term data accessibility. Future implementations may therefore require redundancy strategies, to ensure continued accessibility even if individual carriers degrade.

Static carrier limitation (Breakpoint D)

The absence of long-term maintenance and access-control mechanisms highlights governance-related challenges for material passport systems when reuse cycles extend beyond a single project (**D.2, D.3**). Versioned records and stable persistent links (e.g., URLs encoded in carriers) that update as element information evolves, supported by access control in the backend, may respond to this challenge (Hunhevicz, 2023; Byers and De Wolf, 2023; Byers et al., 2024b). Such mechanisms align with emerging data space approaches, where persistent identifiers are resolved through federated services and access rights are managed across stakeholders, ensuring that data remains accessible and trustworthy beyond individual project life cycles.

Cross-system ID inconsistency (Breakpoint E)

While instance-specific IDs did not provide measurable benefits in homogeneous reuse scenarios (case studies 1 and 2), later case studies suggest their relevance increases in multi-source and parallel reuse contexts (**E.4, E.5, E.7, E.8, E.8.2**). Unifying the ID logic across logistics and

design databases encourages the use of BIM as a shared digital representation to link external identifiers to model data. Digital product passport research also emphasizes interoperable identification across supply chain and design systems (Zhang and Seuring, 2024; Vangelova et al., 2025) and the need for consistent identifiers in BIM exchange. This could be supported through semantic or knowledge graph models, where persistent identifiers act as nodes linking BIM elements, logistics records, and external data sources, enabling consistent referencing across systems and lifecycle stages.

Unlinked data repositories (Breakpoint F)

The recurring separation between ID storage (e.g., Excel, Rhino model, web apps) and digital design models (e.g., BIM and Rhino) reveals a structural limitation in current infrastructures, where material allocation and tracking remain manual (**F.4, F.5, F.7, F.8, F.8.2**). Integration of ID storage and digital model syncing could employ cloud-based data spaces that reduce redundancy and support linked data for the design phase (Bucher, 2019; van Zandwijk et al., 2025a). Beyond technical fragmentation, the separation of ID storage and model storage also exposes limitations in data longevity and governance, as material information must persist beyond individual software tools and project-specific repositories, which may motivate future exploration of distributed and decentralized data infrastructures (Bucher et al., 2025). Building on distributed data storage, data spaces could automate currently manual synchronization processes by enabling real-time data exchange between stakeholders, reducing coordination effort and improving data consistency across tools (van Zandwijk et al., 2025b; Hagedorn et al., 2025).

Discussion

This study proposes that integrating logistical and design data pipelines has the potential to improve data continuity across stakeholders in reuse-oriented construction. The contribution is threefold. First, a framework is defined that integrates logistics and design perspectives within a shared data infrastructure. Second, breakpoints within this framework, namely where data continuity is disrupted, are identified and defined. Third, instances of these breakpoints are examined and analyzed across multiple case studies. Based on these findings, recommendations for addressing material data–related challenges in reuse projects are derived.

The results show that material identities are frequently detached from physical elements during transformation, reduced to type-based classifications, or stored in isolated systems that are not linked to design models. As a result, logistical inventories and design representations diverge, forcing manual coordination and limiting digitally integrated workflows. Data resolution typically drops after initial construction or first reuse cycles, when material passports and identifiers are no longer maintained or integrated into subsequent planning phases, which aligns with findings by Whyte and Hartmann (2017) and Papadonikolaki et al. (2020). This also indicates that one primary barrier to linking logistics and design lies in the absence of consistent cross-system IDs. Without robust interfaces between physical elements and digital identities across life cycle phases, material data cannot reliably support reuse-oriented design decisions. The results of this study help address these structural discontinuities by making data breakpoints between logistics and design explicit, thereby providing a basis for developing continuity-oriented infrastructures that enable traceable and effective material reuse in circular construction.

Research on digital product passports and material passports in both product and construction sustainability states persistent, unique identifiers as a prerequisite for lifecycle traceability across design, use, deconstruction, and reuse (Byers et al., 2024c, 2025). To extend traceability beyond static documentation, semantic and ontology-based data structures are increasingly proposed to represent enriched metadata, provenance, and relationships resulting from material transformation (Vangelova et al., 2026). At the same time, interoperability research in BIM emphasizes aligning identifier-based data structures with cross-system standards to enable consistent integration across logistics databases, digital design models, and fabrication workflows (Forth et al., 2025). Despite these advances, material identity is still frequently detached from physical elements, reassigned new identifiers, or reduced to coarse classifications, disregarding materiality and product decomposition completely. This raises the question of whether increased data granularity and detailed representation in design and construction actually improve data continuity into subsequent reuse phases. In this context, emerging construction data space initiatives and decentralized data infrastructures provide a promising direction, addressing persistent identification, provenance tracking, and cross-organizational data exchange at scale, complementing the breakpoints presented in this study.

Limitations and outlook

This study is based on a limited number of case studies, most of which were analyzed retrospectively and conducted at the same institution, the Chair of Circular Engineering for Architecture at ETH Zurich. All case studies are short-term, student-led, pavilion-scale projects, intentionally designed as exploratory testbeds to assess data carrier feasibility, with limited incentives for maintaining track-and-trace beyond the course duration. While this allows for in-depth analysis of reuse processes, it limits the generalizability of the findings. In addition, data collection relied partly on informal expert insights in cases where partial data was unavailable. Although these insights provide critical contextual understanding, they introduce a degree of subjectivity that cannot be fully eliminated.

The study does not propose or validate a specific technical implementation, data standard, or software system. Instead, it adopts an analytical and diagnostic perspective to

identify recurring infrastructural challenges across reuse scenarios. As such, the findings do not constitute a prescriptive solution but rather highlight structural conditions that future systems must address. Validation of the identified breakpoints will require applied system development and longitudinal testing in further reuse projects. To support analytical rigor despite these limitations, all case studies were examined using the same framework and evaluated against the same set of breakpoints (A–F). Multiple case studies allowed isolated incidents to be distinguished from recurring patterns, strengthening internal validity. While the results remain context-dependent, the systematic application of the framework and transparent mapping of observations to breakpoints provides a robust basis for further empirical and technical investigation. Future research should focus on translating the identified breakpoints into implementable system architectures, for example by combining persistent identifier systems, semantic graph models, and construction data spaces to enable FAIR (Findable, Accessible, Interoperable, Reusable) (Wilkinson et al., 2016) material data across reuse cycles. In addition, questions of long-term governance and incentive alignment remain critical: responsibilities for maintaining data quality, storage, and access must be shared across stakeholders, potentially supported by decentralized governance infrastructures (Hunhevicz et al., 2024) that reduce individual burden while preserving collective value.

Acknowledgments

SCENARIO-BASED MATERIAL-FLOW AND CIRCULARITY ASSESSMENT OF DEEP RENOVATION PROJECTS

Mohamed T. Elnabwy[1], Omar Doukari[1], and Pablo Martinez[1]
[1]School of Architecture and Built Environment, Faculty of Science and Environment, Northumbria University, Newcastle upon Tyne, NE1 8ST, United Kingdom

Abstract

Waste generation in deep renovation is driven by onsite activities and their temporal sequencing and scheduling, yet most existing circularity assessment approaches remain scenario and execution agnostic. This paper proposes a schedule-aware BIM-based approach that integrates activity-zone modelling with precedence-constrained scheduling to enable time-based estimation of material flows and waste generation. Implemented through the Circular Intelligent-based Waste Engine (CIWE), the approach supports activity-level waste estimation and onsite circularity assessment. A multi-residential renovation case in Lille, France is used to compare three renovation scenarios. Results show that renovation sequencing significantly influences waste intensity, recovery potential and circularity outcomes.

Introduction

The construction sector is a major contributor to global resource consumption and waste generation, making it a central target for circular economy transitions (dos Santos Gonçalves et al., 2025). In Europe, deep renovation of existing buildings is increasingly promoted to reduce operational energy demand while limiting embodied environmental impacts associated with new construction (Hertwich et al., 2019). However, deep renovation causes substantial material inflows and demolition waste that must be effectively managed to support circular economy goals such as waste reduction, reuse, and recycling (Hossain et al., 2017).

Building Information Modelling (BIM) has significantly advanced construction and demolition waste estimation by enabling element and activity-level quantification and supporting evaluation of renovation and deconstruction strategies (Cheng and Ma, 2013). Recent studies have extended BIM-based approaches toward circularity principles by incorporating material recyclability, reuse potential and whole-life performance indicators (Akanbi et al., 2018). Nevertheless, the literature shows that most BIM-based circularity assessments remain largely static, relying on aggregated material quantities and overlooking the temporal and operational dynamics of renovation execution (Zhao et al., 2025).

Renovation sequencing, spatial dependencies and access constraints influence waste intensity, recovery feasibility and onsite logistics, particularly in multi-storey residential renovation context (Mrema et al., 2023). However, many existing BIM-based frameworks treat renovation activities as temporally independent, failing to integrate scheduling logic with material-flow and circularity assessment (Ashrafi et al., 2025). As summarized in Table 1, prior approaches generally lack zone-based modelling, precedence-constrained scheduling and time-resolved waste profiling. To address these gaps, this paper proposes a scenario-based, schedule-aware BIM-enabled framework integrating activity-zone modelling with precedence-constrained scheduling, implemented through CIWE, and demonstrated on a deep renovation case study in Lille, France.

Material and Methods

Framework overview

The proposed framework enables schedule-aware circularity assessment by structuring renovation projects around activity-zone execution logic and precedence-constrained scheduling. By integrating BIM-derived quantities with execution sequencing, it supports time-resolved quantification of material inflows, waste outflows and circularity indicators, which captures the influence of renovation sequencing on waste generation and recovery outcomes. The methodological workflow consists of five sequential stages:

1. Definition of renovation activities and scenarios
2. BIM-based activity-zone mapping
3. Precedence-constrained renovation scheduling

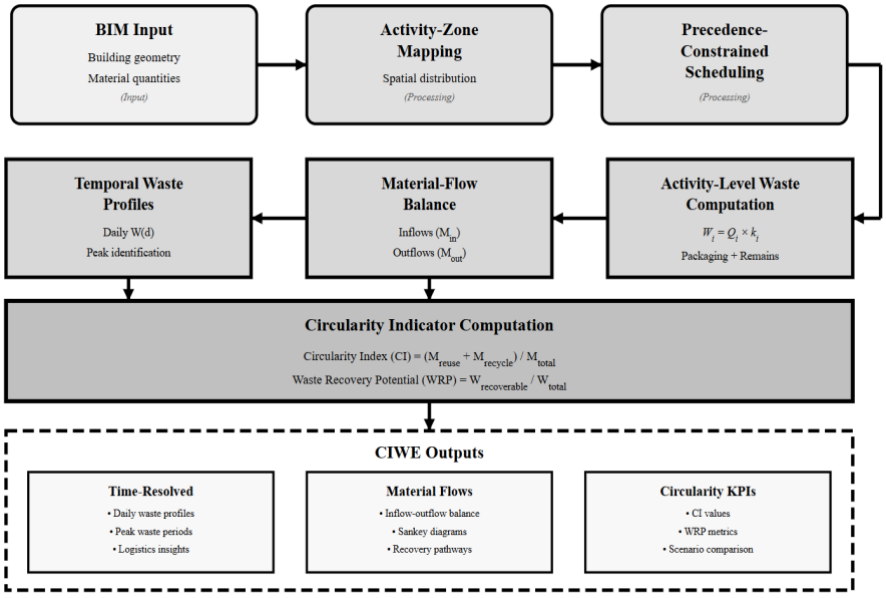

Figure 1: Overview of the CIWE framework for schedule-aware material-flow and circularity assessment

4. Activity-level waste and material-flow estimation
5. Computation of circularity indicators

Figure 1 illustrates the overall workflow and highlights the interaction between BIM data, activity sequencing, and temporal material-flow modelling implemented through CIWE. The CIWE, developed in this study, is implemented as a plug-in tool within Autodesk Revit, enabling automated extraction and activity-level quantification of material flows and waste generation during renovation projectsParts of the paper.

Case study

The proposed framework is demonstrated using a multi-residential building undergoing deep renovation in Lille, France, representative of a typical European multi-storey residential typology targeted by current renovation and circular economy policies (Figure 2). The building includes five floors, envelope elements, circulation areas, and external zones, enabling analysis of both vertical and horizontal renovation sequencing. A BIM model was developed as the primary source of geometric, material, and zoning data, supporting activity-zone mapping and consistent definition of renovation activities within CIWE. The model enables extraction of activity-level quantities required for material-flow and waste estimation. Three renovation scenarios with increasing intervention depth are analysed. All scenarios share identical geometry and zoning to ensure comparability, with differences arising only from renovation scope and system upgrades. Scenarios vary in envelope insulation levels, window specifications, HVAC configurations, ventilation systems and renewable energy integration, including photovoltaic and solar-thermal installations (see Table 2). It should be noted that the three scenarios are defined as alternative renovation strategies rather than sequential extensions of one another. Differences in waste generation arise primarily from variations in activity composition and execution logic, particularly the balance between demolition-intensive and installation-based interventions.

Activity-zone execution model

Renovation works are structured using an activity-zone execution model that explicitly links each renovation activity to the building zones where it is performed. The defined activities include envelope insulation, window and door replacement, HVAC and ventilation installations, internal insulation measures, pipe insulation, and renewable energy systems. This structure enables consistent allocation of material inflows and waste outputs at activity level while preserving spatial differentiation across the building.

Figure 3: Activity-zone execution matrix defining the spatial distribution and repetition of renovation activities across building

Repetitive activities, such as internal insulation, HVAC installations and pipe insulation are replicated across the building floors, reflecting vertical execution patterns typical of multi-storey renovation projects. In contrast, envelope-related and renewable energy activities are assigned to specific zones, including roofs, external façades, and external areas, capturing horizontal differentiation in renovation execution. Figure 3 presents the activity-zone execution matrix, which links spatial activity allocation with BIM-derived quantities to support consistent material-flow and waste estimation.

Precedence-constrained renovation scheduling

Renovation execution is governed by a zone-level precedence logic that defines spatial and temporal dependencies between activities, reflecting access, safety, and coordination constraints typical of multi-storey deep renovation projects. This ensures feasible sequencing while maintaining operational continuity.

Three categories of precedence constraints are applied. Vertical precedence enforces a top-down execution order for internal works, requiring upper-floor activities to be completed before lower-floor interventions. Horizontal precedence coordinates envelope and internal activities, ensuring façade insulation and window replacement are completed before internal installations commence, while preserving functional access routes.

Controlled parallelisation allows selected activities to proceed concurrently across zones once prerequisite conditions are satisfied. All precedence relationships are formalised as a directed scheduling network integrated with BIM-derived activity-zone mappings and activity durations. This enables CIWE to generate feasible renovation schedules that underpin time-resolved allocation of material inflows, waste generation, and circularity assessment. Figure 4 illustrates the zone-level precedence network applied in this study.

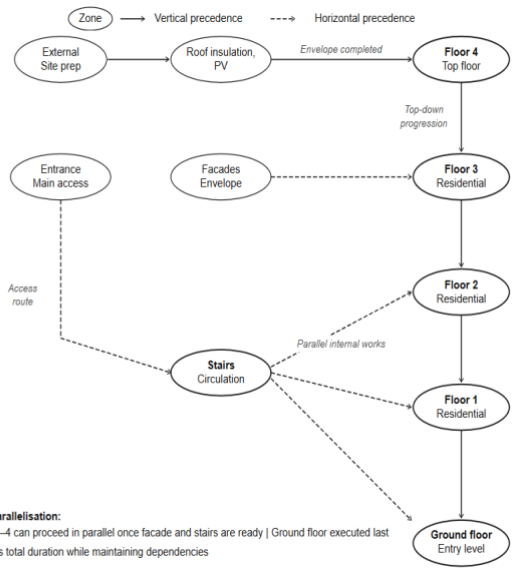

Figure 4: Zone-level precedence network governing spatial and temporal renovation sequencing in CIWE.

Activity-level waste and material-flow estimation

Waste generation is estimated at activity level using predefined waste and demolition coefficients applied to BIM-derived quantities. For each activity ($\boldsymbol{i}$), total waste generation is calculated as:

$$W_i = Q_i \cdot k_i \quad (1)$$

where (W_i) is the total waste generated by activity ($\boldsymbol{i}$), (Q_i) is the BIM-derived quantity of the activity ($\boldsymbol{i}$), and (k_i) is the corresponding waste coefficient of activity ($\boldsymbol{i}$).

The activity-level waste coefficients, packaging shares, reuse, recycling and recovery assumptions applied in this study are derived from literature (Llatas and Osmani, 2016; Quiñones et al., 2022) and expert-informed calibration (Table 3). To account for the temporal distribution of waste, activity-level waste is evenly allocated over the scheduled duration of each activity:

$$W_i(d) = \frac{W_i}{D_i} \text{for } d \in [S_i, E_i] \quad (2)$$

Where ($W_i(d)$) is the waste generated on day (d), (D_i) is the activity duration, and (S_i) and (E_i) are the scheduled start and end days respectively for activity **($\boldsymbol{i}$).**

Daily project-level waste generation is then computed as the sum of waste contributions from all active activities:

$$W(d) = \sum_{i=1}^{n} W_i(d) \quad (3)$$

Waste outputs are divided into packaging waste and remains waste. Packaging waste corresponds to installation and transport losses, while remains waste represents demolition debris and residual materials.

For each activity ($\boldsymbol{i}$), packaging and remains waste are calculated respectively as follows:

$$W_{i,pack} = W_i * p_i \quad (4)$$

$$W_{i,rem} = W_i * (1 - p_i) \quad (5)$$

where (p_i) is the packaging share in Table 3. In parallel, material inflows associated with new installations are quantified, allowing the construction of material inflow-outflow balances:

$$M_{\text{net}} = \sum M_{\text{in}} - \sum M_{\text{out}} \quad (6)$$

Where (M_{in}) represents materials introduced through new installations and (M_{out}) represents materials removed as waste.

Circularity indicator computation

Circularity performance is evaluated using two indicators derived from CIWE outputs. The Circularity Index (CI) quantifies the share of material flows directed towards reuse and recycling pathways relative to total material throughput:

$$CI = \frac{\text{Recovered Material}}{\text{M}_{throughput}} = \frac{\sum_{i=1}^{n} \text{W}_i\left(r_i^{reuse} + r_i^{recycle}\right)}{\sum_{i=1}^{n} M_i^{in} + \sum_{i=1}^{n} \text{W}_i} \quad (7)$$

where $W_i$is the waste generated by activity i, $M_i^{in}$is the material inflow associated with activity i, $r_i^{reuse}$and $r_i^{recycle}$are the reuse and recycling coefficients assigned to activity i, respectively, and $M_{throughput}$represents the total material throughput of the renovation system, defined as the sum of all material inflows and waste outflows across renovation activities.The Waste Recovery Potential (WRP) represents the proportion of total generated waste that can be directed to recovery pathways. In this study, material-specific recovery routes refer to the predefined post-generation pathways assigned to each activity-related waste stream, namely reuse, recycling, and landfill disposal, based on the recovery assumptions reported in Table 3. Accordingly, WRP captures the share of generated waste that is recoverable through reuse and recycling pathways:

$$WRP = \frac{\sum_{i=1}^{n} \text{W}_i \times r_i^{recover}}{\sum_{i=1}^{n} \text{W}_i} \quad (8)$$

Where, $r_i^{recover} = r_i^{reuse} + r_i^{recycle}$represents the total recoverable fraction of waste for activity i. Both indicators are computed at scenario level by aggregating activity-level results using the recovery coefficients reported in Table 3.

Table 3: Activity-level waste coefficients, waste fractions, and recovery assumptions

Activity Category	Activity	Unit	Waste Coefficient (k)	Packaging Share (%)	Reuse Potential (r_i^{reuse}) (%)	Recycling Potential (r_i^{recycle}) (%)	Total Recovery Potential (r_i^{recover}) (%)
Envelope	Roof insulation replacement	dm³/m²	23	35	20	50	70
	Façade insulation + render	dm³/m²	28	25	15	50	65
	Window replacement	dm³/unit	30	40	30	45	75
Internal works	Internal insulation	dm³/m²	18	30	20	48	68
	Pipe insulation	dm³/m	8	45	25	55	80
	LED lighting replacement	dm³/unit	5	65	20	65	85
Building services	HVAC system installation	dm³/unit	30	70	18	60	78
	MVHR unit installation	dm³/unit	25	75	17	65	82
	Ventilation ductwork	dm³/m	12	55	20	55	75
Renewable energy	Roof PV panels	dm³/kW	15	80	15	70	85
	Solar thermal collectors	dm³/m²	10	75	15	65	80
	Storage tanks	dm³/unit	20	60	25	50	75

$W_i$represents the total waste generated from activity i, and the recovery coefficients $r_i^{reuse}$and $r_i^{recycle}$are applied to the total waste, not limited to the packaging fraction. Adapted from Llatas and Osmani (2016); Quiñones et al. (2022), with expert-informed calibration.

Recovery coefficients are applied to the total waste generated from each activity, not limited to the packaging fraction, and are defined at the aggregated activity level to ensure modelling consistency.

Results and Discussion

This section presents a schedule-aware assessment of renovation waste on the Lille case study. It examines how material inflows, waste generation, spatial execution, and temporal sequencing interact across the three renovation scenarios. Waste is analysed as a time-dependent and activity-driven process rather than a static cumulative outcome, to enable explicit evaluation of waste intensity, recovery potential, and circularity trade-offs.

Scenario-level material inflows and waste generation

Table 4 summarises scenario-level material inflows and waste outputs for the Lille renovation case study. As renovation depth increases, total new materials installed rise from 18,500 kg in Scenario 1 to 24,100 kg in Scenario 3, primarily due to the introduction of renewable energy systems and expanded building services. In contrast, material inflows associated with insulation and window replacement remain relatively stable across scenarios, indicating that envelope upgrades constitute a baseline intervention independent of renovation depth.

Table 4: Scenario-level material inflows and waste outputs for the Lille renovation case.

Indicator	Unit	Sc. 1	Sc. 2	Sc. 3
Material Inflows				
Total new materials installed	kg	18,500	21,200	24,100
Insulation materials (EPS)	kg	4,200	4,200	4,850
Windows and doors	kg	3,100	3,600	3,600
HVAC systems	kg	2,800	3,400	3,400
Renewable energy systems	kg	--	1,850	3,200
Other building services	kg	8,400	8,150	9,050
Material Outflows (Waste)				
Total waste generated	dm^3	50,664	42,127	33,736
Packaging waste	dm^3	13,173	11,796	10,121
Remains waste	dm^3	37,491	30,331	23,615
Packaging fraction	%	26	28	30
Remains fraction	%	74	72	70

Across the scenarios, higher material inflows do not translate into higher waste quantities, indicating a clear decoupling between material throughput and waste generation. This outcome reflects differences in renovation activities rather than overall material volumes, as scenarios with greater emphasis on system installation generate proportionally less demolition-related waste. The results highlight that waste generation in deep renovation is primarily driven by activity composition and execution logic, rather than by the magnitude of material inflows alone. At the same time, waste composition shifts toward packaging-dominated streams as renovation depth increases. This qualitative change reflects the growing contribution of packaged building services and renewable energy systems and has direct implications for on-site handling and recovery strategies. These findings demonstrate that scenario-level waste performance cannot be evaluated solely through cumulative waste quantities, motivating analysis at activity, spatial and temporal levels.

While Table 4 provides a scenario-level summary of material inflows and total waste outputs, it does not explicitly reveal the origin of waste generation across renovation systems. To improve interpretability, Table 5 presents a disaggregated breakdown of waste by renovation system and activity for each scenario.

Table 5: Waste generation by renovation system and activity across scenarios (dm^3)

Renovation System	Activity	Sc. 1 (dm^3)	Sc. 2 (dm^3)	Sc. 3 (dm^3)
Envelope		**48396**	**18363**	**1883**
	Flat roof insulation	**21302**	**0**	**0**
	Façade insulation	**27094**	**0**	**1883**
	Windows & doors replacement	**0**	**18363**	**0**
Internal works		**0**	**3794**	**0**
	Internal insulation (all floors)	**0**	**3794**	**0**
Building services		**2268**	**19975**	**31448**
	Pipe insulation (all floors)	**0**	**19975**	**0**
	Wall-mounted HVAC / storage	**2268**	**0**	**0**
	Radiant floor installation	**0**	**0**	**24511**
	Mechanical ventilation	**0**	**0**	**2320**
	Mini split installation	**0**	**0**	**2368**
	Condensing boiler installation	**0**	**0**	**2249**
Renewable energy		**0**	**0**	**405**
	Photovoltaics (roof)	**0**	**0**	**405**
Total waste generated		**50664**	**42127**	**33736**

Table 5 clarifies the origin of waste generation across scenarios. Scenario 1 is dominated by envelope-related activities, particularly façade and roof insulation, which are associated with demolition-intensive processes and therefore generate high waste volumes. In Scenario 2, part of this contribution shifts toward windows and internal works, resulting in a more distributed waste profile.

In contrast, Scenario 3 shows a significant reduction in envelope-related waste and a shift toward building

services and renewable energy systems. These activities are primarily installation-based and generate lower waste per unit compared to demolition-driven processes. Additionally, the integrated execution of multiple systems within the same intervention cycle reduces redundant removal and rework operations. This explains why Scenario 3 generates lower total waste despite involving a broader scope of interventions.

Activity-level and zone-level waste generation

Figure 5 indicates that waste generation across all scenarios is dominated by envelope-related and building services activities, with broadly consistent contribution patterns as renovation depth increases. Envelope insulation and window replacement remain major contributors, although their relative importance decreases as renovation strategies shift toward more system-based interventions. Internal insulation and HVAC-related activities contribute a stable share of total waste across scenarios, reflecting the influence of spatial repetition across residential floors rather than renovation depth. In contrast, renewable energy systems introduce a distinct pattern, increasing the share of installation- and packaging-related waste as renovation depth increases.

From a spatial perspective, activities repeated across floors generate substantial cumulative waste, while envelope and roof-related works produce more localised concentrations. Overall, these results confirm that waste generation is driven primarily by activity composition and spatial execution logic rather than by renovation scope alone, underscoring the value of activity-zone modelling for effective waste management planning.

Temporal waste profiles and schedule-induced intensity effects

Figure 6 and Table 6 illustrate the temporal waste intensity patterns across the three renovation scenarios, revealing substantial differences driven by activity sequencing and scheduling logic rather than total waste quantities. Although cumulative waste generation decreases from Scenario 1 to Scenario 3, the timing and concentration of waste generation vary markedly across scenarios. Scenario 1 exhibits the highest waste intensity, with an average daily waste generation of 160 dm³/day and a peak of 377.7 dm³/day, resulting in a peak-to-average ratio of 2.36. These pronounced peaks coincide with extensive activity overlap, generating elevated operational pressure on on-site waste handling, storage capacity, and collection logistics. Scenario 2 presents a more balanced temporal profile. Reduced parallelisation and more sequential execution of major activities lower the average daily waste generation to 113 dm³/day and the peak-to-average ratio to 1.38. This smoother distribution indicates improved alignment between execution sequencing and on-site waste management capacity.

Table 6: Daily waste generation intensity indicators across renovation scenarios.

Indicator	Sc. 1	Sc. 2	Sc. 3
Project duration (working days)	321	376	317
Total waste generated (dm³)	50,664	42,127	33,736
Average daily waste (dm³/day)	160	113	108
Peak daily waste (dm³/day)	377.7	156	136.2
Peak-to-average ratio	2.36	1.38	1.26

Despite the highest material inflows, Scenario 3 achieves the lowest waste intensity, with an average daily waste generation of 108 dm³/day and a peak-to-average ratio of 1.26. This demonstrates that extended execution durations and controlled activity overlap can substantially mitigate waste intensity, even in deeper renovation scenarios. Overall, these results confirm that waste intensity is primarily a scheduling-driven phenomenon rather than a function of cumulative waste volume. Peak waste formation, driven by execution overlap, represents a critical determinant of operational feasibility and directly influences the effectiveness of on-site logistics, labour coordination and waste segregation strategies.

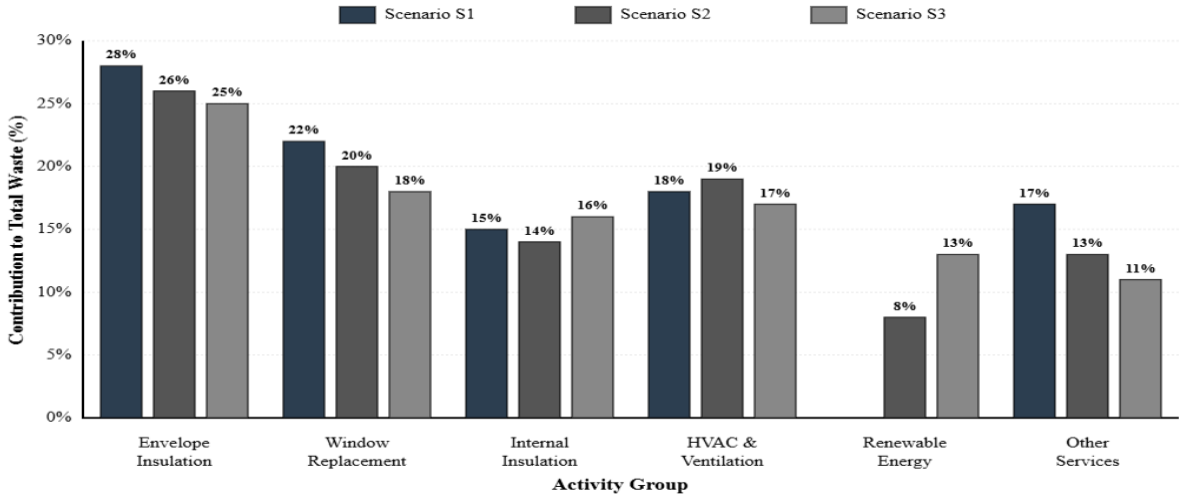

Figure 5: Waste contribution by activity group across the three renovation scenarios

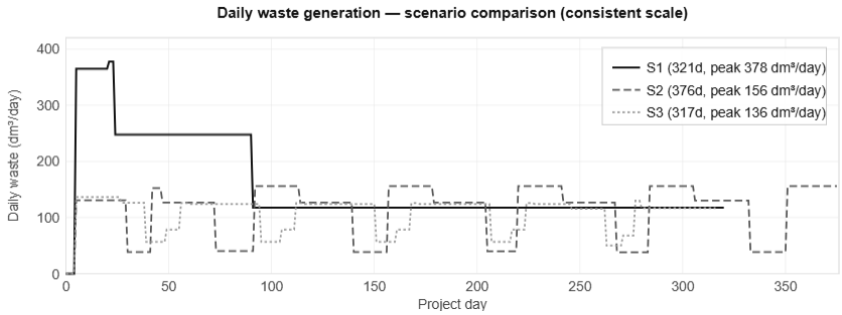

Figure 6: Daily waste generation profiles across the three renovation scenarios plotted on a consistent scale (0-400 dm³/day).

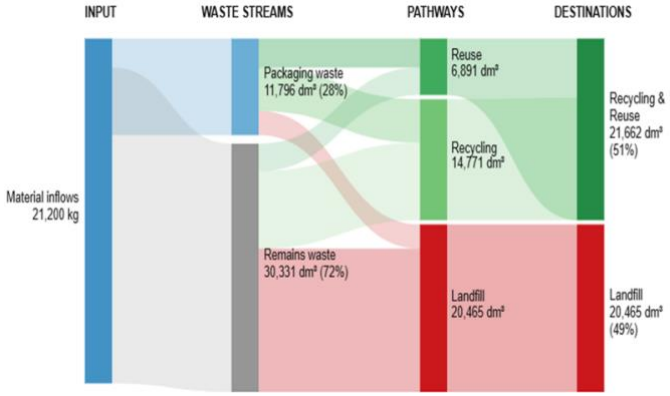

Figure 7: Material-flow pathways and recovery routes (Scenario 2)

Material-flow pathways and recovery routes

Figure 7 illustrates the material-flow pathways and reuse and recycling routes for Scenario 2 by linking material inflows, waste streams, and final destinations. From total material inflows of 21,200 kg, the renovation process generates 42,127 dm³ of waste, consisting of 11,796 dm³ of packaging waste (28%) and 30,331 dm³ of remains waste (72%). The Sankey diagram indicates that a substantial share of both waste streams is directed toward reuse and recycling pathways. In total, 29,910 dm³ (71%) of generated waste is directed toward recycling and reuse, while 12,217 dm³ (29%) is sent to landfill. Packaging waste exhibits high reuse and recycling potential due to its relatively homogeneous and uncontaminated nature, making it well suited to established reuse and recycling processes. In contrast, remains waste constitutes the primary contributor to landfill disposal, reflecting the presence of mixed, damaged, or contaminated materials generated during removal and demolition activities

It should be noted that recovery coefficients for remains waste are literature-derived estimates representing theoretical potential under optimized sorting conditions, and actual rates may be lower in practice due to material contamination and heterogeneity. Although remains waste dominates total volumes, its relatively lower recoverability drives landfill dependency, underscoring the need to distinguish waste streams at activity and scheduling levels. Scenario 2 illustrates how structured material flows aligned with reuse and recycling pathways can enhance overall recovery performance.

Circularity performance and scenario trade-offs

Circularity performance across the three renovation scenarios is evaluated using the Circularity Index and the Waste Recovery Potential, which together capture the balance between material recovery and overall waste generation. These indicators provide an integrated view linking material inflows, waste composition, and recovery outcomes. Circularity performance improves consistently with increasing renovation depth (Table 7).

Table 7: Scenario-level circularity indicators for the Lille renovation case.

Indicator	Sc. 1	Sc. 2	Sc. 3
Circularity Index (CI)	0.58	0.62	0.65
Waste Recovery Potential (WRP)	0.67	0.71	0.74
Total material throughput (kg)	28,400	31,800	35,200
Recoverable waste fraction (%)	67	71	74
Landfill fraction (%)	33	29	26

CI improves from 0.58 to 0.65 and WRP from 0.67 to 0.74 across scenarios, alongside a rise in total material throughput from 28,400 to 35,200 kg. Recoverable waste rises from 67% to 74% and landfill fraction decreases from 33% to 26%, confirming that deeper renovation strategies enhance circularity when recovery pathways are effectively integrated. However, as relative indicators can mask absolute flow increases, results should be interpreted alongside the absolute waste quantities in *Tables 4 and 5.*

Implications, limitations, and outlook

The results demonstrate that schedule-aware waste modelling provides actionable decision support beyond cumulative assessments by capturing activity-level, spatial, and temporal waste dynamics. This enables more informed planning of onsite logistics, waste segregation, and recovery strategies, particularly through identifying waste-intensity peaks and their scheduling drivers during renovation execution. Limitations include fixed waste coefficients, uniform daily waste distribution assumptions, and fixed recovery coefficients that reflect theoretical pathways rather than dynamic site conditions. In practice, packaging waste may occur in short bursts, and sorting efficiency may vary under peak generation. Another limitation concerns the use of relative circularity indicators. While CI and WRP improve consistently across scenarios, relative indicators can mask increases in absolute material flows. As total material throughput grows from 28,400 kg in Scenario 1 to 35,200 kg in Scenario 3, absolute landfill quantities may not decrease proportionally despite improved relative indicators. This rebound-effect risk suggests that the results should be interpreted alongside the absolute waste quantities reported in Tables 4 and 5, not solely through relative indicators. These findings should therefore be considered in light of the underlying modelling assumptions. Future work will focus on calibrating the framework using empirical site data and extending it to capture dynamic execution conditions through real-time sensing and digital twin integration, thereby strengthening its robustness and applicability for execution-aware circular renovation planning.

Conclusions

This paper introduced a schedule-aware, BIM-based approach linking activity-zone modelling with precedence-constrained scheduling to enable time-resolved assessment of material flows, waste generation and circularity performance in deep renovation. Application to a multi-residential case in Lille demonstrated that scenarios with comparable material throughput can exhibit markedly different waste intensity profiles and recovery outcomes, confirming that activity sequencing, spatial repetition and controlled parallelisation are decisive drivers of circularity performance. Deeper renovation strategies can enhance circularity despite increased material inputs when execution logic is appropriately managed. These findings position scheduling as a central lever for circular renovation performance, underscoring the need to integrate execution planning into material-flow and circularity assessment.

TOWARDS HYBRID DIGITAL TWIN FOR PERFORMANCE-BASED CONTROL EVALUATION IN HYDROGEN FACILITIES

José L. Hernández[1], Ismael Lozano[1], Víctor I. Serna[1], Luis V. Jimeno[1], Jesús Samaniego[1] and Francisco J. Miguel[1]
[1] CARTIF technology center, Boecillo, Spain

Abstract

Current digital twins for hydrogen energy systems mainly rely on physics-based simulations. Still, data-driven approaches are not fully deployed, limiting the ability to support systematic evaluation of control strategies under diverse operating scenarios. This paper addresses this gap by proposing a hybrid digital twin framework for hydrogen-based testing and experimentation facilities, integrating physics-based and data-driven models, which combines time-series and contextual data. The framework enables scenario-based experimentation and performance-oriented control evaluation. While no experimental results are yet presented, the proposed approach establishes a scalable foundation for performance-based feedback loops, supporting future development of adaptive, energy-efficient, and low-carbon control strategies.

Introduction

Hydrogen energy systems are increasingly recognized as a cornerstone technology for decarbonizing energy systems and enabling high penetration of renewable energy sources. The major potential of hydrogen (H_2) lies in its versatility in production, storage, and utilization, as well as its ability to mitigate grid imbalance through long-term energy storage (Taghavi, 2026). As a versatile energy carrier, hydrogen can support sector coupling between electricity, heating, and mobility, while providing long-term storage and flexibility to energy systems with high shares of variable renewable generation.

Recent research highlights the expanding role of hydrogen in integrated energy systems. The objective is to enhance system flexibility across electricity, heat and transport sectors (Bhandari, 2024). A significant growth in both pilot projects and commercial demonstrations, including industrial facilities, is exemplified by large-scale deployments such as the Fukushima Hydrogen Energy Research Field, which produces green hydrogen from solar energy (JapanGov, 2021).

Despite these advances, hydrogen energy systems present significant technical and operational challenges due to their multi-domain nature. First of all, there is a need for efficient storage technologies and dynamic interactions between production, conversion and end-use subsystems (Kamran, 2024). Second, its design and operation are complex due to their multi-domain nature, non-linear dynamics and strong dependency on external conditions such as renewable generation, demand profiles, and operational constraints. These challenges drive to solutions to ensure safe, efficient and low-carbon operation through the application of advanced analysis and control approaches capable of capturing system interactions across multiple time scales and operating scenarios. Conventional modelling and management approaches frequently lack the capability to capture complex system dynamics under diverse operating conditions, constraining systematic performance assessment and optimization.

Under this perspective, digital twins (DTs) arise as a research initiative for hydrogen systems and this solution has expanded rapidly. In this work, a DT is defined as a dynamic digital representation of a physical system that combines data-driven and model-based components to replicate system behavior, support simulation under varying conditions, and enable decision-making through virtual experimentation.

Its main motivation is the need for a safer operation, higher reliability and scalable deployment across the hydrogen value chain (Naanani, 2025). Recent works show how hydrogen DTs are increasingly used for monitoring, anomaly detection, and risk-informed operation, but also stress the ongoing challenges of model fidelity, data availability, and real-time integration across heterogeneous subsystems (Naanani, 2025). Some works, for instance, some DT methods have been proposed to support operational decision-making for electrolyzers. They combine structured modelling workflows with plant data to maintain alignment between the virtual and physical assets (Monopoli, 2024). Beyond single assets modelling, architecture-level DT concepts have been introduced for fleets of electrolyzers (Alsharif, 2024), enabling unified data management and scalable analytics across distributed hydrogen production units.

Scaling up the asset perspective, some studies focus on facility level. These works demonstrate DT modelling for integrated hydrogen energy systems, coupling electrolysers, fuel cells, hydrogen storage and batteries. This research shows the direction towards holistic, system-level twins suitable for experimentation and control evaluation (Weerakoon, 2025). In the same line, (Alsharif, 2023) proposes software and reference

architectures for electrolyser digital twins intended to support scale-up and industrial digitalization.

Complementary to the DTs, experimental platforms and testing and experimentation facilities (TEFs) are gaining importance as environments to validate AI (Artificial Intelligence)-enabled control and operational strategies in realistic, safety-critical conditions. Some EU initiatives explicitly include hydrogen testing platforms within large-scale TEF ecosystems, reflecting the strategic role of experimentation infrastructures for accelerating innovation and deployment (CORDIS, 2025).

However, existing research rarely integrates physics-based and data-driven approaches within a unified framework. In this context, a hybrid digital twin is defined as a digital representation in which physics-based and data-driven models are combined to jointly represent system behavior. This approach leverages the complementary strengths of both paradigms. On the one hand, physics-based models rely on first-principles knowledge, ensuring physical consistency. On the other hand, data-driven models capture complex, non-linear patterns directly from operational or sensor data through adaptive learning mechanisms. By combining both approaches, hybrid digital twins can improve predictive accuracy, computational efficiency, and robustness, particularly in scenarios where neither modelling paradigm alone is sufficient (Hunde, 2025). Within this work, hybridization is implemented at component level, where different modelling paradigms are assigned to system components depending on data availability and physical knowledge.

According to (Langlotz, 2022), these hybrid methodologies follow a sequential integration. Data-driven modules perform adjustments or corrections thanks to the physics models. By coupling both frameworks, the active interaction between models is enabled (Langlotz, 2022). Moreover, hybrid modeling facilitates real-time monitoring, predictive analytics and performance optimization by continually updating models with real-world data while constrained by governing physical laws, thus enhancing reliability in complex systems (ANSYS, 2024). Hybrid analysis further show that embedding physics knowledge can reduce uncertainty and improve generalizability of data-driven predictions (Pawar, 2021).

Despite these advances, existing digital twin approaches for hydrogen systems and TEFs remain limited in their ability to support systematic, performance-based evaluation of control strategies within testing and experimentation facilities. Although efforts are put in place, current implementations typically focus on either physics-based simulation or data-driven analytics, with limited integration between both paradigms. Moreover, many DT solutions prioritize monitoring or fault detection rather than scenario-based experimentation, and they often rely predominantly on time-series data while underutilizing contextual information such as system configurations, operational modes, and boundary conditions. As a result, the potential of digital twins as virtual experimentation environments for control strategy assessment and iterative performance improvement remains largely underexplored. Additionally, existing research on hydrogen digital twins addresses different levels of granularity, ranging from detailed component-level models, such as electrolyzers, to system-level representations of integrated hydrogen energy facilities. While component-focused approaches enable high-fidelity modeling of specific assets, system-level digital twins aim to capture interactions across multiple subsystems, albeit often at the expense of detailed component dynamics. Nevertheless, no works are represented in the coupling of multi-level granularity.

Keep in mind these gaps, this paper addresses these challenges by proposing a conceptual hybrid digital twin framework for hydrogen-based testing and experimentation facilities. The proposed approach integrates physics-based and data-driven models and explicitly combines time-series and contextual data to enable scenario-based experimentation and performance-oriented control evaluation. Rather than presenting experimental results, this work focuses on defining a scalable and modular digital twin architecture that supports performance-based feedback loops and systematic comparison of control strategies. Moreover, this work combines multiple levels of granularity, while modelling single components, optimization algorithms combined them to provide a whole system recommendation for optimal operation. The lasting contribution of this paper lies in establishing a foundation for future implementation and validation of adaptive, energy-efficient, and low-carbon control solutions within hydrogen testing and experimentation environments.

The rest of the paper is organized as follows. First of all, the hydrogen-based testing facility is described. Next, the digital twin concept is explained, with the detailed approach that is the contribution in this paper. Following, the combined data sources, time-series and contextual information, are explained as the foundation of the digital twin. Finally, the discussion and conclusions section is stated.

Hydrogen-based testing facility

Hydrogen-based testing and experimentation facilities are designed to provide controlled, flexible and safe environments for the development, validation, and assessment of hydrogen technologies and operational strategies. By the integration of multiple energy systems (both generation and consumption assets and storage subsystems) with AI-driven management strategies, it is enabled the experimentation under realistic operating conditions, taking into consideration real-time data and operation conditions. At the same, safety and regulatory constraints are applied. Their modular and configurable nature makes them particularly suitable for evaluating advanced control approaches, system interactions, and scenario-based operational strategies.

The hydrogen-based testing facility considered in this work couples electrical, hydrogen and thermal subsystems in order to emulate the operation of a small-

scale, multi-domain hydrogen energy system. The facility is designed to support experimentation under different operating configurations while respecting safety, power, and communication constraints inherent to laboratory-scale infrastructures.

The hydrogen testing facility is located in the CARTIF technology center building, placed in Valladolid (Spain). Figure 1 illustrates the facilities.

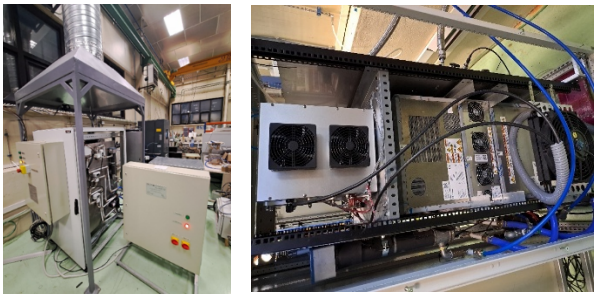

Figure 1: Hydrogen testing system in CARTIF building

The facility is centered on an AEM (Anion Exchange Membrane) electrolyzer with a hydrogen production capacity of up to 500 Nl/h (1.08 kg/day) and nominal power consumption between 2 and 3 kW, operating at pressures up to 35 bar. Hydrogen conversion is supported by a 2 kW PEM fuel cell, enabling cogeneration with fast start-up and flexible load response. The electrolyzer operates within a defined power range, introducing minimum power constraints that are representative of real-world hydrogen production systems. The installation includes metal hydride hydrogen storage, providing a storage capacity of approximately 1.6 kg.

The electrical subsystem provides power conversion bidirectional DC/DC converters. These converters couple the fuel cell output to the electrical bus, enabling regulated power delivery from hydrogen-based electricity generation. This subsystem also includes electrical energy storage in form of lithium-based batteries with a nominal capacity of approximately 2.56 kWh and a nominal voltage of 25.6 V. These batteries support high charge and discharge currents, enabling short-term buffering and fast dynamic response during experimental scenarios. Finally, electronic loads allow controlled consumption of electrical power to reproduce variable demand profiles.

The thermal subsystem provides additional flexibility for future experimentation involving thermal energy management. It includes a heat pump capable of delivering both heating and cooling, as well as an electrically heated water storage tank with a capacity of 300 liters. The thermal assets allow partial coupling between electrical, hydrogen, and thermal domains, supporting future extensions of the digital twin towards integrated energy management scenarios.

The facility is also equipped with an advanced data acquisition and control system based on PLCs (Programmable Logic Controller) and Node-RED communicating with all main components (electrolyzer, fuel cell, hydride tank, batteries, and heat pump). It allows real-time monitoring of parameters such as temperature, pressure, flow, current, and voltage, as well as the implementation of AI-based predictive and adaptive control strategies.

This hydrogen-based system is designed to operate under multiple configurations and operating modes, allowing flexible interaction between subsystems. Hydrogen can be produced stored, or converted back to electricity depending on system conditions, control objectives, and external inputs such as renewable generation and demand profiles. Electrical and thermal loads can be varied to represent different usage patterns, while storage systems provide buffering and flexibility across time scales. This multi-domain interaction introduces non-linear dynamics and strong coupling effects, which are characteristic of real-world hydrogen energy systems. In this sense, the system can reproduce variable generation and demand profiles, enabling the study of renewable integration, load shifting, and storage optimization at building and microgrid scales. For that reasons, the facility supports scenario-based analysis by enabling controlled variation of boundary conditions, system configurations, and control strategies. Forecasts of renewable generation and energy demand can be incorporated to emulate prospective operational scenarios.

Last but not least, the constraints should be taken into account. Minimum and maximum power limits for the electrolyzer, DC/DC converters, and power supply, a maximum system power rating of 2 kW, limited configurability of battery electrical connections, and the absence of direct control over fuel cell internal operating parameters. Additionally, communication limitations between certain components introduce non-ideal behaviors, which further motivate the use of digital twin-based experimentation to evaluate control strategies under realistic conditions.

In short, this hydrogen-based testing facility provides the physical foundation for the digital twin framework proposed in this paper. Its modular structure, multi-domain nature, and configurable operation make it well suited for investigating performance-based control evaluation, system-level interactions, and feedback-driven optimization through virtual experimentation.

Hybrid digital twin for performance-based control evaluation

The complexity and multi-domain interactions of hydrogen-based testing facilities require advanced digital representations capable of supporting systematic control analysis beyond conventional simulation approaches. In this context, hybrid digital twins emerge as an effective solution by combining physics-based models with data-driven components to capture both system dynamics and operational variability. This section introduces the proposed hybrid digital twin framework, designed to enable performance-based evaluation of control strategies through scenario-based experimentation. By integrating time-series and contextual data, the digital twin provides a virtual environment for analyzing control performance, exploring alternative operational configurations, and

supporting feedback-driven decision-making without interfering with real facility operation.

Digital twin conceptual approach

Figure 2 illustrates the conceptual approach of the proposed hybrid digital twin. The digital twin is fed with two data inputs: trained models and real time data. The models are trained using both time-series and contextual data to provide component-level models to be operated with the AI algorithms. The outputs of this process include control strategies and performance indicators used for evaluating operational configurations to compare the original strategy and the AI-based one, as indicated in Figure 4.

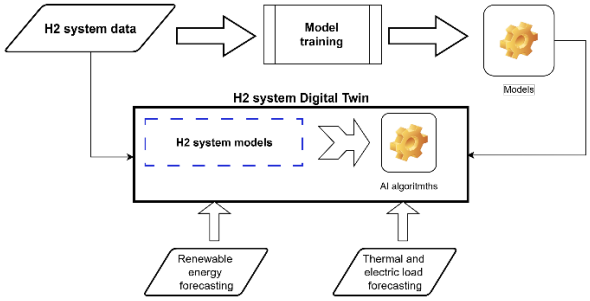

Figure 2: Digital twin conceptual approach

Entering into details, at the top level, historical, operational and contextual H_2 system data are collected from the testing facility and used within the model training process. This stage is responsible for preparing and calibrating the digital representations of the physical system. These digital representations are implemented at component level (see next section for more details). These models include both physics-based and data-driven details. The outcome of this process is a set of validated models that capture the dynamic behavior of the hydrogen system under different operating conditions.

The lower layer represents the operational digital twin, where the trained models are instantiated as H_2 system. Combined with AI-based algorithms, optimal configuration and parametrization can be obtained. Scenario-based experimentation is thus enabled through the integration of renewable energy forecasting and thermal and electrical load forecasting to determine future conditions of the operational stage. These external inputs provide prospective boundary conditions to the digital twin, allowing the evaluation of control strategies under varying demand and generation profiles.

By decoupling model training from operational experimentation and embedding forecast-driven scenarios, the proposed digital twin supports systematic and repeatable evaluation of control strategies. This structure enables performance-based comparison of alternative control approaches and establishes the foundation for feedback-driven optimization and future adaptive control deployment in hydrogen testing and experimentation facilities.

Detailed digital twin components

As explained previously, the proposed hybrid digital twin is composed of a set of modular, component-level models that collectively represent the behavior of the hydrogen-

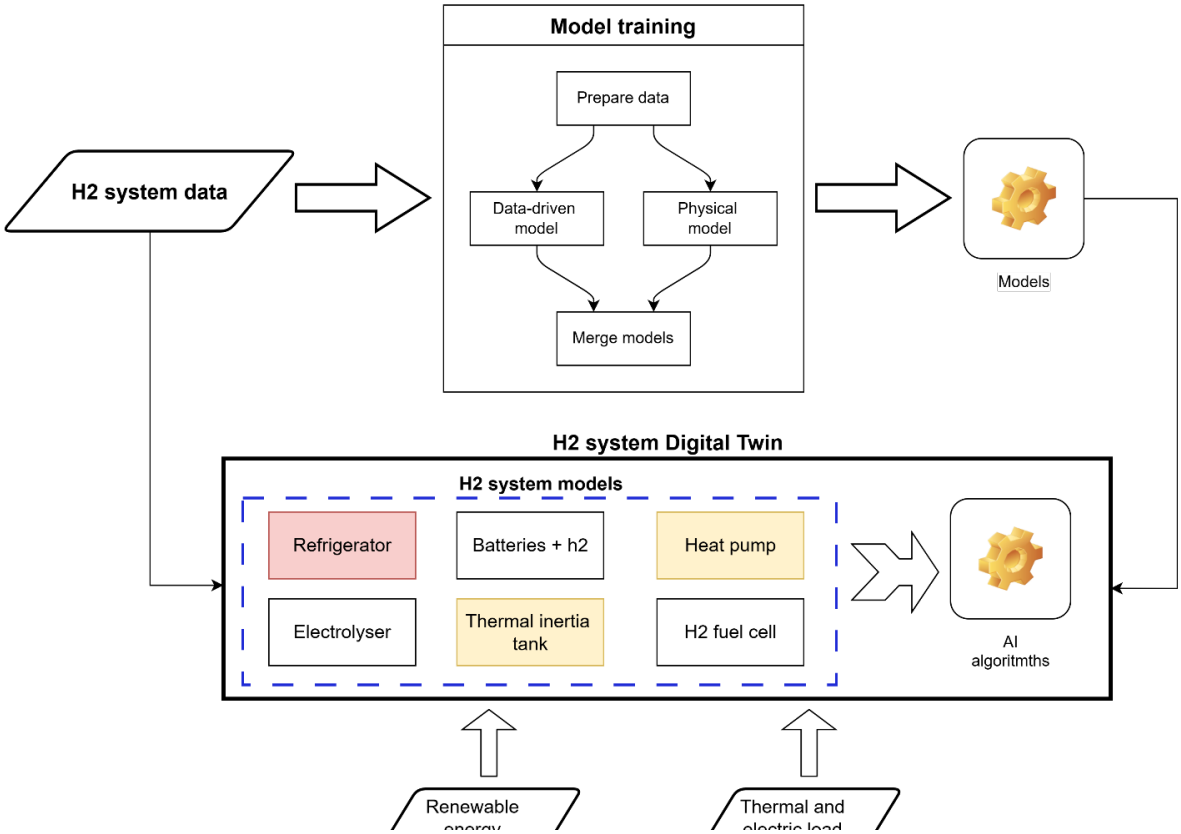

Figure 3: Detailed configuration of the digital twin for the H_2 facilities

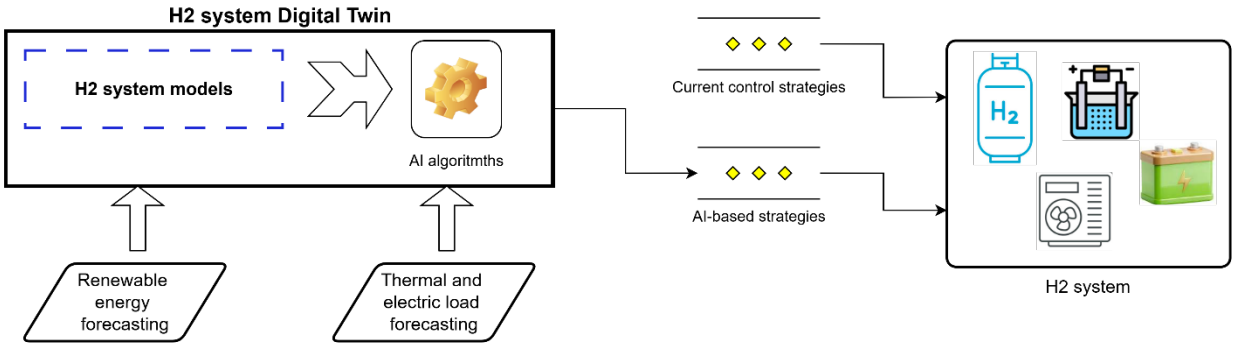

Figure 4: Comparative operational strategies for performance-based control scenarios

based testing facility. These models correspond to the main subsystems of the facility, including hydrogen production, storage, conversion, and associated electrical and thermal components. Within this layer, the digital twin operates as a virtual experimentation environment, enabling the execution of multiple scenarios without interfering with real system operation.

Figure 3 illustrates how the different component-level models are grouped and how they interact with AI-based algorithms to support scenario-based control evaluation. Each digital twin component captures the dynamic behavior and operational constraints of a specific physical asset, while their coordinated integration enables system-level analysis across electrical, hydrogen, and thermal domains for a system-level analysis.

In Figure 3, the color coding is used to explicitly represent the hybrid modelling approach adopted in the proposed digital twin.

Red components correspond to mathematical or estimation-based models, which is used for the refrigerator. The reason for this approach relates to the lack of real physical assets, while the estimation of the amount of energy used for refrigeration is estimated via indirect measurements. This allows to approximate system behavior by estimations.

Yellow components denote physics-based models derived from first-principles formulations. In the proposed architecture, this approach is adopted for the heat pump and the thermal inertia tank, where thermodynamic relationships are used to represent heat generation, storage, and dissipation processes. The use of physics-based models in these assets is motivated by the limited availability of real-time operational data.

Finally, white components represent data-driven models trained directly from historical and operational data. This modelling approach is applied to the electrolyzer, batteries, hydrogen storage system, and fuel cell, for which sufficient experimental data are available from real operation. These models capture complex, non-linear behaviors and component-specific dynamics that are difficult to describe analytically.

By combining mathematical estimations, physics-based representations, and data-driven models within a unified framework, the proposed digital twin achieves a balanced trade-off between model fidelity, adaptability, and computational efficiency. This hybrid structure enables systematic, performance-based evaluation and comparison of control strategies under forecast-driven operating conditions.

Performance-based strategies comparison

Figure 4 illustrates how the proposed hybrid digital twin is used to support performance-based comparison of alternative control strategies. In this stage, the integrated H_2 system models are coupled with AI-based algorithms. These AI algorithms interact with the system models to generate control actions, assess system responses, and compute performance indicators related to efficiency, energy balance, and operational feasibility. These algorithms include model predictive control (MPC) or reinforcement learning (RL).

To further formalize the control evaluation process, the problem addressed by the digital twin can be formulated as a constrained optimization problem. The objective is to minimize energy consumption from the grid, while maximizing renewable energy use and system efficiency. This can be expressed as:

$$\min\left(\alpha_1 \cdot E_{grid} + \alpha_2 \cdot C_{oper} + \alpha_3 \cdot H_{2_loss}\right) \quad (2)$$

where, E_{grid} is the energy supplied by the grid, C_{oper} is the cost of the operation and H_{2_loss} is hydrogen losses.

Scenario definition is driven by renewable energy forecasting and thermal and electrical load forecasting, which provide prospective boundary conditions for system operation. These forecasts allow the digital twin to emulate future operating conditions, such as variations in renewable generation availability and demand profiles. For each scenario, AI algorithms determine control actions related to hydrogen production, storage usage, energy conversion, and subsystem coordination.

Each candidate control strategy is executed within the digital twin, where the system response is simulated at component level and, then, aggregated at system level. Performance indicators are computed based on predefined metrics, split into three groups: model calibration, AI-based predictive control and hybrid energy integration and flexibility.

Table *1*,

Table 2 and Table 3 summarizes these Key Performance Indicators (KPIs) with the baseline (monitored before the implementation of the DT) and target values to be

achieved by the application of the digital twin. By repeating this process across multiple scenarios and strategies, the digital twin enables objective, quantitative comparison of alternative control approaches.

Table 1: KPIs for the model calibration

KPI	KPI description	Baseline	Target value
Model accuracy index	Quantifies deviations between simulated and experimental variables.	±10% average deviation	< ±5% deviation across all monitored variables
System response time	Time to reach steady state after a setpoint change.	> 60s average	< 30s for 90% of test cases
Operational data completeness	Proportion of data successfully integrated into the AI data lake.	85% completeness	≥ 95% completeness

Table 2: KPIs for the AI-based predictive control

KPI	KPI description	Baseline*	Target value
Prediction accuracy of AI models	Measures forecasting error for energy demand and hydrogen production	MAE = 0.15	MAE ≤ 0.05
Energy cost reduction through AI control	Quantifies reduction in energy consumption.	0%	≥ 10% reduction
Renewable energy utilization rate	Ratio of renewable input energy used in hydrogen production.	70%	≥ 90%
Ratio H2 stored energy vs renewable	Ratio of energy stored in the H2 system versus the renewable input energy.	n.a.	> 65%
Ratio battery stored energy vs renewable	Ratio of energy stored in the batteries versus the renewable input energy.	n.a.	> 30%
Ratio H2 cell energy vs energy demand	Ratio of energy generated by the H2 cell versus the energy that is demanded.	n.a.	< 30%
Net consumed energy	Energy that is used from the grid.	n.a.	
Hydrogen storage cycle efficiency	Ratio between energy recovered and energy input per cycle.	80%	≥ 90%

** n.a. refers no baseline is available, just a target value to be achieved with the implementation of the DT.*

Table 3: KPIs for the hybrid energy integration and flexibility

KPI	KPI description	Baseline	Target value
System flexibility index	Ability of the integrated system to adapt to variable generation and demand.	Flexibility ratio = 0.6	≥ 0.85
Thermal–electrical coupling efficiency	Performance of heat recovery and utilization in cogeneration mode.	70%	≥ 85%

The outcomes of this comparison process support the identification of control strategies that best satisfy performance objectives and operational constraints. Moreover, the results provide structured feedback for refining control logic and parameterization, establishing the basis for performance-driven optimization and future adaptive control deployment within hydrogen testing and experimentation facilities.

Time-series and contextual data integration

The effectiveness of the proposed hybrid digital twin relies on the coherent, explicit and structured integration of time-series and contextual data originating from the hydrogen-based testing facility. This approach ensures ensure consistent model instantiation, execution, and evaluation. Unlike conventional approaches that treat operational data in isolation, this work defines a unified data representation in which dynamic system behavior and static system description are jointly exploited within the digital twin lifecycle. The proposed architecture is drawn in Figure 5, where both data types are managed through a data lake-oriented approach, ensuring continuous synchronization between them.

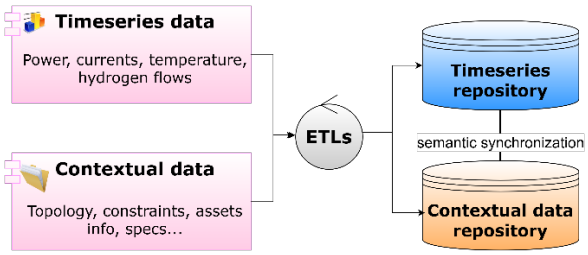

Figure 5: Integration of time-series and contextual data for hybrid digital twin execution

Data typology and roles

Time-series data represent the dynamic evolution of the hydrogen-based testing facility and consist of high-frequency measurements acquired from the physical system. These include electrical variables (power, current, voltage), thermodynamic variables (temperature, pressure), hydrogen flows, and state variables such as battery state of charge or hydrogen storage level. Additionally, forecasted inputs, including renewable generation and thermal and electrical demand profiles, are incorporated as time-dependent boundary conditions for scenario-based experimentation.

In contrast, contextual data provide the structural and semantic description of the system. This includes asset definitions (e.g., electrolyzer, fuel cell, storage units), system topology, operational constraints (e.g., power limits, pressure thresholds), nominal capacities, and configuration parameters. Contextual data also define the relationships between variables and assets, enabling the correct interpretation of measurements and ensuring consistency across models and scenarios.

This integration enables the digital twin to instantiate component-level models with the correct configuration and constraints while being continuously driven by dynamic operational data and forecasted inputs. During scenario-based experimentation, contextual data define the system configuration and control boundaries, while time-series and forecasted data provide evolving boundary conditions. As a result, the digital twin can execute reproducible simulations, evaluate control strategies under varying conditions, and compute performance indicators in a consistent and traceable way.

By combining time-series and contextual data within a unified and governed data infrastructure, the proposed approach ensures that digital twin simulations remain physically meaningful, adaptable to changing conditions, and suitable for systematic performance-based control evaluation in hydrogen TEFs.

Data model and semantic mapping

To enable integration, both data types are represented through a shared data model based on three core entities: assets, variables and observations. Each asset (e.g., electrolyzer) is associated with a set of variables (e.g., input power, hydrogen production rate), which are linked to time-series observations through unique identifiers. Contextual data define the attributes and constraints of each asset, while time-series data provide their temporal evolution. Formally, a time-series observation can be represented as the equation (2):

$$o = (a_i, v_j, t_k, x_{ijk}) \quad (2)$$

where, a_i is the asset, v_j is the associated variable, t_k the timestamp and x_{ijk} the measured or forecasted value. Contextual data define the admissible domain of the measurement, as well as the relationships between variables across assets.

This mapping enables the digital twin to interpret each data point within its physical and operational context, avoiding ambiguity and ensuring that model inputs are aligned with system constraints.

Integration and synchronization mechanism

While time-series data are stored in a repository optimized for temporal queries, contextual data are maintained in a structured repository capturing system configuration and semantics. Therefore, a synchronization mechanism is required to both repositories through:

- shared asset identifiers,
- timestamp alignment for dynamic data,
- semantic tagging of variables and units.

The data model is designed to be compatible with semantic standards such as SAREF and SAREF4ENER, enabling formalized representation of assets, variables, and their relationships, and supporting scalable and interoperable digital twin implementations.

This process ensures that each time-series input used by the digital twin is consistently mapped to its corresponding asset and variable definition. Furthermore, updates in contextual data (e.g., configuration changes or operational constraints) are propagated to the digital twin to ensure that simulations reflect the current system state.

This integrated approach enables the digital twin to operate in two complementary modes: model instantiation and scenario execution. During model instantiation, contextual data are used to configure component-level models, defining parameters such as capacities, limits, and connectivity between subsystems. During scenario execution, time-series data and forecasted inputs drive the dynamic behavior of the models, providing evolving boundary conditions.

Discussion and conclusions

This paper has presented a conceptual hybrid digital twin framework for hydrogen-based testing and experimentation facilities, aimed at enabling performance-based evaluation of control strategies under realistic and forecast-driven operating scenarios. The proposed approach addresses key limitations identified in the current state of the art, namely the fragmented use of physics-based and data-driven models, the limited exploitation of contextual data and the lack of systematic support for scenario-based control comparison within testing environments.

By combining component-level digital twins with multiple modelling paradigms, such as mathematical estimations, physics-based representations, and data-driven models, the proposed framework achieves a balanced trade-off between physical fidelity, adaptability, and computational efficiency. This hybrid structure allows the digital twin to capture both the dynamic behavior of hydrogen systems and the operational constraints imposed by real testing facilities. The explicit integration of time-series and contextual data further ensures consistency, traceability, and reproducibility across scenarios, which is essential for meaningful performance-based control evaluation.

The framework has been designed with a strong focus on modularity and scalability, enabling its application across different levels of granularity, from individual components to integrated multi-energy systems. In this sense, the digital twin acts as a virtual experimentation environment, supporting the systematic comparison of alternative control strategies based on clearly defined performance indicators. Although no experimental validation results are presented in this work, the proposed architecture establishes the necessary foundations for structured experimentation, optimization and decision support in hydrogen TEFs.

Future work will focus on the implementation and experimental validation of the proposed hybrid digital twin within the CARTIF hydrogen testing facility. This includes the deployment of the component-level models, the integration of real-time data streams, and the execution of representative operational scenarios to assess the effectiveness of different AI-based control strategies. Further developments will address the extension of the control layer towards closed-loop adaptive operation, the calculation of performance indicators, and the inclusion of additional assets and use cases. In the longer term, the proposed framework will be evaluated for scalability and transferability to other hydrogen-based facilities and multi-energy systems within large-scale testing and experimentation infrastructures.

A MULTI-MODEL FRAMEWORK INTEGRATING CLIMATE PROJECTIONS AND SYSTEM DEGRADATION FOR CLIMATE-AWARE RETROFIT PLANNING

Avinash Myakal[1], Ranjith K. Soman[1], and Igor Nikolic[1]
[1]Delft University of Technology, Delft, the Netherlands

Abstract

Current building energy simulations often rely on static assumptions, neglecting dynamic factors such as climate change and component degradation, leading to performance gaps and suboptimal retrofit decisions. This research applies a multi-model framework that integrates climate projections with building envelope and HVAC degradation models within an automated workflow. Using an office building case study, the results demonstrate the efficacy of the multi-model framework while also improving understanding of maintenance–retrofit trade-offs under climate uncertainty. The analysis reveals key sensitivities and limitations of dynamic energy modelling, advancing insight into how the multi-model framework can support climate-aware, lifecycle-oriented retrofit decision-making.

Introduction

The global building sector represents a primary driver of energy demand and environmental impact, currently accounting for approximately 40% of total energy use and 36% of greenhouse gas emissions (Farahani et al., 2019). Within the European context, a significant majority of the building stock was constructed before the implementation of stringent energy efficiency standards, with many structures remaining in operation for over 50 years (Feng et al., 2022). Consequently, the pressure on primary energy resources is increasing, necessitating a rapid increase in the rate and effectiveness of energy retrofitting (Roetzel and Tsangrassoulis, 2012). Energy retrofitting, defined as the upgrade of existing building technologies, materials, and features, is essential for reducing operational costs, improving occupant comfort, and achieving long-term sustainability goals (Wang et al., 2014; Asadi et al., 2014).

Despite the importance of these interventions, the planning and scheduling of retrofits are often hampered by inaccurate energy consumption projections. Building energy consumption is a highly dynamic and complex system shaped by an intricate interplay of thermophysical properties, construction quality, local climatic conditions, and the aging of mechanical systems (Delzendeh et al., 2017; Li et al., 2021). Conventional simulation methods frequently rely on static inputs that ignore the degradation of the building envelope or the shifting baseline of future weather patterns driven by climate change (Thomas et al., 2016b). Research indicates that ignoring these factors can lead to discrepancies between predicted and actual energy use of up to 100%, resulting in misdirected investments and policy failures (Thomas et al., 2016b; Delzendeh et al., 2017).

In the domain of computing in construction, the emergence of digital twins and integrated modeling offers a pathway to address these complexities. Digital twins provide virtual abstractions of physical assets, enabling continuous monitoring and scenario-based analysis throughout the building's lifecycle (Lu et al., 2025). However, the integration of heterogeneous models (such as climate projections, material science degradation laws, and mechanical engineering maintenance factors) remains a significant technical challenge (Nikolic et al., 2019). Most existing workflows are either too simplified to capture physics-based volatility or too labor-intensive to scale across large scenario grids (Li et al., 2021; Waddicor et al., 2016).

This paper presents a novel Multi-Model (MM) framework, the Multi-Model Building Energy Consumption Simulator (MM-BECS), designed to automate and integrate the simulation of building energy systems under varying future scenarios. By leveraging the multi-modelling infrastructure (MMI) principles established in the MMviB project, the framework ensures loose coupling between participating models, facilitating the reuse of validated components (Nikolic et al., 2019; Matthijssen et al., 2023). The research question addresses how an integrated multi-model framework can provide high-fidelity annual energy trajectories to inform effective retrofitting and maintenance decisions over a building's entire 60-year lifespan. The primary contribution of this work is the development and demonstration of a containerized, tool-agnostic workflow that bridges the gap between specialised and validated physics-based models and lifecycle investment planning. The novelty of this work lies not in individual sub-models, but in their integration into a fully automated, containerised, and tool-agnostic workflow capable of generating annual energy trajectories over a full 60-year lifecycle.

Background

The scientific literature surrounding building energy simulation has increasingly recognized the limitations

of single-model approaches when applied to long-term projections. Traditional decision-support tools often frame building retrofit planning as a life cycle cost optimization (LCO) problem, utilizing Net Present Value (NPV) to identify cost-effective interventions (Wang et al., 2014; Ascione et al., 2015).

While studies by Wang et al. (2014) and Luo and Oyedele (2022) provide valuable economic insights, they frequently treat energy savings as fixed, stable inputs. This assumption is a significant deficiency, as it ignores the reality that insulation performance and HVAC efficiency decline as components age, while climate warming shifts the underlying demand baseline (Eleftheriadis and Hamdy, 2018). Consequently, many LCO and Life Cycle Assessment (LCA) models rely on externally generated, time-invariant energy trajectories that do not endogenously account for combined, time-varying effects. Such simplifications reduce the realism of the guidance provided to facility managers and policy makers.

Prior research has attempted to integrate multiple influencing factors through various coupling methods, yet each approach presents distinct trade-offs. Scripted multi-run approaches, as exemplified by de Wilde et al. (2011), are transparent and tool-agnostic but become computationally and manually burdensome as the scenario space expands. Waddicor et al. (2016) utilized decadal snapshots to evaluate the joint impact of climate warming and system aging on a historic library in Turin, finding that rising temperatures and declining chiller efficiency can double cooling demand. However, the decadal resolution used in such studies is a notable limitation, as it smooths out the inter-annual volatility driven by extreme weather events, which are critical for sizing mechanical systems and assessing resilience. In contrast, runtime co-simulation allows for bi-directional feedback between models, but introduces significant technical challenges in time synchronization and interface validation (Thomas et al., 2016a).

Existing methods also suffer from limitations in temporal horizon and spatial applicability. While Li et al. (2021) produced annual trajectories, their analysis was restricted to a 25-year horizon, which is insufficient for representing a building's full 60-year service life. Furthermore, many current climate-forcing methods rely on statistical extrapolation or morphing techniques that fail to capture the rising frequency of climate uncertainties and extremities such as heatwaves (Rodrigues et al., 2023). Finally, many approaches are geographically constrained due to reliance on local probabilistic datasets, limiting their applicability across regions in the building sector.

The critical research gap identified is the absence of an automated end-to-end methodology capable of generating annual energy consumption series for the entire operational life of a building while accounting for joint trajectories of climate change and envelope degradation. Despite the successful application of multi-modelling infrastructures in other complex energy domains, such as national infrastructure planning (Huang and Nikolic, 2024), this approach has not yet been realized for high-fidelity building energy simulation. There remains a lack of a containerized, tool-agnostic workflow that uses standardized interfaces to execute large scenario ensembles without manual oversight, thereby producing the consistent annual trajectories required for robust lifecycle financial and environmental appraisal.

Method

The methodology adopted in this study follows a structured multi-model framework, focusing on the development of an integrated simulation system that can represent the building energy consumption system as a whole (Matthijssen et al., 2023). In this paper, the term 'multi-model framework' is used consistently to describe the integration of independently developed simulation components. The framework is conceptualized using the XLRM structure, which organizes Exogenous Uncertainties (X), Policy Levers (L), Relationships (R), and Performance Metrics (M) to enable systematic decision analysis (Lempert et al., 2003). The XLRM framework for building energy systems decomposes the complex dynamics of building energy use into manageable components.

The Exogenous Uncertainties (X) include climate change pathways (RCP 2.6, 4.5, and 8.5) alongside the degradation rates of insulation materials and HVAC components. The Policy Levers (L) represent the decision space, encompassing maintenance regimes, the choice of energy-saving measures, and the timing of retrofit interventions. The Relationships (R) are governed by the physics-based energy simulation engine, while the Performance Metrics (M) are the annual values of site energy consumption, heating/cooling loads, and cumulative energy savings.

Case

Figure 1: Office building at Green Village, Delft.

The developed system will be demonstrated using the

case of the Office building at Green Village, Delft. This building features XPS polystyrene as insulation and a four-pipe fan coil unit as an HVAC system. Additionally, passive ventilation measures have been integrated into the building's design to enhance energy efficiency. This building was selected as a case study because it represents the implementation of traditional Dutch construction designs and practices. The size of the building was suitable for demonstration purposes.

Model Identification and Formulation

The research identifies validated models for three distinct domains: future weather data generation, building component degradation, and whole-building energy simulation.

Weather Model

Dynamic Downscaling and Bias Correction.
To provide future climate forcing, the study utilizes dynamically downscaled weather data from the Coordinated Regional Downscaling Experiment (CORDEX) archive. For the office building case study in Rotterdam, the MPI-ESM-LR global model and KNMI-RACMO22E regional model were selected. A hybrid bias-correction scheme was implemented using Multivariate Bias Correction (MBCn) for inter-dependent variables (temperature, humidity, wind) and univariate Quantile Delta Mapping (QDM) for shortwave irradiance (Machard et al., 2024).

Ageing Model

Degradation Laws and Maintenance Scenarios.
The degradation of the building envelope is modeled via the thermal conductivity (λ) of insulation materials. For extruded polystyrene (XPS), a polynomial degradation law was applied (Eleftheriadis and Hamdy, 2018):

$$\lambda_{\text{age}} = \Big(-0.000097502(\text{age}-1)^5 + 0.0054(\text{age}-1)^4 - 0.1126(\text{age}-1)^3 + 1.0895(\text{age}-1)^2 - 4.9677(\text{age}-1) + 28.7371 \Big)^{-1} \ \text{W m}^{-1}\,\text{K}^{-1} \quad (1)$$

For HVAC components, the study utilizes linear and exponential degradation laws for the Coefficient of Performance (COP) as a function of time (t) and maintenance factor (r) (Griffith et al., 2008; Hendron, 2006):

$$\text{COP}(t) = \text{COP}(0)\,(1 - r\,t) \quad (2)$$

$$\text{COP}(t) = \text{COP}(0)\,(1 - r)^t \quad (3)$$

Simulation Model

EnergyPlus Configuration.
EnergyPlus was selected as the simulation engine due to its feature-rich capabilities and widespread scientific validation (Crawley et al., 2008; Barbosa et al., 2015). The

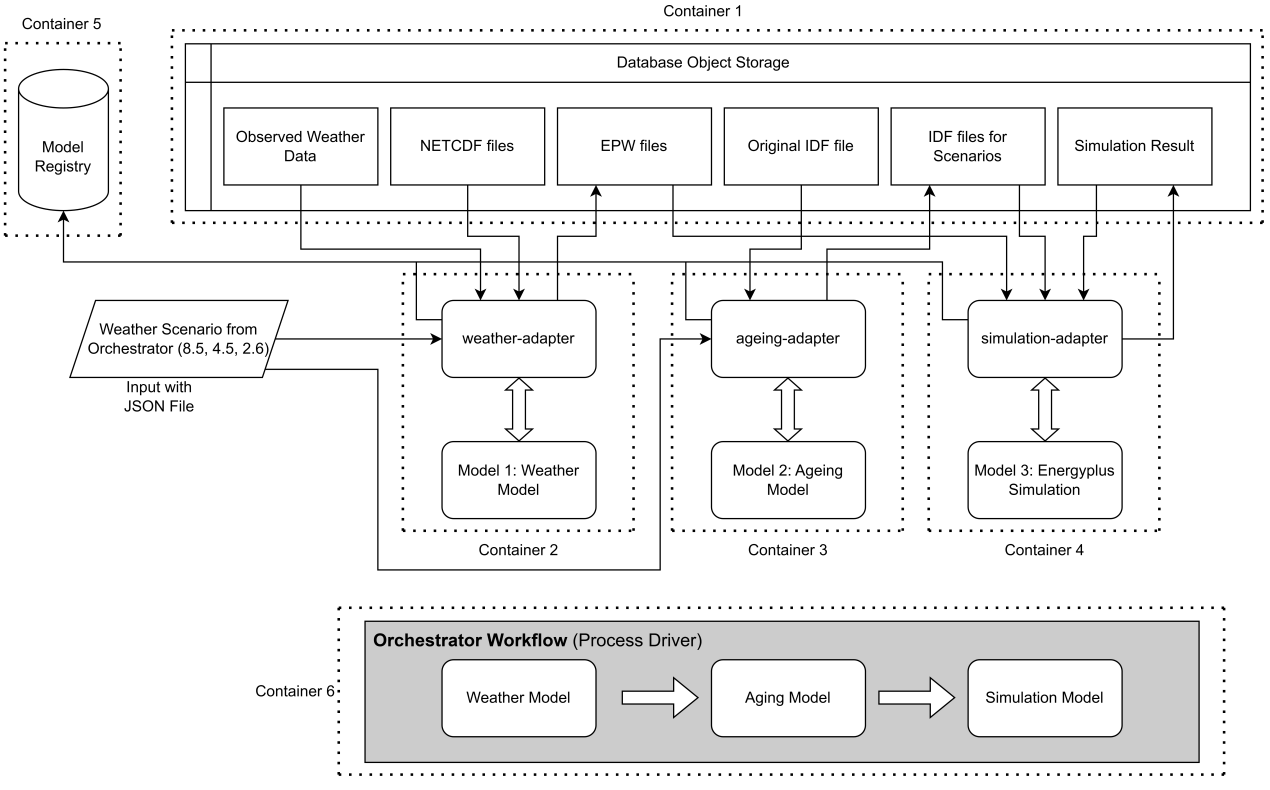

Figure 2: Multi-model Building Energy Consumption Simulator (MM-BECS) system.

engine was configured to run year-by-year simulations by pairing scenario-specific building description files (IDF) with annual weather files (EPW).

Implementation

The technical realization of the MM-BECS system utilizes a containerized architecture to achieve loose coupling and high portability, following the architectural guidelines of the MMviB project (Matthijssen et al., 2023; Nikolic et al., 2019).

Architecture and Service Adapters

Each participating model (Weather, Ageing, and Simulation) is packaged as a Docker container, providing isolation of libraries and dependencies (Matthijssen et al., 2023). Communication is mediated by adapter services, which are lightweight web applications exposing standardized RESTful APIs. These adapters handle the interplay between model-specific inputs and the central object storage service, Minio, which serves as the data repository for the multi-model workflow.

Orchestration and Workflow Automation

A model registry service maintains a catalog of available models and their health status. The orchestrator, implemented as a Directed Acyclic Graph (DAG) in Apache Airflow, automates the sequence of events: (1) preparing future weather inputs, (2) generating scenario-specific building models, and (3) executing the EnergyPlus simulations. This automated execution allows for large scenario grids to run unattended, ensuring computational tractability as the scenario space expands (Huang and Nikolic, 2024).

Results

The MM-BECS system generated annual site energy consumption, cooling load, and heating load for 28 distinct scenarios over a 60-year lifespan (2025–2084) based on the designed simulation configuration. Scenarios E1–E28 represent combinations of maintenance regimes, HVAC replacement timing, and envelope retrofit interventions.

Baseline Performance and Volatility

The baseline scenario (E1) under the RCP 8.5 climate pathway indicates a steady rise in total annual energy consumption, increasing by approximately 43% over the horizon. This trend is driven by the compounding effects of climate warming and the gradual degradation of insulation and mechanical systems. Notably, annual cooling loads nearly double, reflecting rising sensitivity to extreme summer temperatures as chiller performance decays.

Evaluation of Retrofitting and Maintenance Scenarios

A single HVAC replacement in 2055 (Scenario E2) reduces cumulative lifecycle energy consumption by 8.0%. However, implementing regular maintenance without any

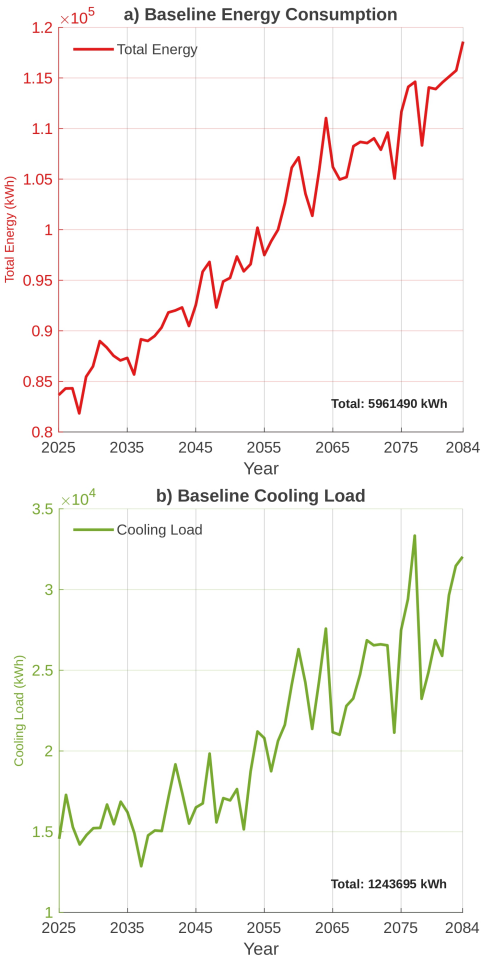

Figure 3: Performance metrics in baseline scenario under RCP 8.5.

HVAC replacement (Scenario E8) achieves lifecycle savings of 10.4%—identical to a dual-replacement scenario (E4) without maintenance. This suggests that a continuous maintenance policy can be as effective as capital-intensive retrofits if initiated early.

Integrated Policy Pathways

Scenario E28, combining dual HVAC replacements, an envelope retrofit in 2055, and regular maintenance, reduces total energy use by 13.6%. While this represents the maximum savings, Scenario E3 demonstrates that a single HVAC retrofit in 2055 followed by regular maintenance still captures 75% of these maximum savings, offering a balanced approach for resource-constrained asset management.

Discussion

The results generated by the MM-BECS system underscore the critical need for integrating dynamic factors into building energy assessments. Traditional methods relying on static models fail to capture the long-term trends and intra-decadal volatility revealed by this multi-model framework (Waddicor et al., 2016; Li et al., 2021).

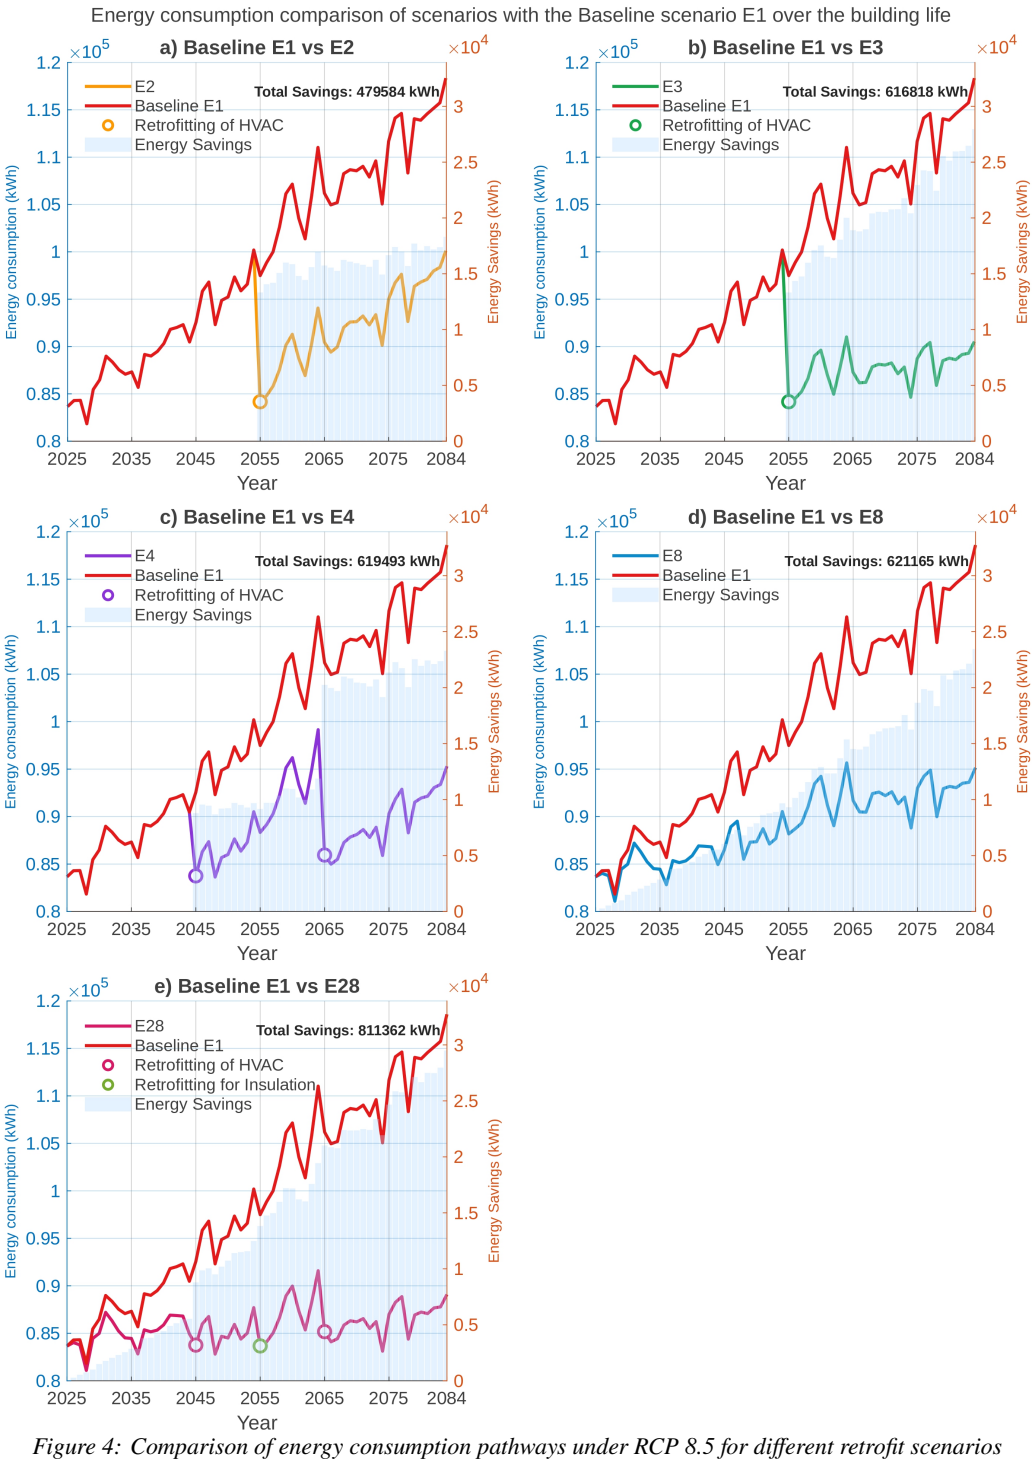

Figure 4: Comparison of energy consumption pathways under RCP 8.5 for different retrofit scenarios

The comparative analysis demonstrates that the value of an intervention is highly dependent on its timing relative to climate forcing and equipment aging (Farahani et al., 2019). Maintenance acts not only to reduce efficiency loss but also to dampen the volatility of cooling loads. For facility managers, this suggests that investment in regular maintenance can defer the need for expensive capital retrofits while ensuring performance stability.

Methodologically, the containerized architecture addresses interoperability challenges that plague bespoke simulation scripts (Huang and Nikolic, 2024). The use of RESTful adapters and centralized object storage allows for a ‘‘plug-and-play’’ environment where sub-models can be updated as new data becomes available. Furthermore, the automation of these workflows significantly reduces human labor; while traditional practice for building energy modeling can take 8 to 32 hours per case, automated pipelines like MM-BECS (and comparative frameworks like Data2BEM) can execute large-scale analyses in minutes (Lu et al., 2025). The MM-BECS framework is

transferable to other building types and regions, provided appropriate climate datasets, degradation parameters, and building models are available. The modular architecture facilitates substitution of sub-models without altering the overall workflow.

Despite its advantages, the current system treats occupant behavior as a static schedule. Future iterations should integrate agent-based occupancy models to capture socio-technical feedbacks (Delzendeh et al., 2017; Thomas et al., 2016a). Additionally, moving toward stochastic ensembles would allow for the generation of probabilistic energy trajectories, providing risk-aware guidance for investment (de Wilde et al., 2011). Furthermore, each sub-model (climate forcing, degradation, and energy simulation) is based on previously validated approaches in the literature. However, the integrated system has not been empirically validated against long-term measured datasets, which remains an area for future work. Also, this study is limited to a single office building archetype and a specific climatic context (Delft, NL). While the framework is generalisable, quantitative results are case-specific. Additionally, occupant behaviour is represented using static schedules, and uncertainty is explored through scenario variation rather than probabilistic ensembles.

Conclusions

This research has demonstrated a multi-model framework for building energy simulation that successfully integrates the dynamic, interdependent influences of climate change, envelope degradation, and HVAC aging. By operationalizing the Multi-Model Building Energy Consumption Simulator, the study has addressed the critical performance gaps inherent in conventional static energy assessments relying on fixed assumptions, neglecting dynamic factors such as climate change and component degradation. The research successfully identified and validated modular sub-models for climate forcing, envelope degradation, and system aging (linear/exponential efficiency loss). These were integrated into a containerized architecture that leverages loose coupling, enabling tool-agnostic execution across large scenario grids. Through the demonstration of a 60-year analysis horizon for an office building, the framework proved capable of generating annual site energy consumption series that capture both long-term trends and intra-decadal volatility. The systematic comparison of 28 scenarios highlighted the efficacy of strategic maintenance as a policy lever, showing that early and consistent maintenance can deliver energy savings comparable to capital-intensive retrofits while damping demand fluctuations caused by extreme weather events.

Methodologically, the study advances the state-of-the-art by moving from decadal snapshots to continuous annual trajectories, providing the high-fidelity data required for sophisticated lifecycle assessments and financial appraisals. The use of standardized interfaces and orchestration logic (Apache Airflow) ensures that the workflow is scalable, reusable, and reproducible—a significant improvement over the bespoke, labor-intensive scripts common in current professional practice. Practically, the findings empower facility managers to optimize the timing of interventions, showing that clustering or splitting retrofits based on divergent heating and cooling load trajectories can significantly improve the cost-effectiveness of energy transition strategies.

Currently, the annual trajectories produced by MM-BECS require manual export for financial evaluation. Future development should focus on the direct integration of lifecycle cost and lifecycle assessment models into the automated pipeline to provide real-time economic and environmental performance indicators. Additionally, the incorporation of a monitoring and calibration layer—utilizing real-time sub-metering and local weather observations—would transform the framework into a climate-responsive digital twin. Such a cognitive system could iteratively update degradation parameters and occupant behavior patterns, allowing for adaptive management that ensures long-term building resilience and sustainability in an increasingly volatile climatic context. This work provides a foundational template for the next generation of data-driven, portfolio-scale decision-support tools in the built environment.

HEATING DEMAND AS AN INDICATOR OF RENOVATION DEPTH IN SOVIET-ERA APARTMENT BUILDINGS

Fariha Harun, Ergo Pikas, Jaanus Hallik
Tallinn University of Technology, Tallinn, Estonia

Abstract

Incremental renovation creates uncertain inputs for archetype-based UBEM, especially in Soviet-era apartment blocks with incomplete renovation records. This study proposes a dynamic archetyping methodology using heating demand as a diagnostic indicator for renovation depth (none/partial/deep). Simulating 44 buildings in Tallinn using the ReST (Renovation Strategy Tool), this study derives performance ranges rather than deterministic values, which account for uncertainties in user behavior and construction quality. Results show a proportional decrease in heating demand with respect to renovation depth. Deep renovation forms a distinct low-demand tier, while overlap among partial states limits identification of specific measures from energy data alone.

Introduction

In the European Union, the built environment accounts for roughly 40% of energy consumption and 36% of CO_2 emissions (Commission, 2020). Significantly reducing these numbers requires robust methods to estimate energy use across scales, from individual units to nationwide systems. While Urban Building Energy Models (UBEM) are essential for large-scale planning, their accuracy is frequently undermined by a lack of reliable, building-level input data. To address this, many UBEM studies utilize an archetype approach, grouping buildings by typology, construction period, and use (Ferrando et al., 2020; Verellen and Allacker, 2019). While archetype-based UBEM can be suitable for aggregated city-level analyses, it can be unreliable at the level of a district or individual buildings, where renovation history, system condition, and occupant behavior strongly influence energy use (Ferrando et al., 2020).

Renovation often occurs incrementally and unevenly over several decades, meaning that buildings of the same archetype often differ substantially in current envelope condition, system upgrades (such as air-to-air heat pump installation or ventilation system modification), and operational characteristics. Furthermore, national registries like the Estonian Building Register (EBR) frequently lack up-to-date records (Hamburg and Kalamees, 2019; Iliste et al., 2023). Although geometric information is often available, missing data on building service systems and envelope upgrades introduce substantial uncertainty into UBEM. Consequently, policies are often implemented based on limited information, despite significant variations in actual building conditions, rendering static, archetype-based solutions unreliable. To address this challenge, systematic data collection is essential to minimize modelling errors and uncertainty (Iliste et al., 2023).

This study addresses this gap by developing the methodological foundation for a dynamic archetyping framework that uses heating-demand distributions to infer renovation depth. To establish this framework, we adapted the European Commission's renovation depth classifications traditionally defined by primary energy savings as light (<30%), medium (30–60), and deep (>60) (European Commission, 2019) into operational renovation classes: baseline (no savings), partial (covering light and medium renovations, from (1%-60% savings), and deep (>60% savings).

This study analyzes how simulated heating demand varies across incremental renovation scenarios and evaluates whether these energy patterns can be translated into these operational renovation-depth tiers. The core research question is: Can heating demand be used to classify renovation depth (none/partial/deep) in Soviet-era apartment buildings? As a simulation-based proof-of-concept, this analysis establishes the classification logic and methodological structure required for future tool development.

Literature Review

Building envelope renovation is an effective way to reduce energy consumption and improve indoor comfort (Cai et al., 2025). Evidence from Northern European contexts: Ruokamo et al. (2025) analysed 416 Finnish housing companies' data and found that partial, maintenance-driven actions, such as window or door replacements, are significantly more common than deep renovations. These low-cost measures typically serve as the initial step in a renovation sequence, while capital-intensive upgrades like façade insulation and heating system modernization occur at later stages (Ruokamo et al., 2025).

Similar patterns are reported in Eastern Europe. Nowak-Dzieszko and Rojewska-Warchał (2015) found that many

large-panel buildings in Poland have undergone basic modernization, like balcony glazing, which can reduce heating demand in adjacent rooms by up to 22% due to increased solar gains. Large-scale renovation studies confirm that multifamily renovation typically follows a stepwise, component-by-component sequence (Abdul Hamid et al., 2018). According to Abdul Hamid et al. (2018), renovation projects commonly start with envelope measures such as façade insulation, roof improvements, and window upgrades because they directly influence energy performance, durability, and indoor comfort. Next in the sequence are actions targeting ventilation and heating systems, particularly upgrades from existing natural ventilation to mechanical ventilation with heat recovery (MVHR) or installing heat pumps. Plumbing system upgrades appear further down the renovation order and are less frequently implemented (Abdul Hamid et al., 2018). The reviewed literature indicates that technical needs, such as façade degradation and energy-performance priorities, consistently establish envelope measures as the starting point in multifamily renovation pathways.

In the Estonian context, heating energy use is strongly influenced by envelope condition, service-system operation, renovation quality, and occupant behavior. Iliste et al. (2023) show that actual wall thermal performance often deviates from calculated values due to air leakage, insulation gaps, and workmanship defects. Operational factors such as indoor temperature settings, ventilation airflow, and air leakage can further affect heating demand (Hamburg et al., 2020; Hamburg and Kalamees, 2019). Even buildings with similar typology can therefore display substantial variation in energy use.

Based on the reviewed studies, renovation in multifamily apartment buildings typically follows a sequential and incremental pathway. Moving from window replacement and minor envelope repairs, followed by roof and façade insulation, while more complex upgrades such as ventilation and heating-system improvements are generally implemented at later stages or within coordinated deep-renovation projects. This gradual evolution produces uncertain intermediate renovation states. Because heating demand may not uniquely distinguish between specific renovation combinations, this study assesses whether these patterns can instead be used to reliably infer overall renovation depth in Soviet-era buildings.

Methodology

The primary objective is to evaluate whether heating demand can be used to classify renovation depth (none/partial/deep). To demonstrate and validate this approach, a pilot study was conducted in a residential neighborhood in Mustamäe, Tallinn, Estonia. The dataset includes 44 multifamily apartment buildings (Figure 1), of which 26 belong to the 464A series and 18 to the 317A series. In Estonia, buildings are grouped by series, reflecting the industrialized, standardized designs used to address post-WWII housing shortages. (Iliste et al., 2023). Series-level classification is more reliably available and widely used in practice. While each series contains subtypes (Type) varying by story count or minor details, this study adopts the series level as the primary analytical unit. This choice ensures the tiering approach remains practical and applicable even when building registries lack granular subtype data. To verify that the proposed heating-demand tiers reflect physical renovation depth rather than modeling artifacts, a subset of 12 buildings belonging to subtype 1-464A-1kE is analyzed separately as a validation case.

Figure 1: Study area in Mustamäe, Tallinn, apartment buildings

Modelling approach

All buildings were modelled in ReST tool (Renovation Strategy Tool) (Hallik et al., 2024). Each model was based on building-specific as-built data obtained from the Estonian Building Register (EHR). Input parameters include building geometry, net heated floor area, envelope properties, window areas, and façade orientation.

Although buildings are grouped by series, they are not treated as identical archetypes; each building retains its specific physical characteristics. Therefore, baseline heating demand may still vary within the same series due to subtype-driven differences in geometry, heated area, and façade orientation. To isolate the effect of envelope modifications, all non-envelope assumptions (including user behavior, ventilation settings, air leakage parameters, and heating-system settings) were held constant across simulations. At the subtype (type) level, buildings sharing identical geometric and envelope inputs produce single baseline values. However, unless geometric and orientation-specific inputs are identical, variation in baseline heating demand can still occur between buildings.

Renovation scenarios and input parameters

Renovation scenarios were generated by systematically modifying selected envelope thermal properties within each building model. Specifically, thermal transmittance values for windows (U_{window}), walls (U_{wall}) and roof (U_{roof}) were applied according to the combinations described in Table 1. For renovation-depth classification *Table 1*, scenarios were grouped into three categories: (i)

non-renovated, (ii) Partial (one or two envelope measures), and (iii) Deep (full envelope upgrade: windows, walls, and roof). No ventilation system upgrades (e.g., heat-recovery ventilation) or HVAC system modifications were modelled in this study. In this study, 'Wall insulated' refers exclusively to full envelope insulation to ensure a consistent comparison of renovation depth. To represent typical incremental renovation pathways in Soviet-era apartment buildings, a set of envelope scenarios was defined by varying insulation thickness and the corresponding thermal transmittance (U-values) of walls and roofs.

Table 1: Renovation scenarios and renovation-depth labels used in the ReST simulations

Scenario	Envelope measures applied	Renovation depth
None	Baseline	None
Single measure	Windows replaced	Partial
Single measure	Roof insulated	Partial
Single measure	Wall insulated (full)	Partial
Double measure	Window and roof	Partial
Double measure	Window and wall	Partial
Double measure	Wall and roof	Partial
All Combined	Window, roof, and wall	Deep

For both building series, insulation thicknesses of 150 mm and 250 mm were applied to both walls and roofs. This corresponds to a range between $U_{wall,max}$= 0.21 W/m²K and $U_{wall,min}$ = 0.17 W/m²K, and for roof $U_{roof,max}$= 0.21 W/m²K and $U_{roof,min}$ = 0.17 W/m²K, respectively, to represent a practical minimum-maximum range for heating demand. Window performance was modelled using $U_{window,max} = 1.8$ W/m²K (improved condition) and $U_{window,min} = 0.9$ W/m²K (best-case performance). In this study, all existing windows were assumed to be replaced in window upgrades involved in renovation scenarios. To complement the absolute heating-demand ranges, the impact of each renovation scenario is expressed as a percentage reduction relative to the non-renovated baseline $HD_{baseline}$. Percentage reduction is calculated as:

$$\%\Delta HD = \frac{(HD_{baseline} - HD_{scenario})}{HD_{baseline}} \times 100 \qquad (1)$$

Where HD represents annual heating demand. This proportional view supports comparison across buildings with different baseline levels and clarifies the practical effect of each renovation package.

Results

Across both building series (317A and 464A) (Table 2), window-only and roof-only measures deliver modest heating-demand reductions. Full window replacement results in reductions of 12–14%, while roof insulation yields 13–28%. In contrast, wall insulation produces significantly larger reductions, ranging from 45% to 55%. Combinations involving wall insulation result in even higher performance gains. For both series, double measure (e.g., window and wall) achieves reductions of 57–64%, while full-envelope renovation reaches the highest overall savings at 68–75%.

Table 2: Heating demand reduction (%) relative to non-renovated baseline min/max range across buildings per series.

Scenario	464A (%)	317A (%)
Windows replaced	12–14	12–13
Roof insulated	14	13–28
Wall insulated	47–50	45–55
Window and roof	24–26	23–24
Window and wall	59–61	57–64
Wall and roof	58–62	56–66
Window, roof, and wall	68–73	69–75

The intervals in Table 2 show the minimum and maximum heating reductions across the entire building series (n=44), accounting for variations in geometry, orientation, and the 150-250 mm insulation thickness used in the simulations. The pattern observed in Table 2 is consistent with the incremental renovation sequence identified in the literature review. Window-only measures result in relatively modest reductions in heating demand and are typically associated with early-stage, maintenance-driven interventions.

In contrast, wall insulation and full envelope renovation lead to substantially larger reductions, reflecting their more comprehensive and capital-intensive nature. This gradual increase in reduction levels across measures supports the interpretation of heating-demand performance as an indicator of renovation depth.

Analysis of renovation impacts on heating demand (464A series)

Figure 2 summarizes the heating-demand distributions (kWh/m²·yr) for the 464A building series.

The reported intervals and violin densities represent the overall results obtained across the entire dataset of 26 buildings, capturing the full range of performance variations caused by building-specific geometry and orientation. Heating demand decreases consistently as renovation measures accumulate, indicating a consistent correlation between renovation depth and energy performance. The violin plots provide deeper insight into the data. The "width" of each violin illustrates the probability density of the data, while the median values identify the typical performance for a building in this series under each scenario.

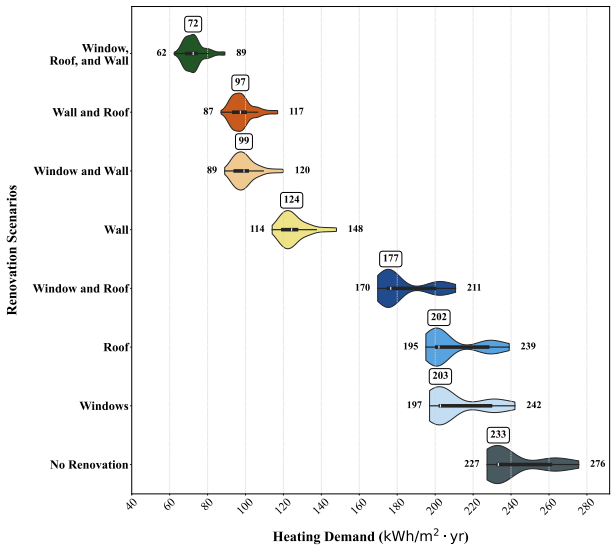

Figure 2: Heating-demand distributions (kWh/m²·yr) for renovation scenarios (464A series). The intervals and violin densities represent the overall results obtained across the entire building dataset.

However, despite the clear decrease in heating demand, most partial renovation states are not uniquely identifiable because their heating-demand ranges and densities overlap significantly. The yellow-orange shade range has been assigned to visualize wall measures better.

Influence of individual renovation measures

Wall (façade) insulation produces the most significant reduction in heating demand, forming a clearly lower performance band (114–148 kWh/m²·yr) compared to the non-renovated baseline (227–276 kWh/m²·yr). As shown in Table 2, this separation corresponds to a substantial 47–50% reduction. This shift is visually captured by the yellow-orange-shaded violins in Figure 2, where the sharp drop in the median to 124 kWh/m²·yr from 202-203(roof and window) highlights wall insulation as the key driver for lower heating demand.

In contrast, window replacement and roof insulation deliver more modest improvements. Full window replacement results in reductions of 12–14% (spanning 197–242 kWh/m²·yr with a median of 203 kWh/m²·yr), while roof insulation yields a 14% reduction (195–239 kWh/m²·yr with a median of 202 kWh/m²·yr). The blue-shaded scenarios exhibit substantial distribution overlap with each other and the baseline. The wide, irregular violins in Figure 2 show that single-measure upgrades affect buildings differently. Because of variations in size and orientation across the dataset, the impact of an upgrade can vary. This high variability makes these partial states (except wall insulation) difficult to distinguish from unrenovated buildings using heating-demand data alone.

Effects of combined renovation measures

Combining renovation measures further reduces heating demand, though several partial combinations remain difficult to distinguish. In particular, the window and wall (89–120 kWh/m²·yr) and wall and roof (87–117 kWh/m²·yr) scenarios fall within a nearly identical band. The medians for these two scenarios, 99 kWh/m²·yr and 97 kWh/m²·yr, respectively, indicate that once wall insulation is included, adding a second measure provides limited additional separation in heating-demand ranges. However, the distinct clustering of these two-measure scenarios provides strong evidence that wall insulation is present, making heating demand a reliable indicator for identifying wall-involved renovations. Although window replacement is common in practice, in this analysis, window upgrades are treated as a distinct scenario and are not assumed to be universally present across the building stock.

In contrast, full envelope renovation (window, wall, and roof) forms a clearly isolated, low-demand tier (62–89 kWh/m²·yr). With a median of 72 kWh/m²·yr, this scenario shows no overlap with any single-measure case. This clear separation indicates that deep renovation can be robustly identified from heating-demand data alone. These results align with the percentage reductions in Full window replacement results in reductions of 12–14%, while roof insulation yields 13–28%. In contrast, wall insulation produces significantly larger reductions, ranging from 45% to 55%. Combinations involving wall insulation result in even higher performance gains. For both series, double measure (e.g., window and wall) achieves reductions of 57–64%, while full-envelope renovation reaches the highest overall savings at 68–75%.

Table 2, where full envelope upgrades consistently deliver the highest performance gains across the entire building series.

Analysis of renovation impacts on heating demand (317A series)

Figure 3 shows broader ranges and stronger overlap across the partial renovation scenarios compared to 464A. Despite this increased variability, the data follow a consistent trend: heating demand decrease is proportional to the increase in renovation measures. The "width" of the violins in Figure 3 highlights higher densities, while the median values identify the typical performance for a building in this series.

Effects of Individual and Combined Measures (317A)

Wall (façade) insulation remains the primary driver of heating demand, shifting the median demand from 242 kWh/m²·yr(baseline) down to 137kWh/m²·yr, causing a reduction of approximately 45–55%. While combined measures yield larger absolute reductions, they remain partially non-unique (Figure 3). For instance, the window-and-roof scenario displays a wide range (163–240 kWh/m²·yr) that overlaps heavily with both the window-only state and the non-renovated baseline. This reinforces the finding that envelope upgrades excluding wall insulation are difficult to identify reliably from heating demand data alone. In contrast, wall-involved combinations reduce demand more substantially and consistently. Scenarios such as window-and-wall (76–136 kWh/m²·yr) and wall-and-roof (73–140 kWh/m²·yr) occupy nearly identical low-demand tiers. This suggests

that once wall insulation is implemented, adding a secondary measure provides limited additional separation in the demand range. However, full envelope renovation (window, wall, and roof) forms the lowest and most distinct band (54–104 kWh/m²·yr).

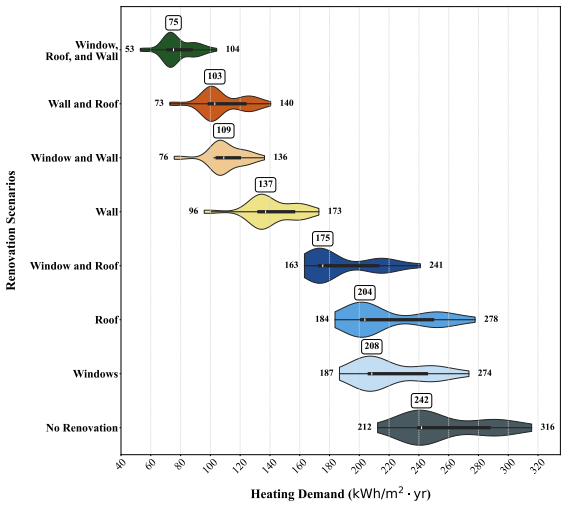

Figure 3: Heating-demand distributions (kWh/m²·yr) for renovation scenarios (317A series). The intervals and violin densities represent the overall results obtained across the entire building dataset.

Energy-Based Tiering and Classification Logic

The heating-demand distributions across both series (Figure 2 and Figure 3) indicate that while renovation depth generally correlates with heating demand reduction, specific partial renovations often overlap. To translate these simulated distributions into a practical screening tool, a consistent classification logic was applied to both the 464A and 317A series. While building-specific geometry and orientation create overlapping ranges, the following two rules were established to ensure robust categorization:

Prioritization of Common Practice: Since window replacement is the most frequent initial renovation measure in Estonia, the overlapping intervals between the non-renovated baseline and window-only ranges are intentionally assigned to Tier 2. By setting a high threshold for Tier 1, we minimize the risk of misclassifying partially renovated buildings as entirely unrenovated.

Median-Based Classification: For deeper renovations (Tiers 3 and 4), where ranges often intersect, boundaries are defined using median values rather than absolute ranges. Medians provide high-confidence statistical centers that allow for distinct classification despite the overlapping "tails" of the distributions. For the 464A series, the Tier 3 wall-involved median (99 kWh/m²·yr) is significantly higher than the Tier 4 deep-renovation median (72 kWh/m²·yr) (Figure 2). Similarly, for the 317A series, the wall-involved median (103 kWh/m²·yr) is clearly distinguished from the full-envelope median (72 kWh/m²·yr). Using this logic, typology-specific thresholds were established to categorize buildings into four distinct operational tiers (Table 3).

Table 3: Heating-demand tiering ranges (kWh/m²·yr) for renovation depth classification

Renovation Tier	464	317
Tier 1	≥242	≥275
Tier 2	170-240	163-274
Tier 3	87-147	104-162
Tier 4	<87	<103

From Table *3*, the tiers are as follows:

- **Tier 1** = None: non-renovated baseline
- **Tier 2**= Partial: Window and/or roof only
- **Tier 3** = Partial: Wall-involved renovation
- **Tier 4** = Deep: Full envelope renovation

Robustness of Heating-Demand Tiers

To ensure that the identified heating-demand tiers and their overlapping boundaries reflect the physical relationship between envelope measures and renovation depth rather than modeling artifacts, we performed two targeted checks on the 464A building series. First, we tested the stability of the boundaries against highly optimistic envelope-performance assumptions. Second, we isolated the effects of geometric variability by analyzing a subtype with identical inputs.

Impact of Optimistic U-Values

To verify the stability of the identified heating-demand tiers, we performed a robustness check on the 464A building series. We evaluated the theoretical best-case scenario for the same buildings from the 464 series using optimistic envelope values (U_{window} = 0.9; $U_{wall,min}$= 0.17 and U_{roof} = 0.08 W/m²K). Figure 4 shows the largest absolute reductions occurring in combined renovation scenarios.

Figure 4 demonstrates that every renovation scenario involving wall insulation (green) results in a non-overlapping heating-demand tier. This isolation is more pronounced under optimistic assumptions than in the realistic ranges (grey). While overlaps continue in the orange categories, the actual area of overlap is significantly reduced compared to the grey. Despite these absolute shifts, both cases follow a consistent logic: as envelope renovations intensify, heating demand decreases. This proves that the relationship between renovation depth and demand reduction is a stable physical property of the building series, rather than an artifact of specific U-value inputs.

Impact on Type-level (1-464A-1kE)

To isolate the effect of geometric variability, the same renovation scenarios were applied to subtype 1-464A-1kE. Because buildings within this subtype share identical geometric and envelope parameters, the baseline heating demand remains constant at 233 kWh/m²·yr (Table *4*).

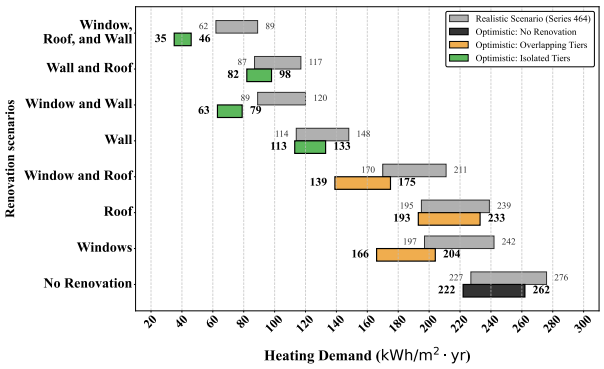

Figure 4: Robustness check (464A series) heating-demand tiers. Grey bars (realistic) vs. colored bars (optimistic U-values) show a consistent lower demand proportional to renovation scenarios. Orange signifies overlapping tiers, and green bars are non-overlapping tiers. Values represent min/max heating demand (kWh/m²·yr).

This deterministic result confirms that the wide variability observed at the broader series level is fundamentally driven by building-to-building geometric differences rather than modeling artifacts. For the renovated states, the remaining "Highest-Lowest" variation shown in Table *4* reflects envelope-performance levels (U-values). The "Highest" demand values corresponds to standard performance inputs ($U_{window,max}$ = 1.8; $U_{wall,max}$= 0.21 and $U_{roof,max}$ = 0.21 W/m²K), while the "Lowest" demand scenario corresponds to higher-performance specifications (U_{window} = 0.9; $U_{wall,min}$= 0.17 and $U_{roof,min}$ = 0.17 W/m²K).

Table 4: Heating demand (kWh/m²·yr) for subtype 1-464A-1kE, with identical geometric inputs and varying envelope U-value.

Variables	Highest	Lowest
No Renovation Applied	233	233
Windows Replaced	203	182
Wall insulation	125	120
Roof insulation	202	198
Window Replaced and Wall Insulated	99	74
Window Replaced and Roof Insulated	177	152
Wall Insulated and Roof Insulated	98	90
Window, Roof, and Wall	73	45

While real-world buildings certainly show performance variation due to partial window replacements, workmanship quality, and operational differences, those exact mechanisms are not explicitly modelled here. Instead, the high-low U-value intervals are used to represent those plausible real-world performance variations and construct realistic heating-demand ranges for each envelope upgrade.

Compared to the broader series level, the type-level analysis demonstrates significantly fewer overlapping ranges (green colors for non-overlap scenarios in Table 4), allowing for cleaner renovation tiering. However, even at this more granular type level, some overlaps remain. As marked in Table 4, these fall into two groups: single-measure overlaps (orange: windows [182–203 kWh/m²·yr] vs. roof [198–202kWh/m²·yr]) and combined-measure overlaps (blue: window and wall [74–99kWh/m²·y] vs. wall and roof [90–98kWh/m²·y]). This persistent overlap confirms that heating demand alone is insufficient to uniquely identify specific renovation states, suggesting that supplementary information (e.g., renovation records or imagery) may be required to distinguish between overlapping states.

Small Vignette:

The proposed workflow (Figure 5) is the first step of a decision-support pipeline using a rule-based classification. The tool takes building data (ID, series, and heating demand) as inputs, maps typology-specific rules, and assigns each building to a renovation-depth tier (none/partial/deep). To assist in decision-making, the output includes a confidence proxy based on the building's proximity to the nearest typology threshold. The workflow can classify a national (or large-scale) building stock into heating-demand tiers, supporting identification of deeply renovated buildings and prioritization of renovation targeting across large scales.

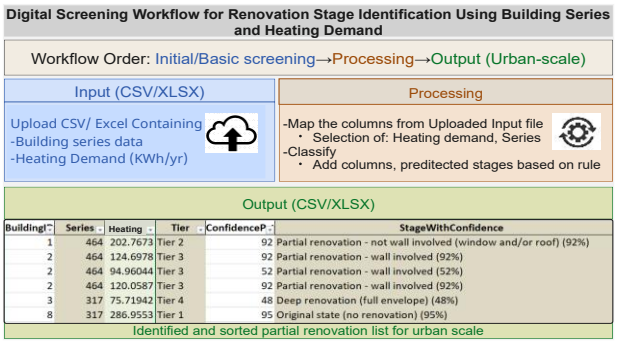

Figure 5: Digital screening workflow to classify renovation stage from building series and energy use (CSV/XLSX input and output)

By automatically post-processing heating-demand patterns as output, this workflow fills gaps in missing renovation records and establishes the operational logic for a dynamic archetyping framework.

Discussion

The findings demonstrate how simulated heating-demand patterns can be translated into renovation-depth indicators at the stock level. By combining series-level modelling, subtype validation, and robustness testing, the study establishes the analytical basis of a dynamic energy-profiling framework.

Across both building series, heating demand decreases proportionally with renovation depth, supporting a coarse renovation-depth (none/partial/deep) classification. However, substantial overlap among partial renovation scenarios shows that heating demand alone cannot uniquely identify specific intermediate measures (e.g., window-only vs roof-only). This happens because an average 1 °C increase in indoor temperature can raise

heating demand by 15% (Hamburg et al., 2020), thereby masking the 12-14% savings gained from window replacement. Consequently, when demand falls within overlapping ranges, use the logic from Table 3, or use the interactive evidence-based extension (Figure 6) to refine the classification.

A key finding is that wall insulation represents the clearest threshold intervention. In both 464A and 317A, wall-involved scenarios consistently shift buildings into a lower heating-demand tier than window-only or roof-only upgrades. While heating demand cannot fully resolve intermediate measures, it provides strong evidence for identifying wall-involved renovation states.

The robustness analysis further demonstrates that while optimistic envelope assumptions shift absolute heating demand downward, the qualitative patterns remain stable: wall insulation remains the dominant threshold intervention, deep renovation remains identifiable, and the overlap among shallow partial renovation states persists. This indicates that uncertainty among partial renovation states is not an artifact of a specific parameter choice, but rather a structural limitation of energy-only classification.

The type-level analysis is included as a controlled validation case and demonstrates how the approach could be refined when reliable subtype data are available. Because the subtype buildings share identical geometric and envelope input parameters, the baseline heating demand remains constant and does not form a range. Under these conditions, renovation scenarios also produce single deterministic values, as non-envelope assumptions are held constant (Table 4). The only remaining variation reflects differences in envelope U-value levels, resulting in a narrower and clearly defined performance range. This confirms that the broader ranges observed at the series level arise from building-to-building geometric and input heterogeneity rather than modelling instability. When reliable subtype data are available, the tiering approach can be applied at that level to improve classification accuracy. While absolute tiering ranges are series-specific, the methodology is transferable to other building stocks by using specific building geometry as the primary analytical unit to derive new, series-specific medians.

Limitations

This study is a simulation-based proof-of-concept using ReST-derived heating demand under predefined envelope scenarios. Ventilation system type can significantly affect heating demand; incorporating alternative ventilation strategies (e.g., exhaust vs balanced with HRV) may change absolute demand values. Here, ventilation was held constant to focus on envelope measures. In this study, operational and behavioural assumptions were held constant across buildings, which can affect heating consumption. Furthermore, in real buildings, uncertainty arises from (i) EBR data inaccuracies (Iliste et al., 2023), (ii) operational and occupant behavior (e.g., thermostat setpoints, ventilation operation, window airing) (Hamburg et al., 2020; Hamburg and Kalamees, 2019), and (iii) physical degradation and workmanship-related performance gaps (Hamburg et al., 2020; Hamburg and Kalamees, 2019; Iliste et al., 2023) (e.g., air leakage, insulation defects). These factors can shift heating demand from one renovation tier to another. Finally, as tier thresholds are series and heating-demand-dependent, transferability requires typology data and is limited in cooling-dominated regions, such as Southern Europe, without first adjusting the models.

Future Work

Future research will focus on calibrating this classification logic against real-world performance gaps by validating simulated results against measured heating data. This will include refining typology definitions through automated façade feature recognition and testing

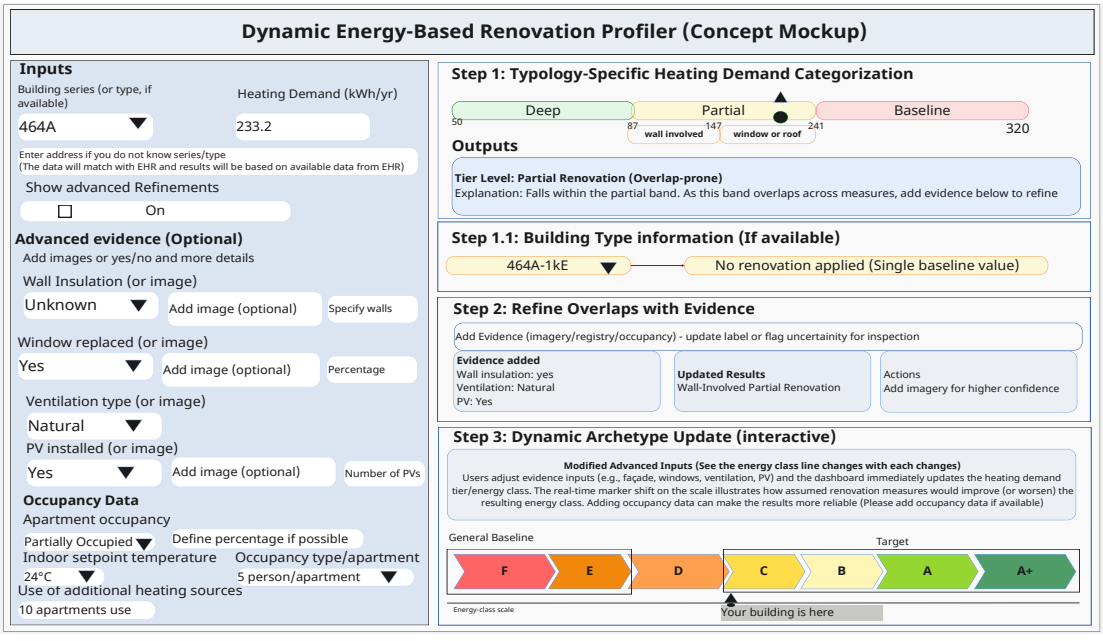

Figure 6: Concept mockup of an interactive Energy-Based Renovation Profiler

a wider variety of ventilation strategies (e.g., heat recovery variants). Furthermore, integrating heterogeneous data such as occupancy data and imagery-based assessments, through Bayesian calibration, offers a promising pathway to reduce UBEM performance gaps further (Wang et al., 2020). These steps will transition the current proof-of-concept into a reliable, multi-source decision-support tool for large-scale renovation.

Interactive heating-demand based tiering (mock-up)

The proposed heating-demand tiering provides a practical first step for archetype updating when renovation records are missing: buildings can be assigned a typology-specific renovation-depth tier from heating demand, with deep renovation being the most reliably detectable. However, overlap among partial renovation states means that energy-only classification should not be used to confidently infer specific measures (e.g., window-only versus roof-only). To address this limitation, we outline a conceptual interactive heating-demand-based tiering dashboard (Figure 6). The interface translates typology-specific thresholds into a decision-support workflow: users enter a building series and baseline heating demand to obtain an initial renovation-depth tier (none/partial/deep). Optional evidence inputs (e.g., ventilation type, registry attributes, occupancy behavior, or image-based façade) can then be incorporated to refine the classification. Users may test alternative renovation assumptions (façade, windows, roof, ventilation, PV) and observe how the assigned tier changes. This interactive layer allows rapid comparison of scenarios and highlights how additional evidence or renovation choices influence the inferred renovation status and energy class. This illustrates how typology-specific thresholds and supplementary evidence could be combined within a practical decision-support setting.

Conclusions

This study demonstrates that heating demand can be used to classify renovation depth (none/partial/deep) in Soviet-era multifamily buildings. Series-level analysis captures realistic stock heterogeneity, while subtype-level validation confirms deterministic model behaviour under identical inputs. The findings are a practical step toward establishing the methodological foundation for a dynamic archetyping framework, defining the analytical logic required for future integration with measured energy data and auxiliary building information within a decision-support environment.

INTEGRATING INDICATOR REVIEW AND SOCIAL NETWORK ANALYSIS FOR SUSTAINABLE PUBLIC INFRASTRUCTURE

Anagha Divakaran, Ann Francis
Department of Civil and Environmental Engineering,
Indian Institute of Technology Delhi, New Delhi, 110016, India

Abstract

The construction sector's current sustainability frameworks are centered around private buildings, with little consideration for public infrastructure. This study reviews global rating frameworks to address these gaps and examines 629 indicators grouped into quantitative and qualitative categories. Social Network Analysis (SNA) is applied to examine the relationships among indicators, identifying 113 distinct indicator groups with a high modularity of 0.975, suggesting weak cohesion and fragmentation among the frameworks. Based on network structure centrality analysis, refined 56 cross-cutting indicators are identified. A three-level hierarchical framework is developed to select and make decisions about indicators for sustainable public infrastructure in India.

Introduction

Infrastructure development plays a significant role in the nation's overall development. Several studies confirm that the infrastructure has an important and beneficial impact on productivity, output, and long-term growth rates (Boix-Cots, Pardo-Bosch and Pujadas, 2023). Beyond economic performance, public infrastructure systems enable the delivery of critical services essential for social justice, public health, economic productivity, and overall quality of life. However, the long-term viability of these services is increasingly threatened by climate change, making sustainability and climate resilience central concerns for infrastructure planning and operation. The operational and structural integrity of the infrastructure is at risk due to the growing frequency and intensity of extreme weather events, including heatwaves, hurricanes, droughts, and floods. (Das, 2025) found that these vulnerabilities lead to service disruptions, economic losses, and increased social inequality in impoverished areas. Sustainability encompasses an assessment of environmental conservation, economic feasibility, and social equity throughout the life cycle of an asset (Sánchez-Silva and Baker, 2024). On the other hand, climate resilience involves planning for, responding to, and recovering from climate-based disruptions while maintaining services (Ferrari, 2020). Incorporating both sustainability and climate resilience into decision-making is critical for developing a sustainable and climate-resilient infrastructure (Cardin, Mijic and Whyte, 2023). This paper presents a conceptual framework that connects short-term development and performance metrics with long-term sustainability and climate resilience goals. The findings aim to assist policymakers, planners, infrastructure agencies, and asset owners by providing a cohesive method for indicator selection, benchmarking, and decision-making in public infrastructure planning and policy formulation. The following section discusses the study's literature background.

Research Background

The rating framework is not homogeneous in assessing environmental, social, and economic aspects across project lifecycles (Khan and Henschel, 2024). Widely used frameworks such as LEED, GRIHA, and IGBC primarily support environmental performance in buildings, focusing on aspects such as energy efficiency, water conservation, and indoor environmental quality in both commercial and residential buildings (Leal *et al.*, 2024), while GRIHA and IGBC focus on integrated habitat assessment and green townships according to the Indian climatic and regulatory context (Kumar, Santara and Banerji, 2020).

However, these frameworks have a drawback in that they primarily focus on private-sector buildings and individual assets with relatively short ownership cycles (Liu *et al.*, 2018). Also, these frameworks do not account for the unique characteristics of public infrastructure, including networked structures (e.g., highways, water grids), multi-decadal lifecycles, multi-level governance coordination, climate risk exposure, and long-term resilience (Liu *et al.*, 2018; Sanad *et al.*, 2025).

There are also infrastructure-centric rating frameworks globally, such as ENVISION, CEEQUAL, Greenroads, SuRe, and the IS Rating tool (Mehraban *et al.*, 2025). However, upon arrival in India, no overarching system exists for rating public infrastructure across environmental, social, economic, and resilience dimensions. Existing rating frameworks, such as GRIHA and IGBC, are for buildings or newly developed highway adaptations and do not provide a comprehensive, integrative, and harmonising system for the entire infrastructure (Kumar, Santara and Banerji, 2020; Jain and Ananda, 2024). Consequently, the existing global rating frameworks, such as ENVISION, CEEQUAL, and IS rating tools, show more bias towards the environmental dimension, and the least concentration on other

dimensions of sustainability, such as social and economic (Diaz-Sarachaga *et al.*, 2016).

The significant research gap in developing countries like India is the lack of an integrated, coherent, and consistent framework that integrates environmental, social, economic, and resilience aspects across the lifecycle of public infrastructure. Moreover, developed frameworks in advanced economies fail to include location-specific vulnerabilities, climate risks, or multi-level governance (Diaz-Sarachaga *et al.*, 2016; Kumar, Santara and Banerji, 2020) . Finally, limited use of network analysis to map interdependencies among indicators, stakeholders, and vulnerabilities hinders the transition from isolated assessments to holistic, adaptive decision-making (Khan and Henschel, 2024).

As a result, they fall short in addressing long-term performance, resilience, and adaptability under climate uncertainty, which are central to public infrastructure systems (Sanad *et al.*, 2025). Therefore, there is a lack of harmonisation of sustainability indicators across different global rating systems, such as LEED, BREEAM, and Envision. Although these frameworks include overlapping environmental, social, and economic indicators, they remain fragmented and non-standardised due to their origins in building-scale and private-sector contexts (Mansell *et al.*, 2019). This fragmentation in the industry has negative implications for sustainability assessment in public infrastructure, due to the lack of robust benchmarking, cross-framework comparisons, and comprehensive integration into decision-making (Liu *et al.*, 2018; Mehraban *et al.*, 2025).

To address these challenges, this study combines a systematic review of indicators with Social Network Analysis (SNA) to better understand how sustainability and resilience indicators relate to one another. SNA uses network-based methods to examine patterns, connections, and groupings within complex systems (Rousseau, 2002). In research concerning infrastructure sustainability, SNA elucidates intricate interconnections among indicators, stakeholders, and vulnerabilities, evolving from discrete assessments to comprehensive, adaptive frameworks that identify critical linkages and systemic issues (Khan and Henschel, 2024). While SNA has been applied in construction management research, including supply chain coordination, site operations, and health and safety (Wang, Zhang and Lu, 2018). Its use in structuring sustainability and resilience indicators for public infrastructure remains limited. Therefore, this study adopts a system-oriented perspective to examine public infrastructure as an interconnected network. Studies applying SNA in similar contexts include those that integrate vulnerability indicators with stakeholder objectives in sustainable infrastructure decision-making (Khan and Henschel, 2024). By combining a comprehensive review of sustainability and resilience indicators with Social Network Analysis (SNA), the research aims to reveal how indicators relate to one another, identify gaps and overlaps, and identify which themes dominate current assessment practices. The study further seeks to reorganise these indicators into meaningful clusters that reflect environmental, social, economic, and resilience indicators within the Indian context.

Methodology and Experiment

A four-phase methodology to develop a 3-level hierarchical conceptual framework is proposed, as shown in *Figure 1*.

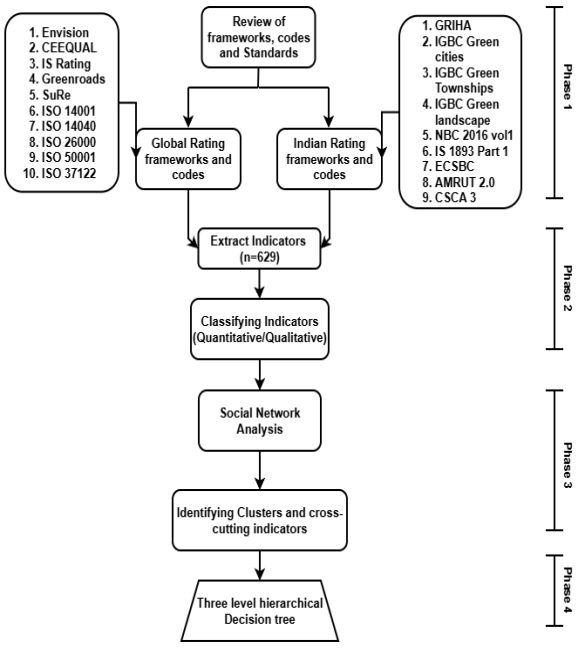

Figure 1: Framework for the development of a 3-level hierarchical decision tree.

Phase 1: Review of Existing Frameworks, Codes, and Standards

A structured review was conducted to identify and analyse sustainability and resilience assessment systems relevant to public infrastructure. This review targets formal rating systems, international standards, national codes, and policy frameworks that define indicator-based assessment criteria. The review covered five major categories:

i. Global sustainability rating systems such as CEEQUAL, SuRe, IS rating, and Greenroads (ICE, 2007; University of Washington, 2011; GIB, 2018; ISCA, 2018; ISI, 2018),
ii. Associated international standards such as ISO 14001:2015, BS EN ISO 14040:2006, ISO 26000; ISO 50001, ISO/CD 37122 (BIS, 2006; ISO, 2011; ISO/TC, 2012),
iii. Indian sustainability rating frameworks such as GRIHA, IGBC (Green township rating, Green cities, and Green landscape rating) (IGBC, 2010, 2013, 2015; TERI, 2010),
iv. Indian building and infrastructure codes such as NBC 2016, ECSBC 2024, & IS 1893 Part 1:2016 (BIS, 2016; IS, 2016; BEE, 2024),
v. Indian policy frameworks, including AMRUT 2.0 and the Climate Smart Cities Assessment Framework 3.0 (MOHUA, 2021, 2022).

Table 1 represents the classification of the Existing Global and Indian frameworks, codes, standards, and policies.

Table 1: Global and Indian sustainability rating systems, codes, and policy instruments

Global rating	Global codes	Indian rating	Indian codes	Indian policies
CEEQUAL	ISO 14001:2015	GRIHA	NBC 2016 VOL 2	AMRUT 2.0
Greenroads	BS EN ISO 14040:2006	IGBC Green Cities	IS 1893 Part 1:2016	Climate Smart Cities Assessment Framework
Envision	ISO 26000	IGBC Green Landscape	ECSBC 2024	
IS Rating	ISO 50001	IGBC Green Townships		
SuRe	ISO/CD 37122			

Frameworks were selected based on their relevance to public infrastructure, including sustainability and climate resilience dimensions, and on the availability of clearly defined indicators.

Phase 2: Indicator Extraction and Classification

In this Phase, sustainability and climate-resilience indicators identified in Phase 1 were extracted and compiled in an Excel database for further analysis. The extracted indicators were then classified into quantitative and qualitative categories to facilitate systematic analysis and standardisation. Indicators were harmonised to remove duplication while retaining their conceptual intent. Quantitative indicators represent measurable variables such as percentages of emission reductions, energy efficiency metrics, and lifecycle costs, while qualitative indicators capture aspects such as stakeholder engagement, community-influenced impact evaluations, and adaptability planning judgments. The quantitative indicators were subsequently used for Social Network Analysis.

Phase 3: Network Construction and Analysis

In this phase, Social Network Analysis (SNA) was used to analyse the relationships among the quantitative sustainability and climate resilience indicators identified in Phase 2. The process involved the following steps.

i. Network construction where each indicator is represented as a node and edges are established based on co-occurrence across multiple rating and assessment frameworks.
ii. Network visualisation and analysis using Gephi, applying the ForceAtlas2 layout to reveal structural patterns.
iii. Community detection or modularity analysis to identify clusters of closely related indicators.
iv. Centrality analysis to identify influential and cross-cutting indicators within the network.

SNA was particularly useful because it enables quantifying inter-indicator relationships, identifying tightly connected clusters, and influential indicators through centrality-based measures. These properties are critical for prioritising indicators that play a bridging or coordinating role in integrated sustainability and resilience decision-making.

Key SNA metrics, such as centrality, density, and modularity, were used to interpret the network structure and identify key structural patterns.

Phase 4: Framework Development

In this phase, the results obtained from SNA were synthesised to develop the conceptual framework. Indicator clusters identified through modularity analysis were interpreted as thematic groupings representing different dimensions of sustainability and climate resilience. The process involved the following steps:

i. Identification of thematic clusters based on community detection results.
ii. Selection of key indicators using centrality measures to identify cross-cutting and influential indicators.
iii. Refinement of indicators based on relevance to the Indian public infrastructure context and removal of redundancy.
iv. Development of a hierarchical structure organising indicators into three levels: indicators, criteria, and requirements.

Based on this process, a conceptual decision framework was established to arrange indicators into coherent thematic hierarchies, thereby facilitating integrated assessment and decision-making for India's sustainable, climate-resilient public infrastructure.

Results and Discussion

Indicator Dataset and Classification

A total of 629 sustainability and climate-resilient indicators were identified from the structured review of global and Indian frameworks, codes, standards, and policy documents relevant to public infrastructure. This comprehensive set of indicators encompasses a broad spectrum of sustainability considerations, including environmental, social, and economic dimensions relevant to infrastructure development.

A total of 387 quantitative and 242 qualitative indicators were identified. To examine the evolution of these frameworks and standards, the temporal distribution of their evolution was studied.

Figure 2 presents a timeline figure illustrating the temporal distribution and contextual diversity of the reviewed global and Indian frameworks, codes, and policy initiatives. The X-axis represents the years from 2000 to 2025, while the Y-axis is classified into five categories: global frameworks, Global codes, Indian

rating systems, Indian codes, and Indian policy documents. The graph depicts the evolution of sustainable governance at the global and national levels. Global framework development was dominated in the early to mid-2000s, reflecting the initial international push for sustainability, climate action, and infrastructure evaluation. Global codes became more prominent between 2008 and 2020.

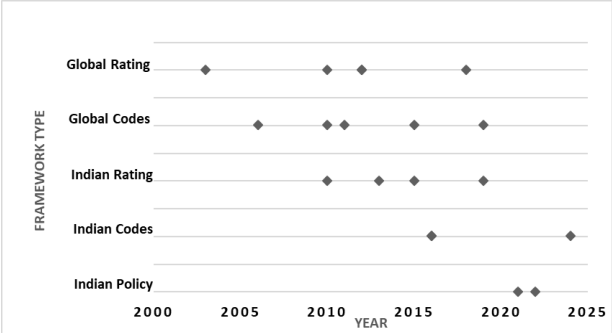

Figure 2: Temporal distribution of global and Indian frameworks, codes, and policy initiatives across different categories.

In the Indian context, rating systems emerged around 2010. This trend indicates the localisation and adaptation of global sustainability concepts into performance-based assessment tools with a specific focus on the building sector, rather than infrastructure systems. Indian codes appear later, primarily after 2015, reflecting a gradual institutionalisation of sustainability principles into formal building regulations and standards. After 2020, the Indian policy, which emphasises the growing role of buildings as key levers for sustainability, decarbonisation, and climate resilience, while broader infrastructure-scale integration remains comparatively limited.

Structural Properties of the Indicator Network

The indicator network was developed by representing each sustainability indicator as a node, with edges indicating co-occurrence across the reviewed frameworks. This strategy enabled systematic mapping of indicator interdependence and redundancy, revealing underlying thematic groupings and highly influential individual indicators. The network was constructed using 387 quantitative indicators identified in phase 2. The indicator network comprises 387 nodes, representing all identified sustainability and climate-resilient indicators. The network exhibits limited connectivity, with an average degree of 1.622, indicating that most indicators are connected to only one or two others. The graph density is very low (0.3%), indicating that only a small fraction of possible connections exists. The diameter of 8 and the average path length of 2.554 indicate efficient local connectivity within the clusters. Multiple connected components exhibited siloed groupings, indicating incomplete integration across the frameworks.

Community Detection and Framework Fragmentation

To understand the internal structure of the indicator network and identify key indicator clusters, community detection was performed using a modularity-based algorithm as discussed in Phase 3. This method enables the identification of clusters of indicators that are more densely connected to each other than to the rest of the network.

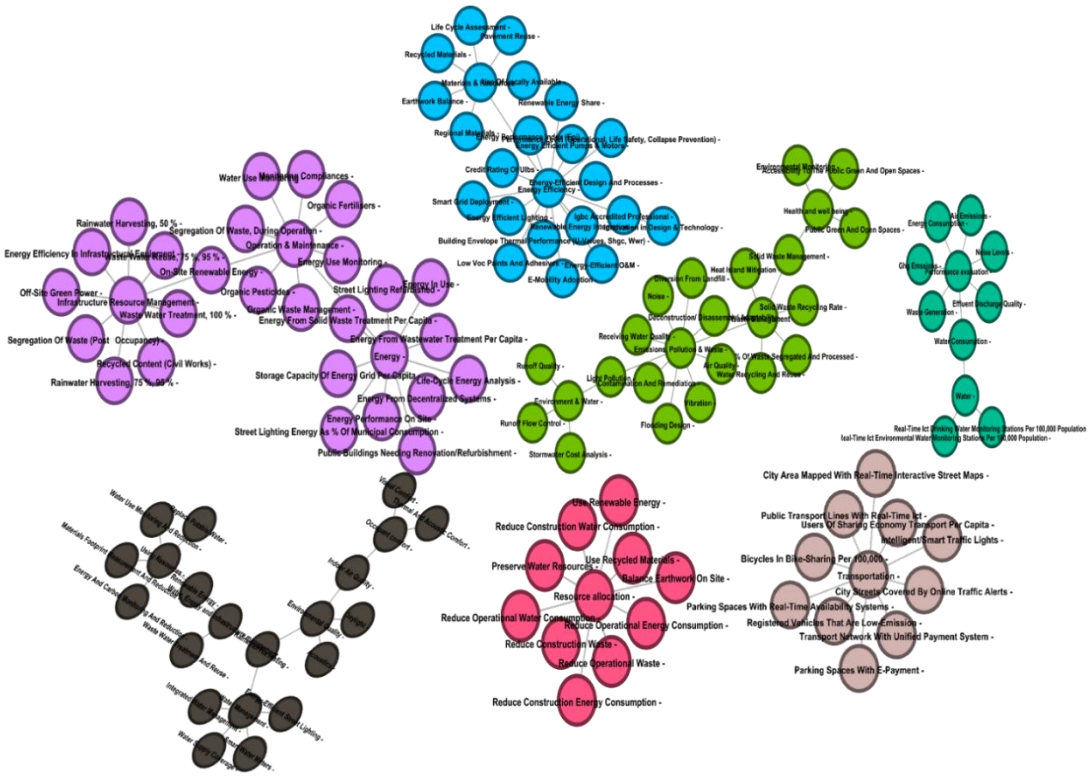

Figure 3: Community structure of the sustainability indicator network showing modularity-based clusters.

The analysis resulted in a high modularity value of 0.974, indicating a strong community structure within the network. A total of 113 distinct communities were identified, suggesting that the indicator network is highly fragmented into multiple, relatively independent groups. This high modularity value indicates strong clustering and limited interaction between groups, confirming a fragmented indicator structure. This highlights the nature of the existing sustainability assessment framework, given the large number of detected communities. Rather than forming an integrated, cohesive assessment system, the indicators tend to cluster by specific thematic domains, sectoral focuses, or framework origins. This implies that current frameworks do not adequately address interdependence among environmental, social, and economic dimensions.

Figure 3 illustrates the community structure of the indicator network, where distinct clusters are visible as separate groupings of indicators. Different groups of indicators were identified by modularity-based community detection, with each color representing a distinct cluster. Indicators in the same color category are more closely related than indicators in other groups.

Identification of Cross-Cutting Indicators

To address the fragmented community structure identified in the indicator network, cross-cutting indicators were identified using betweenness centrality as the primary metric. Based on this analysis, the first 15 indicators were selected to illustrate cross-cutting aspects from the total set of 387 quantitative indicators. These indicators exhibit the highest betweenness centrality values and span multiple modularity classes, confirming their role in bridging distinct indicator communities. Closeness centrality was examined as a supporting measure to contextualise their overall connectivity within the network.

Table 2 presents the identified cross-cutting indicators and their associated network metrics. These indicators provide an empirical basis for integrating fragmented sustainability frameworks and for developing a structured, hierarchical conceptual framework for public infrastructure. These indicators served as key inputs to the development of the conceptual framework presented in the subsequent section.

Table 2: Cross-cutting sustainability indicators identified using network analysis.

Conceptual Framework for Sustainability and Climate-Resilient Infrastructure Assessment

Based on the results of the network analysis, a conceptual framework was developed to support the assessment of sustainability and resilience in public infrastructure in the Indian context.

From the Modularity-based analysis, distinct thematic clusters were identified, and indicators were grouped based on their thematic similarity. These were further examined to identify key indicators using centrality measures. Based on their structural importance, relevance to the Indian context, and to avoid redundancy. A refined subset of 56 indicators was identified from the clustered network based on centrality analysis, thematic relevance, and contextual suitability. The framework is structured into three levels: indicators, criteria, and requirements, to enable systematic aggregation, comparison, and decision support. The framework is designed to support users in selecting indicators based on project-specific priorities by focusing on the refined subset of 56 indicators, which represent the most structurally influential and cross-cutting indicators identified through centrality analysis. Users can further tailor this subset by selecting relevant thematic clusters aligned with project goals and contextual requirements. *Figure 4* represents the conceptual framework.

By combining fragmented indicator groupings and prioritising system-level, cross-cutting indicators, the framework creates a consistent structure that can be applied to various public infrastructure sectors and

decision-making contexts. At the highest level, criteria are consolidated into five broad requirements: (R1) Management and Governance, (R2) Social Well-being and Inclusivity, (R3) Environment and Resource Efficiency, (R4) Energy and Infrastructure, and (R5) Climate Resilience. These requirements serve as modular assessment dimensions that represent strategic sustainability and resilience goals.

At the lowest level, indicators represent measurable variables that capture the institutional, social, environmental, infrastructural, and resilience-related attributes of infrastructure systems.

These indicators are organised into criteria (C), which serve as intermediary aggregation units that represent distinct functional categories. Criterion-level aggregation allows normalisation and consolidation of heterogeneous indicators while preserving thematic coherence. The matrix-based layout of the framework facilitates cross-dimensional evaluation, allowing indicators under a single requirement to contribute to multiple criteria and enabling interlinkages between sustainability and resilience dimensions. Overall, the framework provides a transparent medium for evaluating, summarising, and benchmarking infrastructure projects. Unlike conventional frameworks that present static and often independent indicator lists, the proposed approach explicitly captures interdependencies among indicators, enabling the identification of cross-cutting indicators that enhance integration, reduce redundancy, and improve the coherence of sustainability assessment. It is intended to support evidence-based decision-making, policy formulation, and the prioritisation of interventions to enhance sustainability and climate resilience in public infrastructure systems. The framework enables users to systematically select and prioritise indicators based on their structural importance, thematic relevance, and alignment with project-specific requirements.

Implications for Practice and Research

Existing sustainability assessment frameworks are often fragmented, making decision-making complex and inconsistent across projects. This study provides a structured approach to identify and prioritise indicators using network-based metrics such as centrality, enabling practitioners, including project managers, planners, and policymakers, to focus on the most influential and cross-cutting indicators. The proposed three-level hierarchical framework facilitates systematic selection, aggregation, and comparison of indicators aligned with project-specific requirements, thereby supporting more transparent, consistent, and evidence-based decision-making in public infrastructure planning and evaluation.

From a research perspective, this study demonstrates the applicability of Social Network Analysis as a replicable, data-driven approach for examining interdependencies among sustainability indicators. The framework establishes a foundation for future work on indicator weighting, validation, and integration with multi-criteria decision-making methods, while also opening avenues for extending the approach to different infrastructure contexts and geographic settings. Overall, the study bridges the gap between indicator identification and practical application by offering a structured, scalable approach to sustainability assessment in infrastructure projects.

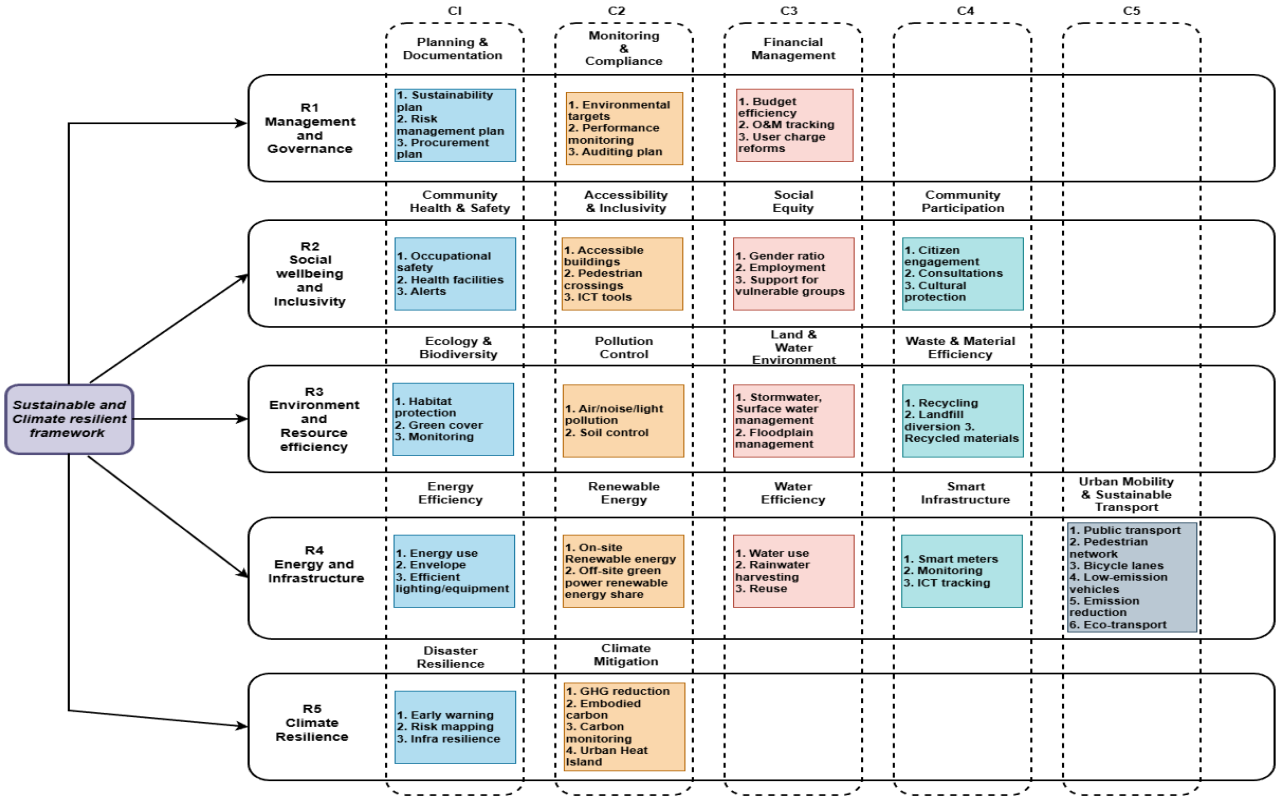

Figure 4: Conceptual sustainability and climate-resilience assessment framework illustrating the hierarchical organisation of indicator-level inputs into criteria and requirement-based modules for integrated evaluation of public infrastructure systems

Limitations and Future Research

On the one hand, this work proposes a conceptual framework for classifying sustainability indicators for public infrastructure. However, the framework is not validated through stakeholder engagement or real-world case applications, and no indicator weighting is performed in this study.

Additional research is required to validate and improve the suggested framework through expert consultation and stakeholder participation. Multi-criteria decision-making methods, such as the Analytic Hierarchy Process, can be employed to assign indicator weights and operationalise the framework. Furthermore, the framework could be extended to a representative set of case studies on public infrastructure projects in India to assess its practical usability and robustness. Periodic amendments to the indicator network should also be made to account for changes in sustainability priorities and climate resilience considerations.

Conclusions

This research develops a conceptual decision framework for sustainable and resilient public infrastructure in India by examining the structure and integration of existing sustainability indicators. A systematic review of global and Indian frameworks, codes, standards, and policy documents identified 629 indicators, which were classified as quantitative and qualitative. The relationships among the quantitative indicators were analysed using Social Network Analysis. The results reveal a highly sparse and fragmented indicator network with very high modularity of 0.974, indicating strong internal categorisation but weak cross-dimensional integration. This structural fragmentation points to limitations in prevailing sustainability frameworks, particularly in their support for integrated assessment of public infrastructure.

To address this limitation, the study identifies a focused set of cross-cutting indicators using centrality-based measures. These indicators capture key interconnections across multiple sustainability dimensions and provide a basis for improving coherence and integration. Based on the modularity analysis, indicators were grouped into different thematic clusters, and a refined subset of 56 indicators was identified from these clusters using centrality measures. Building on this insight, a conceptual decision framework is proposed that reorganises disjointed indicator sets into a context-sensitive structure suited to Indian public infrastructure. The framework supports transparent multi-criteria decision-making and provides a methodological and practical foundation for developing integrated, consistent, and climate-resilient infrastructure assessment and rating systems.

This is an ongoing study, and future work will focus on empirical testing, stakeholder engagement, and operational refinement of the proposed framework. The performance of the proposed framework can be benchmarked against existing frameworks through comparative case studies, evaluating criteria such as reduction in indicator redundancy, consistency in decision outcomes, and the ability to capture cross-dimensional linkages in sustainability assessment. The proposed framework benefits policymakers, infrastructure agencies, planners, asset owners, and researchers by providing a transparent, integrated basis for sustainability- and resilience-informed decision-making and assessment of public infrastructure.

FROM INSPECTION TO DIGITAL PASSPORT: TRACING THE PROVENANCE OF TESTING DATA OF CONCRETE COMPONENTS FOR CIRCULAR REUSE

Lukas Guntermann[1], Nina Krautgartner[1], Hendrik Zielonka[2], Philipp Hagedorn[1], Peter Mark[2], and Markus König[1]

[2]Institute of Concrete Structures, Ruhr University Bochum, Bochum, Germany

Abstract

Circular reuse of construction components, prioritized by the EU over recycling, is limited by the lack of legally reliable, element-specific information in BIM environments. This work proposes a literature-based parameter set for the reuse of reinforced concrete elements as part of a product passport. Data from legally signed inspection certificates are integrated with digital BIM representations using established ontologies (BOT, Metadata4ing, ISOProps). Information is extracted from signed PDF certificates and linked to IFC models. Feasibility is demonstrated through a case study, enabling an interoperable, auditable workflow supporting End-of-Life-to-reuse information continuity for reinforced concrete elements.

Introduction

To reduce the negative environmental impact of the construction industry, the reuse of structural components is increasingly important regarding waste reduction (Sakthibala et al., 2025) and is assigned a higher priority in the waste hierarchy of the European Commission (2008). Reinforced concrete is particularly relevant in this context, as its high mass, significant greenhouse gas emissions, and long service life offer considerable potential to reduce environmental impacts through targeted reuse. Within the Circular Economy (CE), when planning with components that are reused at their End-of-Life (EoL), it is necessary to capture and store component- and reuse-specific information, e. g. from Pre-Demolitions Audits (PDA) according to DIN SPEC 91484. Information requirements for circular components have already been documented in general terms (cf. Akbarieh et al. (2023); Al-Qazzaz (2024)). However, for solid construction and structural components, additional information on the condition of components from detailed inspections and reuse-oriented component testing is necessary, since these typically need to be verified prior to reinstallation in order to determine structural properties such as load-bearing capacity.

For a Building Information Modeling (BIM)-supported reuse workflow, inspection data must be linked with Industry Foundation Classes (IFC) in a machine-readable form (Hagedorn et al., 2025), while the signed inspection certificates for the components must remain available for legal reasons so that it can be determined with certainty which properties can be assumed in subsequent structural planning. These inspection certificates ensure liability for the structural properties of the components for reuse, and are already being used for the reuse of steel components, as defined in EN 10204:2004 and EN 10168:2004. However, the reuse of reinforced concrete (RC) involves other product tests for which no reuse-specific material parameters or inspections have yet been established. This necessary flow of information leads to the following Research Question (RQ).

RQ: *How can information be extracted from PDF-based inspection certificates for RC elements and reliably transferred to the BIM model, ensuring a continuous flow of information in the components lifecycle?*

To answer the RQ, the remainder of the paper is structured as follows. Related work on reuse, product passports, ontologies, and information extraction is gathered. A methodology and workflow is proposed and implemented. Eventually, the workflow is demonstrated and validated before discussing the results and drawing conclusions.

Related work

Reuse of reinforced concrete (RC)

Küpfer and Fivet (2024) examine the structural reuse of concrete pieces, a relatively new practice evidenced by scarce yet diverse built projects. They trace the slow evolution of precast reuse since the 1980s and the recent emergence of cast-in-place reuse, driven by sustainability and design exploration, emphasize reliance on local knowledge and better case documentation, and advocate viewing soon-to-be-demolished structures as material stock. Mark et al. (2025) describe modular reuse of existing structures and focus on component testing in order to overcome usage restrictions and building regulations. Rose et al. (2025) investigate efficient reuse of RC using optimization algorithms and highlight the relevance of load-bearing capacity. Consequently, M–N (Moment-Normal force) charts may be pertinent for future structural assessment of reused components. Krautgartner et al. (2025) propose a network-based approach that integrates GIS (Geographic Information Systems) to manage building deconstruction and match demand for reuse elements. They derive requirements for system components, parameters, and process flows from the literature and formalize them.

Product passports in construction

Aftab and Agliata (2026) review the state of Material Pass-

ports (MPs) and discuss them generically, without addressing the complexity of composite, load-bearing materials such as RC. Their study characterizes BIM primarily as a dynamic repository, supporting the premise that BIM models serve as the starting point for Linked Data to consolidate additional information for reuse.

MPs address material-specific documentation, often in recycling, whereas Digital Product Passports (DPP) cover whole construction products; both rely on similar BIM- and Linked Data–based methods and can cover different scales from building materials to overall assessments. Ruismäki et al. (2025) examine stakeholder perspectives on DPPs for construction products and identify traceability, BIM integration, and resource efficiency as key benefits. Interviews show broad agreement on including EoL data and usage data (e.g., recorded damages). Stakeholders prioritized steel structures in a phased implementation owing to ease of handling, reuse, and major environmental benefits; concrete products were also considered suitable, but onsite modifications complicate information management. Ruismäki et al. (2025) further emphasize the complexity of concrete, which has contributed to the prevailing focus on steel. Senarathne et al. (2025) propose a concrete-specific DPP framework that includes physical properties and parameters across logistics, chemical, biological, cost, safety and health, among others. As it has not yet been validated in real-world settings, this paper adopts a smaller example focused on reuse-specific data instead. Vahidi et al. (2024) focus on recycled concrete and Radio Frequency Identification (RFID)-based MPs. As their work addresses crushed recycled concrete rather than component reuse, its relevance here is limited; however, RFID remains a potential option for tracking reused components. Bernier and Danash (2024) propose DPP based on ontologies. Blomqvist et al. (2023) propose a network of core ontologies for the CE and include process-, actor-, material- and product-information.

Ontologies for circular construction components

Ontologies and Knowledge Graphs (KG) enable machine-interpretable information for the built environment, typically represented in the Resource Description Framework (RDF) and the Web Ontology Language (OWL). The definition of terminology using ontologies is referred to as the TBox, while the instantiation and assertion of facts according to these ontologies is referred to as the ABox. (Pauwels et al., 2022, 2018)

Moreover, ontologies can be categorized as top-level ontologies for providing abstract generic concepts and domain ontologies for representing domain knowledge. Beyond domain-specific efforts, Li et al. (2023) investigate cross-industry general ontologies for the circular economy to create an ontology network that links core ontologies across multiple industry domains. To facilitate ontology discovery and reuse in AECO (Architecture, Engineering, Construction, and Operations), Akbarieh et al. (2025) developed the Built Environment Ontology Lookup Service (BE-OLS) (EC3 M&S Committee, 2025). Within the built environment, examples of domain ontologies include the Decommissioning and Reuse Ontology (DOR); for EoL decision-making, the Construction Circular Product Ontology (CCPO) provides a rule-based EoL product ontology that considers Product Health State, recyclability, and reference service life (Adu-Duodu et al., 2025). Additional ontologies relevant to DPP workflows include the Material Passport Ontology (MPO), the Steel Element Reuse Ontology (SERO), the Building Element Ontology (BEO) for classification of building elements, the Building Product Ontology (BPO), and a Concrete Damage Ontology (CDO). For data structuring and property description in the BIM-based information management, Zentgraf et al. (2026) developed the ISO 23386 Property Ontology (ISOProps), providing modular and reusable descriptions for properties and construction objects. Liu et al. (2021) introduced the Building Concrete Monitoring Ontology (BCOM) for maintaining testing data of cast-in-place fresh concrete properties on the construction site. However, their ontology is not a generic, extendable property dictionary but a strict, encoded TBox ontology with a fixed schema. In the context of managing arbitrary test data from the broader domain of engineering sciences, the Metadata4Ing ontology (Lanza et al., 2025) is relevant. It provides a framework for the semantic description of research data and the entire data-generation process, covering the object of investigation, sample and data manipulation methods and tools, the data files, and the roles of persons and institutions. Its structure and application follow modularity and inheritance, with the processing step as a central element. Ultimately, ontologies also serve information management by structuring extracted data from reports (Zentgraf and Zimmermann, 2025). In summary, existing ontologies already model circular processes and data structuring in AECO but do not address testing-level details for concrete.

Methodology

To answer the RQ proposed, the methodology is defined as shown in Fig. 1. First, relevant background and literature is gathered and analyzed regarding relevant component parameters for the reuse. Next, a methodology and concept are developed on how these parameters can be extracted from signed PDF certificates and be integrated with relevant metadata of the testing procedures for documenting the provenance. As a result, an ABox dictionary of properties assignable to concrete elements based on inspection tasks is developed, reflecting the parameters defined in the literature. This ABox dictionary is based on terminology from multiple ontologies, such as the Building Topology Ontology (BOT) for IFC model alignment (Rasmussen et al., 2021), Metadata4ing for test procedure metadata and material properties (Lanza et al., 2025), and ISOProps for maintaining the tested properties in accordance with ISO 23386 (Zentgraf et al., 2026). The proposed concept is implemented and demonstrated on a case study of a rein-

forced concrete element; results are discussed and conclusions drawn.

Component reuse data flow

Figure 2 outlines the workflow and data concept for component reuse. The process starts with deconstruction; components are tested in the laboratory, and a certificate is issued that must be handwritten-signed for legal accountability. This signature confirms that testing was performed, liability is assumed, and the described properties can be used for future planning in case of reuse. Information from the certificate is extracted and stored in a BIM model. The PDF inspection certificate is linked to the component's IFC model, ensuring that, in subsequent planning, information is available in two forms: within the IFC model for BIM-based design and as a linked PDF report that can be accessed at any time to provide planners with assurance for component reuse. The data linking the component and the inspection results can thus be transferred to the next life cycle of the component.

Inspection certificate for reuse of RC

Properties for a product passport for reinforced concrete are proposed, derived from the literature: Senarathne et al. (2025) present a DPP for concrete; Mecka et al. (2025) outline a framework for the reuse of reinforced concrete components; Ottosen et al. (2024) review non-destructive testing to document properties for reuse; Suchorzewski et al. (2023) propose a classification system for disassembled concrete elements (DCE). Relevant properties were compiled from these sources. The proposed inspection certificate can form part of a DPP and focuses on properties determined through laboratory testing and inspection of the elements. No claim to completeness is made; the proposal serves to demonstrate and model implementation and data flow in this paper. Table 1 lists and explains required parameters, and specifies the investigation methods by which they can be determined. These investigation methods are central to laboratory test reports. Section 1 of the table provides general information; Sections 2 and 3 present mechanical properties, geometry, damage, and durability.

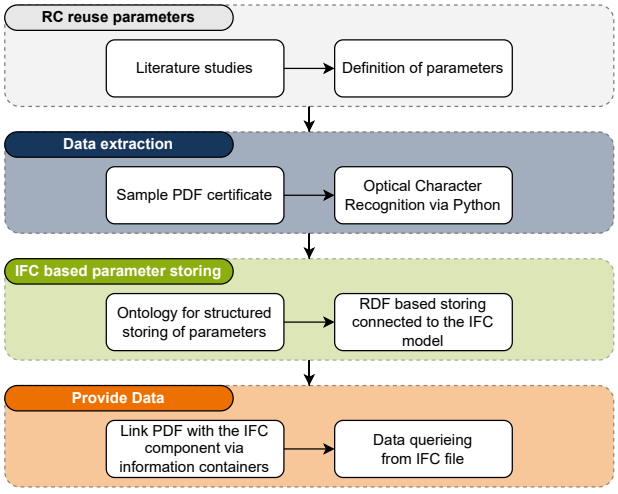

Figure 1: Methodology

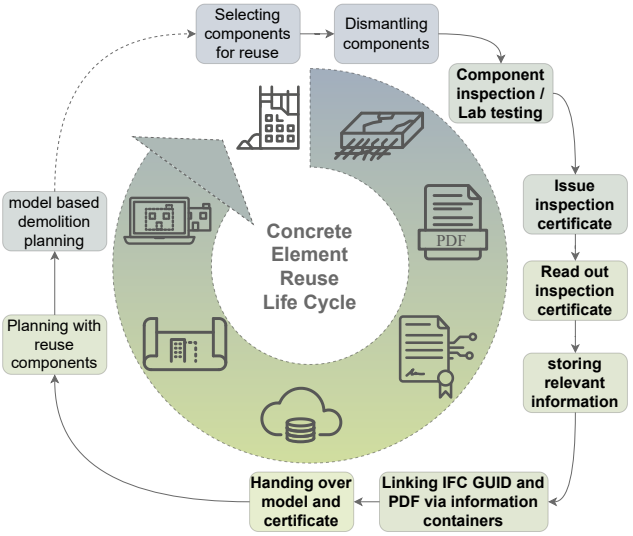

Figure 2: Data Concept for reuse components

Implementation

After having analyzed the literature and provided a template and parameter set for inspection reports according to the methodology in Figure 1, in this section, data extraction is performed. For the first testing of the procedure, a Python library for Optical Character Recognition (OCR) was used. The extracted parameters are ingested into a KG using the Concrete Element Reuse Ontology (CERO) published at `https://w3id.org/cero#` in previous work (Krautgartner et al., 2026). CERO provides standardized ABox properties as `owl:DatatypeProperty` instances annotated with standardized metadata according to the Metadata4Ing ontology and maintenance workflows for the property dictionary according to the ISOProps ontology and ISO 23386. Property values are assigned to concrete components represented in RDF graphs after being converted from the IFC model. Eventually, the extracted data is provisioned into Information Containers for Linked Document Delivery (ICDD) (ISO 21597-1, 2020) and linked to both the PDF and the IFC model to provide the provenance of the properties. Using the ICDD platform as it has been presented in Hagedorn et al. (2023), this interlinked data can be queried from the model and the PDF file of the inspection certificate.

Ontology for structuring the parameters

To embed Table 1 into the Linked Data concept, it must be converted into processable entities following a meaningful structure. Because BE-OLS does not contain an ontology for RC component inspection certificates (as of January 2026, (EC3 M&S Committee, 2025)) yet, a custom implementation of the parameter set into the CERO ontology was necessary. The namespaces used for the implementation are presented in Table 2.

This dataset inside CERO maps the entirety of the proposed information of the test certificates according

to Table 1. The parameters from Section 1 are directly instantiated and persisted into the CERO ontology. The parameters from Sections 2 and 3 are also created as parameters in the CERO ontology, but are recorded via the Metadata4Ing ontology. This means that each test method (see Table 1) has been created there as `metadata4ing:Tool`. In addition, the possible test configurations (`metadata4ing:Configuration`) have been stored, which contain, which parameters can be recorded with which test methods. According to the Metadata4Ing Ontology, for each row, `metadata4ing:Configurations` were initially created to link instances of `metadata4ing:Methods` (e.g., `certificate:CompressiveStrengtTest`) with the testing tools (`metadata4ing:Tools`) (e.g., `certificate:Reboundhammer`) as shown in Figure 3. Numerical parameter Values are stored in the `metadata4ing:ProcessingSteps` in `metadata4ing:NumericalAssignments` in a `metadata4ing:NumericalVariable`. The `metadata4ing` Ontology uses the `qudt` ontology for storing units (as here MPa for the compressive strength).

Table 1: Proposed testing parameters for inspection certificates of reused reinforced concrete components

Section 1: General component and project information		
Parameter	***Description***	
Identification	Identification number/ID/serial number	
Origin	Original building, year of construction, pre-use	
Element type	Type of element (beam, column, slab, etc.))	
Overall dimensions	External geometry of the element, span after processing	
Load capacity	Reduced cross-sectional load-bearing capacity after taking into account all mitigating factors, e.g. via M-N interaction diagram	
Environmental actions	Relevant exposure classes	
Environmental impacts	Environmental data on the original element, on processing the elements after use, and on the cost of dismantling and transport	
Section 2: Condition assessment		
2.1 Mechanical properties		
Parameters	***Description and units, if applicable***	***Investigation method***
Concrete compressive strength	Characteristic compressive strength (fck) [MPa; N/mm²]	Core extraction; non-destructive testing (e.g. rebound hammer); as-built documentation
Concrete stiffness	Modulus of elasticity [MPa; N/mm²]	Core extraction; non-destructive testing (e.g. ultrasonic testing); as-built documentation
Reinforcing steel tensile strength	Yield strength (fyk) [MPa; N/mm²]; modulus of elasticity [MPa; N/mm²]	Reinforcement sampling with tensile test; as-built documentation
2.2 Geometry and damage		
Concrete cover	Minimum and mean concrete cover [mm]	Ground penetrating radar (GPR); as-built documentation
Reinforcement layout	Location, diameter and number of reinforcement bars; effective depth	Reinforcement scanner; covermeter; ground penetrating radar (GPR); as-built documentation; partial exposure of reinforcement
Cracks	Localisation and maximum crack width [mm]	Visual inspection; laser scanning; digital imaging
Internal defects	Presence of delamination, voids or flaws from loading history	CT scans; X-ray tomography
Section 3: Durability and remaining service life		
Carbonation depth	Measured depth compared to existing concrete cover	Phenolphthalein Indicator, Drill dust analysis
Chloride content	Concentration at reinforcement level [% by mass of cement]	Staggered drilling dust analysis
Remaining service life	[a]	Two-phase model according to Tuutti
Classification	According to DCE classification (Suchorzewski et al., 2023)

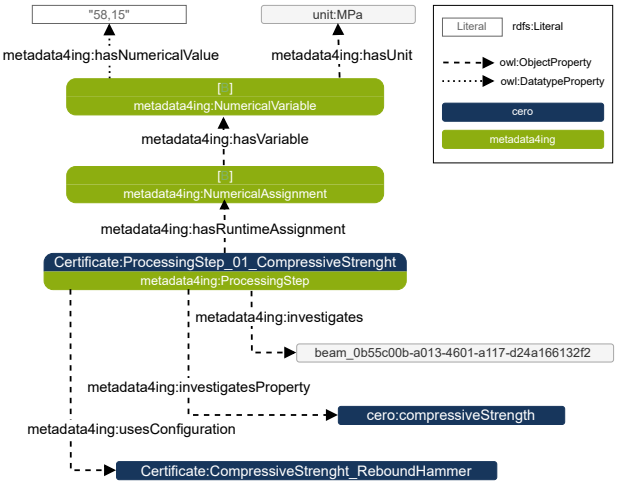

Figure 3: Property for concrete compressive strength

Information extraction of inspection certificates

The information extraction and ontology population for this workflow are inspired by existing research approaches. Sithisint et al. (2025) present engineering drawing interpretation, employing bounding box detection via YOLOv11n and text extraction via OCR with EasyOCR. Schönfelder and König (2025) provide an ontology based approach to structure extracted information from floor plans. Vaatz et al. (2023) show how to link semantic information to BIM using ontologies and ICDD.

In this article, the information extraction from the sample inspection certificates is done by a Python script and the PyTorch library EasyOCR[1]. To do this, the parameters were converted into different spellings in regex pattern, which are then used to search the imported certificates. The following values are then transferred into a template file according to the CERO parameter set.

[1] `https://github.com/JaidedAI/EasyOCR`

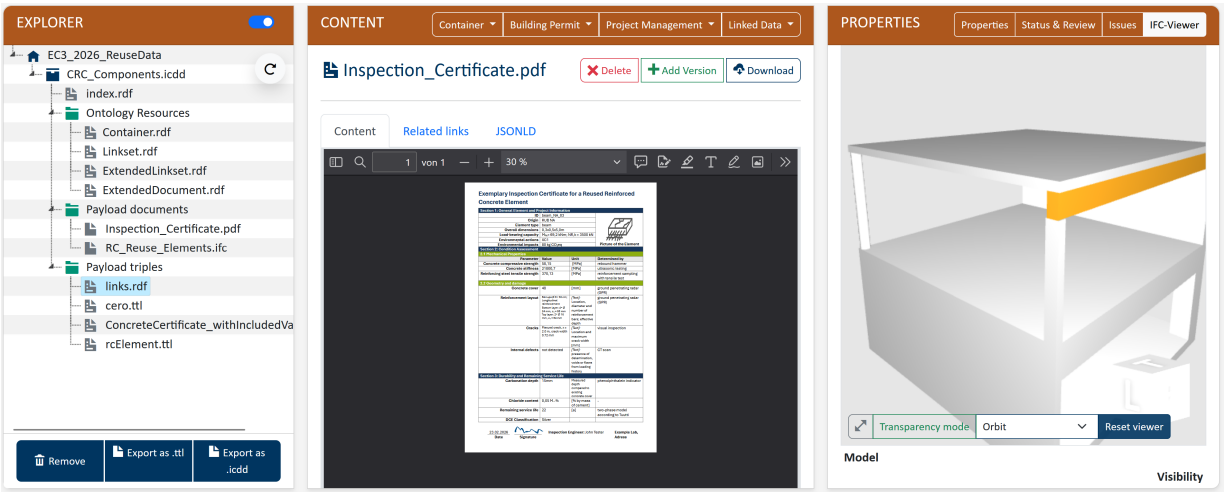

Figure 4: Link of PDF inspection certificate (middle) and RC reuse component (right)

Link of inspection certificate and IFC entity via ICDD

ICDD containers organize and link heterogeneous project data on a dedicated platform. Through Linked Data, documents and files can be associated with a project and with specific IFC elements in the central model. RDF/OWL semantics enable machine-readable linkage and integration with standardized BIM data (e.g., IFC). The ICDD platform has been used for a ReSource Marketplace, where individual components are offered and presented together with their IFC-based data (Hagedorn et al., 2025).

Consequently, the platform's Linked Data concept is suitable for establishing a connection between the PDF inspection certificate and the RC Reuse Element in the BIM model via the IFC GUID, as shown in Figure 4.

Validation and discussion

To validate the concept, an IFC4 model of a solid construction support structure consisting of reinforced concrete components was used (see Figure 4). For this purpose, a sample inspection certificate with realistic values for an RC beam was created, containing all parameters proposed in Table 1 (see Figure 5). In addition, the test engineer's data is provided as an example. The information extraction of this sample inspection certificate was carried out as described, whereby it became apparent that the OCR algorithm has shortcomings with multi-line table entries. The extracted data is stored in the `certificate` KG template using Python by manipulating the text in the Turtle file of the KG. The ontology, the IFC Model and its RDF representation is then uploaded to the ICDD platform (see Figure 4).

To ensure the fundamental functioning of the ontology, Competency Questions (CQs) are formulated according to Bezerra et al. (2013) and checked using SPARQL (SPARQL Protocol and RDF Query Language) queries within the ICDD platform. The aim is to be able to retrieve all data contained in the PDF inspection certificate in the IFC model as well. Due to the different use cases of the data sections, two CQs are checked and the corresponding SPARQL queries are formulated (see Listings 1 and 2).

Exemplary Inspection Certificate for a Reused Reinforced Concrete Element

Section 1: General Element and Project Information			
ID	beam_NA_03		Picture of the Element
Origin	RUB NA		
Element type	beam		
Overall dimensions	0,3x0,5x5,0m		
Load-bearing capacity	M_{Rk}= 69,2 kNm; NR,k = 3500 kN		
Environmental actions	XC1		
Environmental impacts	80 kg CO_2eq		
Section 2: Condition Assessment			
2.1 Mechanical Properties			
Parameter	**Value**	**Unit**	**Determined by**
Concrete compressive strength	58,15	[MPa]	rebound hammer
Concrete stiffness	21800,7	[MPa]	ultrasonic testing
Reinforcing steel tensile strength	370,13	[MPa]	reinforcement sampling with tensile test
2.2 Geometry and damage			
Concrete cover	48	[mm]	ground penetrating radar (GPR)
Reinforcement layout	Stirrups Ø 8 / 30 cm; Longitudinal reinforcement Bottom layer: 4× Ø 24 mm, c_v = 68 mm Top layer: 2× Ø 16 mm, c_v = 64 mm	*[Text]:* Location, diameter and number of reinforcement bars; effective depth	ground penetrating radar (GPR)
Cracks	Flexural crack, x = 2.0 m, crack width 0.72 mm	*[Text]:* Location and maximum crack width [mm]	visual inspection
Internal defects	not detected	*[Text]:* presence of delamination, voids or flaws from loading history	CT scan
Section 3: Durability and Remaining Service Life			
Carbonation depth	15mm	Measured depth compared to existing concrete cover	phenolphthalein indicator
Chloride content	0,05 M.-%	[% by mass of cement]	-
Remaining service life	22	[a]	two-phase model according to Tuutti
DCE Classification	Silver

and demonstrating that the proposed workflow enables information storage and querying in the model.

This research approach is limited by the availability of real inspection certificates, so a sample certificate was provided and validated. Moreover, the implementation of the OCR pipeline is limited because the focus of the study is not the employment of an optimized OCR but on the ontology implementation for inspection certificates with traceable test data provenance and the modeling of the information flow for a reuse RC Element. The OCR algorithm can be supplemented with segmentation to enable the correct reading of other layouts or the extraction of correct information from diagrams (e.g., M–N charts). Another avenue to improve information extraction could be to employ a visual–language model (VLM). However, since text recognition using OCR and VLMs involves uncertainties in data extraction, it should be noted that printed component certificates will be replaced by digitally signed inspection certificates in the long term. Currently, PDF-based certificates are used in the field of steel component reuse, as revealed in an expert interview conducted as part of the ‘‘CLUE’’ (Circular Building Design) research project.
The information flow from an inspection certificate to a digital passport, regardless of product or material passport, relies on the review of literature and has not yet been extensively tested in practice. Employing the proposed workflow is intended as a demonstration case on a reference reuse construction site in the next step. Moreover, an integration of the proposed inspection certificate parameters in addition with the the linking of the signed PDF Version into reuse Marketplaces such as this presented by Hagedorn et al. (2025) would be a meaningful next step in establishing the market for reused components.
Ontology alignment with other CE-specific ontologies remains to be addressed; particularly with the superior approach for CE ontologies across different industries by Blomqvist et al. (2023). The KG for inspection certificates requires further maintenance; missing test methods may need to be added, and additional parameters can be included if necessary. If CERO is further developed, adjustments must be made to the `certificates` KG.

Conclusion and outlook

This paper models the data flow for reused components. The proposed structure of inspection certificates was successfully used to (1) extract data using OCR and transfer it to the corresponding IFC model, and (2) maintain a persistent linkage to the reuse component using ICDD so that the signed PDF remains available at any time. The following research question was addressed as part of the prototype implementation of the workflow: *How can information be extracted from PDF-based inspection certificates for RC elements and reliably transferred to the BIM model, ensuring a continuous flow of information in the components lifecycle?*
To create the inspection certificate, a literature-based analysis of the required information was conducted; see Table 1. In addition to the necessary parameters, measurement methods are central, which is why possible measurement methods for parameter determination are listed. The compilation was implemented as an ontology using existing ontologies, including BOT, Metadata4ing, and ISOProps, in compliance with ISO 23386.
The information can be inserted into the ontology by text recognition (in this work with a simplified OCR algorithm) from PDF-based inspection certificates. To provide the information to users, the ICDD platform was chosen. This platform uses Linked Data to directly link different files to the corresponding IFC GUIDs, and the information can be queried directly on the model via SPARQL queries, which offers potential for further automation through the ICDD platform’s API (Application Programming Interface).
The ontology was validated using two CQs. Although

CERO is still under development, the example presented here shows that CERO supports CE processes for RC reuse elements. The OCR algorithm employed to demonstrate the complete information flow (see Figure 2) is error-prone and cannot be recommended for future work; it would need to be improved or replaced, or it may become obsolete if fully digital product passports become established.
The concept is suitable and expandable to other reuse products, e.g., steel and timber. Future work should investigate approaches without upstream paper documents, i.e., fully digital product passports. There may be new regulations for product passports through the Circular Economy Act. The developed ontologies can also be aligned with the parameters of DIN SPEC 91525 (''Post-Use Concept (PUC) for construction products from existing buildings''), which was published in February 2026, after the implementation of this work was finalized.

INTEROPERABILITY FOR A CIRCULAR BUILT ENVIRONMENT: TOWARDS A ROADMAP

Mustafa Selçuk Çıdık, Irene Josa, Kell Jones, Nicola Moretti and Karim Farghaly
The Bartlett School of Sustainable Construction, University College London, London, UK

Abstract

Circular built environment relies on reliable, reusable information across life-cycle stages; however, current initiatives remain fragmented. Identifying interoperability as a primary barrier, this paper draws on insights from a multi-stakeholder workshop to present a systemic roadmap. The research consolidates expert perspectives into sequenced, mutually dependent interventions across five domains: shared strategic vision; aligned standards and requirements; organisational and human capability; incentives and value realisation; and integrated system architecture. By clarifying cross-domain dependencies, this framework provides an actionable basis for prioritising pilots, policy mechanisms, and digital infrastructure to scale circular practices beyond isolated demonstrators.

Introduction

The Circular Economy (CE) has emerged as a transformative model to address environmental pressures and resource inefficiencies by replacing linear "take-make-dispose" patterns with regenerative systems that preserve material value and reduce waste (Ellen MacArthur Foundation, 2013; Kirchherr, Reike & Hekkert, 2023). The construction sector is a critical arena for this transition due to its high material throughput, complex supply chains, and significant waste generation (Ghisellini, Cialani & Ulgiati, 2016; Peng & Cao, 2025). In practice, CE in construction relies on strategies such as reuse, refurbishment, recycling, and design for disassembly, which are approaches that reduce life-cycle burdens while supporting longer-term sustainability (Konietzko, Bocken & Hultink, 2020). Yet, despite strong policy and industry interest, implementation remains uneven and difficult to scale beyond isolated pilots (Köhler et al., 2025).

Scaling CE depends on life cycle and systems thinking, as circular strategies require actors to coordinate decisions across stages (design, procurement, construction, operation, end-of-life) and across organisational boundaries (Voulvoulis et al., 2022). This coordination is information-intensive: to enable reuse and high-value recovery, stakeholders must trace materials, access reliable product data, assess reuse potential, and align compliance requirements over time (Giorgi et al., 2022). However, the built environment is characterised by fragmented processes and heterogeneous stakeholder needs, creating persistent challenges in communication and accountability (Jones et al., 2022). Consequently, circular initiatives often stall because information sharing is inconsistent, unverifiable, or untrusted across the value chain (Jäger-Roschko & Petersen, 2022; Mosgaard, Kristensen & Bocken, 2025).

Digitalisation is frequently presented as an enabler: through Building Information Modelling (BIM) tools, Digital Product Passports (DPP), Digital Building Logbooks (DBL), Lifecycle Assessment (LCA) tooling, and emerging "data spaces" approaches. However, digital adoption does not automatically translate into circularity (Dervishaj & Gudmundsson, 2024). A central barrier is interoperability: even when data is exchanged, it is often inconsistent in meaning, granularity, and context (Farghaly & Jones, 2023; Parte et al., 2025). This challenge is amplified because circular construction operates as a system-of-systems, where independently governed subsystems must coordinate without losing autonomy (Sadeghi et al., 2024; Farghaly et al., 2025). While technical advances in ontologies and knowledge graphs are progressing, they are often pursued in isolation from governance, incentives, and capability development; this leads to fragmented solutions that do not scale (Kebede et al., 2024; Shaw et al., 2025). What is missing is an integrated change model that clarifies how standards, systems, and data initiatives should be sequenced and reinforced through complementary institutional and market interventions.

This paper addresses this gap by proposing a systemic roadmap for interoperability in support of circular construction. Synthesising emerging insights from a multi-stakeholder workshop, the research organises priority actions into five interdependent domains (i.e. shared strategic vision; aligned standards and requirements; organisational and human capability; incentives and value realisation; and integrated system architecture). The framework is intended as a basis for further development.

Background

Interoperability has been widely discussed in the literature, yet it does not have a single unified definition (Lalli, 2025). It is generally understood as the ability of different systems or components to exchange information and use it effectively for a given purpose. However,

studies show that interoperability has evolved from a purely technical concern to a multidimensional socio technical concept, leading to the emergence of numerous definitions, models, and classifications. A recent tertiary study identified thirty-six different interoperability types and highlighted that ambiguity and overlap across definitions still exist, which can hinder communication and implementation across domains (Maciel et al., 2024).

Within the policy context, the European Interoperability Framework for Smart Cities and Communities identifies five key types of interoperability that should be addressed together, namely technical, semantic, organisational, legal, and culture interoperability. Within this broader landscape, particular attention in both research and practice has increasingly centred on semantic and technical interoperability.

Semantic interoperability refers to the ability of heterogeneous systems to exchange information such that the meaning of the information is preserved and can be interpreted consistently by different tools and stakeholders. In the built environment, this requirement spans multiple data types and scales (e.g., design models, product information, operational records, and assessment outputs) and must hold across long asset lifecycles and organisational boundaries. This is particularly challenging in construction, where fragmentation and specialisation create persistent discontinuities in how information is produced, owned, and maintained (Jones et al., 2022), and where interoperability increasingly resembles a system of systems problem with independently governed subsystems that must coordinate while retaining autonomy (Farghaly et al., 2025). This challenge is often approached through digitalisation and data exchange, yet exchange alone does not guarantee shared meaning. Even when information can be transferred between tools, inconsistencies in terminology, classification, granularity, and context can prevent reliable reuse and automation. This is evident in sustainability-oriented workflows where requirements and evidence must be mapped across heterogeneous sources and interpretations, making consistent meaning a prerequisite for trustworthy decision-making (Farghaly & Jones, 2023). Similar challenges appear in broader digital ecosystems (e.g., IoT-driven environments), where semantic interoperability is explicitly needed to ensure that multiple systems "act on" shared information consistently (Parte et al., 2025).

For circular construction in particular, circularity strategies depend on the availability of reliable lifecycle information to support traceability, assessment, and end-of-life decisions. Digital tools such as lifecycle assessment platforms and emerging passport/logbook concepts are promising, but their ability to deliver circular outcomes depends on the interoperability of underlying data and concepts rather than on tool adoption alone (Dervishaj & Gudmundsson, 2024). Recent work on digital product passports in the built environment demonstrates how ontology-based modelling can improve reuse and interpretability of product information by structuring lifecycle content and aligning concepts with standards, thereby improving cross-platform and cross-stakeholder consistency (Kebede et al., 2024). In parallel, knowledge-graph approaches demonstrate the potential to connect requirements and reporting across policy and practice contexts, supporting more robust and machine-interpretable lifecycle analysis and disclosure (Shaw et al., 2025). However, the literature also highlights persistent constraints that prevent semantic approaches from scaling beyond demonstrators. Information sharing across circular value chains remains difficult due to organisational boundaries, uneven incentives, and limited trust in shared data, all of which reduce the willingness and ability of actors to invest in producing and maintaining high-quality information (Jones, Farghaly & Toth, 2025; Jäger-Roschko & Petersen, 2022).

These socio-technical barriers do not operate independently but interact directly with technical constraints. In the absence of shared requirements, consistent semantics, and distributed implementation capacity across organisations, even technically robust solutions struggle to achieve effective adoption. In this context, "well-designed" refers to artefacts that are internally coherent, formally specified, and semantically expressive, often providing comprehensive coverage of domain concepts and relationships. However, these qualities can also introduce practical challenges and remain difficult to generalise and have seen limited in-practice uptake (Shaw et al., 2025).

Digital solutions in the built environment, such a DPPs and DBLs, are explicitly designed to improve data accessibility, lifecycle transparency, and cross-stakeholder coordination. Yet, despite operating in a data-rich environment, the sector remains highly fragmented, and much of this information is underutilised due to structural discontinuities across the value chain. Crucially, recent empirical evidence shows that barriers to integration are not primarily technical but procedural and organisational, including unstructured data, unclear responsibilities, and weak incentives (Çetin et al., 2026). Even where technical infrastructures are considered advanced, interoperability is constrained by the lack of shared definitions and semantic alignment, making consistent data exchange difficult to operationalise (Jones, Farghaly & Toth, 2025). At the same time, reliance on unstructured formats (e.g., PDFs and fragmented documentation) further limits the usability and automation of data within these systems (Çetin et al., 2026). These constraints are compounded by organisational and human factors. Responsibilities for data provision are often ambiguous, and stakeholders lack both incentives and capacity to contribute to shared systems, resulting in low engagement and inconsistent implementation. Moreover, the proliferation of overlapping digital tools and frameworks can create additional complexity and "digital fatigue," reducing willingness to adopt new systems (Supriyadi et al., 2025).

Consequently, solutions that are "well-designed" in a technical sense may still reproduce fragmentation in practice. Rather than eliminating heterogeneity, they shift the burden of integration onto individual organisations,

each of which must align its internal data structures, classifications, and workflows with shared models. Interoperability is therefore achieved at the level of architectural intent, but not consistently realised in operational settings. This helps explain why, despite their conceptual robustness and policy support, many such systems struggle to scale beyond limited implementations and fail to achieve widespread, routine use across the sector.

Taken together, the above motivates the need for a systemic approach that integrates technical measures (standards, semantics, architecture) with complementary governance and adoption conditions – providing the rationale for the roadmap proposed in this paper.

Methodology

This research is grounded in a structured stakeholder workshop designed to elicit, consolidate, and sequence practical actions for enabling semantic interoperability in circular construction.

In particular, a full day workshop was convened involving 45 participants representing key segments of the value chain and enabling ecosystem (including asset owners, designers, contractors, manufacturers, software providers, policymakers, and standardisation bodies). The participant sample comprises 45 individuals across four stakeholder groups. Solution implementers form the largest group (n=16), with 10 involved in design and construction and 6 in operation and in-use. This is followed by academics (n=13), governance stakeholders (n=9), and solution providers (n=7). Academic participants range from professors to research associates, covering digital technologies, sustainability, project management and supply chains. Governance stakeholders are involved in international and national standards and regulations, while solution providers are primarily focused on data integration and digitalisation. Participants were selected through purposive sampling to ensure coverage of different perspectives (technical, regulatory, delivery).

The workshop followed a three-phase structure:

1. **Shared framing:** Collaborative definition of the interoperability problem, establishing boundaries and identifying critical pain points.
2. **Action elicitation:** Facilitated breakout discussions where participants proposed concrete technical, organisational, and policy interventions required to achieve data interoperability.
3. **Convergence and sequencing:** Consolidation of actions and dependency mapping (identifying which actions are prerequisites for others).

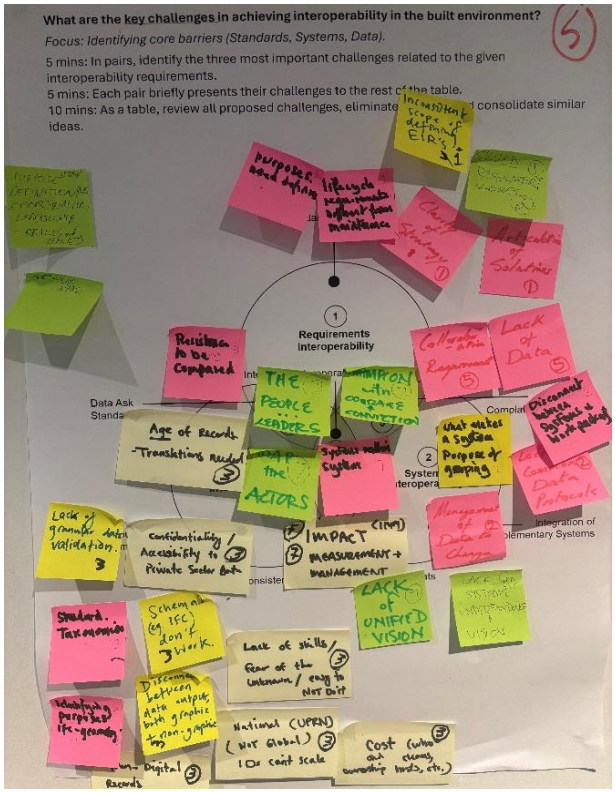

Figure 1: Example of one of the activities carried out in the workshop

Evidence included facilitator notes and group artefacts and worksheets (Figure 1). After the workshop session, the artifacts were digitised using spreadsheets and dashboards[1] for thematic analysis and clustering of the results. Subsequently, research team conducted an iterative qualitative synthesis to identify recurrent themes with the consolidation of overlapping proposals into coherent action statements.

The workshop findings played a central role in shaping the development of the Centre for Built Environment Data Sharing (C-BEDS) direction. A strong consensus emerged during the workshop that many initiatives are already addressing interoperability challenges. However, these efforts remain fragmented and largely disconnected. This creates a situation where solutions exist but their collective value is not realised. Based on this insight, the development process followed two linked directions. First, the activities of initiatives are aligned through a collective impact approach to support coordination, shared goals, and mutually reinforcing actions. Second, CBEDSync platform has been developed which has an open and queryable structure that captures existing initiatives, their outputs, and the relationships between them. This allows the connections between efforts to become visible and usable. In this way, the workshop findings directly informed both the conceptual design and the functional structure of the C-BEDS initiative.

Results and discussion

The synthesised actions were organised into five interdependent domains: (1) shared strategic vision; (2) aligned standards and requirements; (3) organisational and human capability; (4) incentives and value realisation; and (5) integrated system architecture. These are described in what follows and summarised in Table 1.

The actions elicited from the workshop reflect both practical concerns and an interconnected set of considerations. While these interventions are grouped into five thematic domains, their success depends not on isolated implementation but on how they reinforce, enable, or depend upon one another. This section interprets these emerging findings as part of a holistic roadmap, synthesising the identified challenges and enablers with the strategic role each domain plays. The goal is to clarify their function within a coherent change model, highlighting interdependencies and complementarity.

Domain 1: shared strategic vision

A shared strategic vision acts as the anchor of the proposed roadmap; it defines what interoperability is for, whom it benefits, and how value is distributed. Without such a vision, efforts to standardise, invest, or reform institutional practices remain fragmented. Participants widely agreed that strategic misalignment across governance levels and organisations perpetuates inefficiencies and undermines the circular economy agenda. Consequently, the actions in this domain form the foundation upon which all others depend.

These actions emphasise the need to convene key stakeholders early to articulate a shared purpose, formalise commitment across sectors, and embed this vision within regulation. Critically, participants viewed this not merely as a leadership issue but as an operational necessity: without a shared "why," technical or behavioural changes lack legitimacy. Enablers such as cross-sector collaboration, political leadership, and regulatory clarity support this alignment, while the absence of clear attribution remains a systemic risk.

This domain requires institutional continuity. Embedding the vision in procurement, funding frameworks, and leadership roles ensures adaptation to evolving technological and regulatory contexts. It is not merely the starting point of a linear plan, but a persistent condition for success across the roadmap.

Domain 2: aligned standards and requirements

Standards and requirements form the semantic backbone of interoperability. They define how information is structured, understood, and exchanged, underlying every attempt to automate, audit, or regulate the flow of data.

Workshop participants identified that the primary challenge is not the absence of standards, but their incoherence and incompatibility. Fragmented schemas, redundant classification systems, and diverging national regulations impede scalability and render meaningful data reuse nearly impossible.

As such, an interesting and recurring finding across the workshop was that standards are both indispensable and problematic: interoperability depends on shared standards, yet the proliferation of overlapping standards, schemas, and jurisdiction-specific requirements is itself a major source of fragmentation.

The actions proposed for this domain reflect a pragmatic, phased approach: first mapping and analysing existing standards, then consolidating and simplifying them into shared, machine-readable formats. Participants emphasised the need for open definitions and digital tools that support validation, traceability, and compliance without imposing excessive complexity. Importantly, these standards must be dynamic, namely able to evolve with emerging needs and remain adaptable across sectors.

Crucially, standards are not self-sufficient. Their relevance and uptake depend on how they are embedded within procurement and policy frameworks and whether they are understood by the workforce. The system-level implication is clear: aligned standards cannot succeed without prior strategic clarity and simultaneous investment in organisational capability. In this sense, standardisation is both a technical and a political act, defining not just what is possible, but what is prioritised.

Domain 3: organisational and human capability

Where shared vision gives direction and standards provide structure, organisational and human capability enables action. This domain addresses persistent capacity deficits: low data literacy, inconsistent leadership, and siloed technical expertise. These issues are not resolved by training alone; they reflect a broader cultural landscape in which data is undervalued, ownership is ambiguous, and resistance to change remains high.

The actions outlined for this domain propose a multi-layered response: building awareness of data value, implementing training for key roles, and embedding data responsibilities into procurement and professional standards. These are long-term investments in behavioural and institutional transformation rather than quick fixes. Enablers identified by participants (such as cross-sector taskforces, targeted leadership programmes, and revised contracting norms) support this shift. Thus, this domain bridges strategic intention and operational implementation. Without capability, actions in other domains remain aspirational. Moreover, strong leadership and a skilled workforce create feedback loops that accelerate adoption and continuous improvement, making capability the operational foundation of systemic change.

Domain 4: incentives and value realisation

While capability enables action, incentives determine whether actors choose to act, and how consistently. Discussions highlighted that, in the current system, data is often perceived as a cost centre rather than a strategic asset. Ownership is unclear, accountability is weak, and value is poorly articulated. Participants repeatedly stressed that unless data-related behaviours are tied to clear benefits (financial, reputational, or operational), interoperability will not scale.

Table 1: Roadmap domains and aspects for interoperability

Roadmap domains	Core focus	Key challenges	Key enablers	Emerging actions	Strategic role
Domain 1 Shared strategic vision	Establishing purpose, coherence, and direction	Fragmented goals, unclear ownership, siloed strategies	Governance coordination, regulatory alignment, leadership buy-in	Convening stakeholders, formalising commitments, embedding vision in regulation	Vision is the strategic anchor. It defines direction, legitimises action, and enables cross-sector coherence.
Domain 2 Aligned standards & requirements	Creating a shared, usable foundation for data exchange	Incompatible formats, misaligned regulations, excessive complexity	Open ontologies, bsDD, policy alignment, machine-readability	Mapping standards, simplifying formats, developing validation tools	Standards are the semantic backbone. Their adoption depends on clarity, usability, and integration into compliance tools.
Domain 3 Organisational & human capability	Enabling people and institutions to adopt and sustain change	Low data literacy, weak leadership, fragmented skills	Targeted training, communities of practice, procurement reform	Building awareness, role-specific training, revising professional standards	Capability is the human infrastructure. It translates standards into practice and enables culture change across roles.
Domain 4 Incentives & value realisation	Making interoperability worthwhile and accountable	Unclear data ownership, low perceived value, lack of ROI	Outcome-based models, new business cases, financial levers	Demonstrating ROI, embedding contract accountability, risk mitigation	Incentives are the behavioural engine. They must reward outcomes, not just compliance, and reinforce data as a shared asset.
Domain 5 Integrated system architecture	Building a flexible but connected digital ecosystem	Legacy systems, poor integration, document-centric workflows	Open-source tools, federated infrastructure, aligned APIs	Federated architecture, aligned ontologies, prototyping real-time flows	Architecture is the operational backbone. Modular, open systems enable the technical realisation of all other domains.

To address this gap, the roadmap suggests diverse mechanisms: from demonstrating ROI and linking data quality to outcomes, to embedding accountability in contracts and utilising financial instruments to mitigate risk. These actions aim to align economic logic with system goals, transforming data interoperability from a compliance burden into an investment opportunity. The strategic implication is twofold: first, incentives depend on visibility – without clear standards and trustworthy infrastructure, value is difficult to verify; second, incentives are transformative – when tied to outcomes like reuse rates, they shift market behaviour. This domain therefore acts as the behavioural engine for the system, reinforcing positive norms and accelerating diffusion.

Domain 5: integrated system architecture

Finally, the technical realisation of interoperability depends on an integrated but decentralised system architecture. The workshop revealed persistent fragmentation, with data locked in static documents, proprietary systems, or disconnected platforms. The enablers identified – open ontologies, modular APIs, federated platforms – point to a future where interoperability is achieved through structured compatibility rather than centralisation.

Actions in this domain articulate this vision, including developing a federated architecture, aligning ontologies, reducing API complexity, and creating usable tools for real-time data flows. Importantly, these actions position prototyping and demonstration not as side activities, but as essential components for building confidence. From a system perspective, architecture is the operational backbone supporting all other domains. If designed in isolation, it risks reproducing existing silos; but if aligned

with the broader roadmap, it becomes the delivery mechanism for semantic interoperability.

Synthesis of the framework

Together, these five domains form a cohesive implementation framework. Strategic Vision provides the guiding purpose; Standards define the rules of engagement; Capabilities ensure actors can act; Incentives align behaviour with value; and Architecture operationalises the system through technology. The actions synthesised in this report are not isolated fixes, but interdependent interventions requiring coordination across governance levels, sectors, and systems.

Way forward: operationalising the roadmap through C-BEDS and C-BEDSync

The roadmap presented in this paper emphasises that semantic interoperability for a circular built environment cannot be achieved through isolated technical deliverables. Implementation requires sustained coordination across actors and initiatives to reduce duplication, build alignment, and maintain continuity of purpose and measurement.

As a practical response, the authors of this article have established C-BEDS (Centre for Built Environment Data Sharing) as a collaborative "network of networks" designed to connect, support, and amplify existing work rather than introducing an additional competing initiative.

Governance

C-BEDS is framed as a sector-wide collaboration committed to making data-sharing initiatives accessible, connected, and valued, recognising that new activities must build on substantial work already underway. It is explicitly intended to support alignment and collective progress through shared infrastructure, communication, and coordination, while maintaining distributed leadership and ownership across the ecosystem.

The governance framework is informed by a Collective Impact approach and organises alignment through five areas: (i) common agenda, (ii) shared measurement systems, (iii) mutually reinforcing activities, (iv) continuous communication, and (v) backbone support (Kania et al., 2022). Backbone support is described as being coordinated by an organisation while being collectively shaped and governed by the wider community, to sustain momentum, trust, and fairness across participating organisations.

C-BEDSync and the Memorandum of Understanding as implementation instruments

To operationalise "shared measurement" and make ecosystem progress visible, C-BEDS defines two primary outputs. The first is C-BEDSync, a platform that collects, categorises, and visualises data-sharing initiatives to support awareness, learning, and the avoidance of duplication. The governance framework proposes to assess C-BEDSync through indicators such as (a) the number of initiatives captured, (b) the quality of categorisation, and (c) the strength of links established between initiatives (Figure 2). To maintain the live mapping of standards, schemas, and related initiatives as regulations and market practices evolve, CBEDS envisages a backbone stewardship function supported by a cross-sector working group including standards bodies, regulators, software providers, and industry

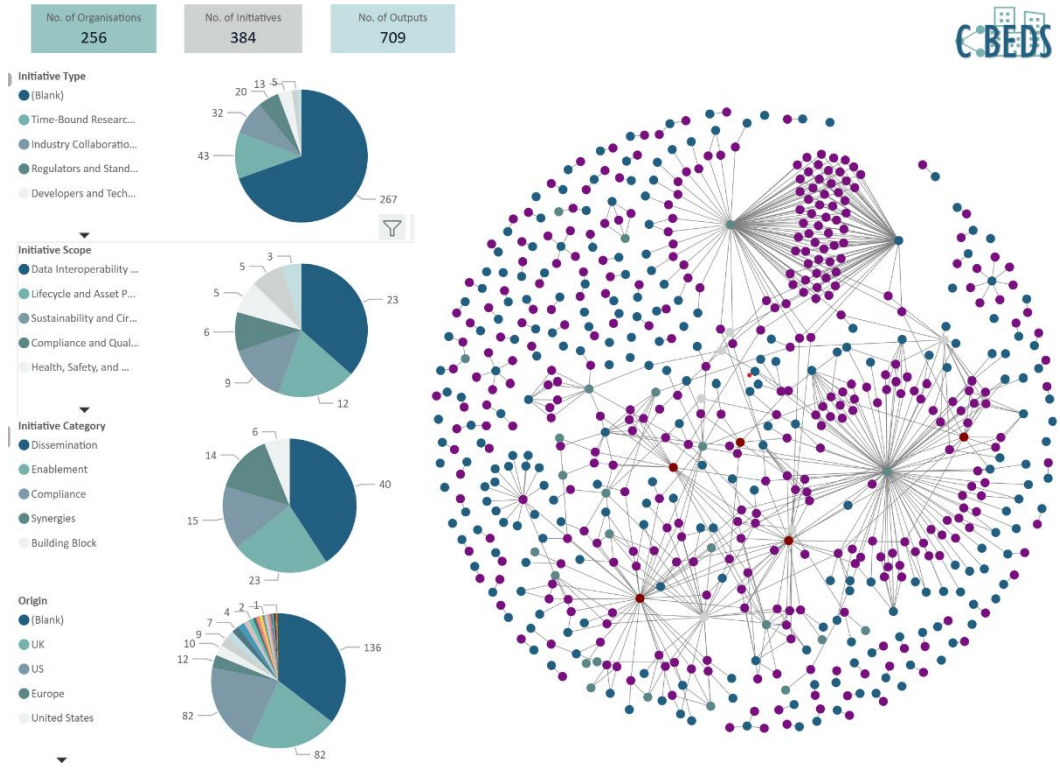

Figure 2: Screenshot from C-BEDSync

Table 2: Implementation pathway across the five domains

Roadmap domains	C-BEDS approach
Domain 1 Shared strategic vision	"Common agenda" mechanisms support alignment on outcomes and priorities across initiatives and governance levels.
Domain 2 Aligned standards & requirements	C-BEDSync's mapping function can improve discoverability of relevant standards, ontologies, and templates and identify overlaps, gaps, and opportunities for consolidation.
Domain 3 Organisational & human capability	Recurring workshops, webinars, and community engagement create a channel for shared learning and diffusion of practices, supporting capability development at ecosystem scale.
Domain 4 Incentives & value realisation	Shared measurement and the MoU provide mechanisms to make collaboration visible and to translate intent into accountable joint action.
Domain 5 Integrated system architecture	By linking initiatives and their outputs, C-BEDSync can help prioritise interoperability pilots and reduce duplicated platform building, increasing the likelihood that architectural work converges on usable, shared semantics.

representatives. This group would be responsible for periodic updates, validation of mappings, and publication of agreed changes.

The second instrument is a Memorandum of Understanding (MoU) intended to formalise collaboration among organisations and enable deeper alignment of objectives. Progress is to be tracked not only through the number and diversity of signatories, but also through tangible collaborative outcomes (e.g., formation of consortia or joint research and innovation proposals).

In addition, C-BEDS outlines a portfolio of mutually reinforcing activities such as workshops and webinars, white papers and academic outputs, community engagement, C-BEDSync platform development, and coordination/project management explicitly positioned to complement rather than duplicate existing networks and initiatives.

How this "way forward" connects to the roadmap dimensions

Positioned against the five-domain roadmap proposed in this paper, C-BEDS provides a practical implementation pathway as shown in Table 2. Overall, C-BEDS and C-BEDSync exemplify a concrete "roadmap-to-action" approach: providing governance, measurement, and connectivity infrastructure that can help translate interdependent actions into coordinated delivery, while preserving distributed ownership across the ecosystem.

Conclusions

This paper reframed semantic interoperability for a circular built environment as a systemic challenge rather than a purely technical integration task. Based on multi-stakeholder workshop evidence, we synthesised a roadmap that organises mutually dependent interventions across five domains – shared strategic vision, aligned standards and requirements, organisational and human capability, incentives and value realisation, and integrated system architecture – and highlighted why progress depends on coordinated sequencing rather than isolated actions. The "Way forward" section illustrates how this logic can be operationalised through cross-initiative coordination mechanisms such as C-BEDS and the C-BEDSync mapping platform, which aim to reduce duplication and strengthen alignment across the ecosystem. Future work should validate the roadmap through applied pilots and shared measurement, assessing whether cross-domain coordination improves data quality, traceability, and circular decision-making at scale.

DECISION SUPPORT FRAMEWORK FOR INTEGRATING CONSTRUCTION CONSOLIDATION CENTRE INTO SUSTAINABLE WASTE MANAGEMENT

Jintian Xu, Thijs Nooijen, Qi Han and Dujuan Yang
Eindhoven University of Technology, The Netherlands

Abstract

Inner-city construction projects face severe spatial constraints during the finishing stage, often leading to mixed construction and demolition waste (C&DW) handling and reduced circular performance. This paper proposes a project-level decision-support framework to evaluate outbound C&DW logistics strategies, addressing the lack of project-level comparative tools. The framework integrates economic, environmental, and social indicators in a scenario-based comparison of conventional handling and CCC-enabled reverse logistics. Applied to three Dutch projects, results show cost and emission reductions, with slightly higher logistics intensity. The framework supports ex ante decision-making under spatial constraints.

Introduction

Problem Context

Inner-city construction projects operate under conditions that fundamentally constrain material handling and logistics. Dense urban environments are characterised by limited on-site space, restricted access time windows, and regulatory constraints on vehicle movements. These conditions significantly reduce the feasibility of conventional construction logistics and waste management practices, particularly when compared to projects located in less spatially constrained areas (Guerlain et al., 2019).

These spatial constraints become especially critical during the finishing stage of construction—i.e., the late phase after the building shell is weather-tight, when interior fit-out, final installations, and snagging activities dominate until practical completion. Although the overall volume of construction and demolition waste (C&DW) often decreases towards project completion, the diversity and complexity of waste streams typically increase. This stage produces a heterogeneous mix of materials (e.g., wood off-cuts, drywall, insulation, plastics, metals, and packaging), which requires frequent handling and effective on-site separation—tasks that are difficult to perform on inner-city sites with limited storage capacity (Gálvez-Martos et al., 2018). Although the finishing stage does not necessarily generate the highest waste volume, it is particularly relevant for this study because it combines high waste-stream heterogeneity, frequent handling, packaging waste, and intensive subcontractor coordination. Under inner-city space constraints, these conditions make on-site source separation especially difficult and increase the likelihood that recyclable materials are disposed of as mixed waste.

Under such conditions, mixed C&DW handling often becomes the default practice. Instead of separating waste streams on-site, different materials are commonly disposed together in a single container and transported to recycling facilities in an unsegregated state. This practice is not the result of a deliberate preference for low-quality recycling, but rather a pragmatic response to severe spatial and logistical constraints at the project site (Wang et al., 2010).

The downstream consequences of mixed waste handling are significant. At recycling facilities, unsegregated waste requires additional mechanical sorting, which increases operational costs and energy consumption. In many cases, the economic feasibility of high-quality separation is limited, resulting in valuable materials being downcycled into low-grade applications rather than reused or recycled at their original value level (Bayram and Greiff, 2023). In addition to material degradation, mixed waste handling contributes to higher transport-related emissions and increased urban disturbance through inefficient logistics operations and additional freight movements (Guerlain et al., 2019).

Decision-Making Challenge

Project teams operating in inner-city construction contexts must continuously balance economic cost, environmental performance, and urban impacts under tight spatial and temporal constraints. Decisions regarding C&DW handling during the finishing stage are often made under pressure, with limited flexibility to revise logistical arrangements once construction activities are underway.

In practice, waste-handling decisions at the project level tend to be reactive and fragmented. Waste is frequently treated as an operational by-product rather than as a strategic component of construction logistics planning. As a result, decisions are commonly driven by short-term cost considerations and immediate site feasibility, without a structured ex ante comparison of alternative outbound waste logistics strategies (Brusselaers et al., 2024).

This fragmented decision-making environment is further reinforced by the absence of transparent, project-specific decision-support tools. While general sustainability frameworks and guidelines exist, they rarely provide actionable support for evaluating how different waste handling strategies perform under the specific spatial constraints of inner-city construction sites. Consequently, project managers lack the analytical means to systematically assess trade-offs between cost, emissions, and urban impacts during the finishing stage, when waste complexity is at its highest (Yuan, 2013).

Research Question

In response to the challenges outlined above, this study addresses the following research question:

How can a Construction Consolidation Centre (CCC) be integrated into outbound C&DW management during the finishing stage of inner-city construction projects, and how can the resulting economic, environmental, and social impacts be quantified and compared to support project-level decision-making?

Contribution

This study contributes to construction logistics and waste management in three related respects. It develops a project-specific framework for comparing outbound C&DW strategies during the finishing stage of inner-city projects. It also extends the discussion of CCCs beyond inbound supply logistics by examining their role in reverse logistics and source-separated waste collection. Finally, it brings cost, emissions, and urban disturbance into one comparative structure, allowing alternative waste-handling strategies to be assessed under the same project conditions.

Literature Review and Research Gap

C&DW Management Assessment

Assessment of construction and demolition waste (C&DW) management has been widely addressed in the literature, with a strong emphasis on life-cycle-based evaluation methods. Life Cycle Assessment (LCA) is frequently applied to quantify environmental impacts associated with waste treatment, transport, and recycling processes, while Life Cycle Costing (LCC) is commonly used to assess economic performance across collection, sorting, transport, and disposal activities (Finnveden et al., 2009). Together, these approaches provide valuable insights into the environmental and economic implications of alternative waste management strategies.

However, the majority of existing assessments operate at an aggregate, sectoral, or policy-oriented level. Many studies focus on national waste streams, generic building types, or average treatment scenarios, rather than on individual construction projects with specific spatial and logistical constraints (Yuan, 2013). As a result, the outcomes of such assessments are often descriptive in nature and insufficiently sensitive to project-level conditions such as site size, access restrictions, or construction phase.

In addition, social impacts are only marginally addressed in most C&DW assessment studies. Where social considerations are included, they are often treated qualitatively or discussed conceptually, rather than being operationalised through quantifiable indicators (Zhao et al., 2023). Urban disturbance effects related to freight movements, congestion, and nuisance are therefore rarely integrated alongside environmental and economic performance in a systematic manner (Muñuzuri et al., 2005).

Consequently, while existing C&DW assessment literature provides important methodological foundations, it offers limited support for project-level, scenario-based decision-making in complex inner-city construction contexts, particularly during the finishing stage when waste diversity and logistical pressure are the highest.

Construction Consolidation Centre (CCC)

A Construction Consolidation Centre (CCC) is an off-site logistics facility, typically located outside the dense urban core, where construction materials are received, consolidated, and re-dispatched to site in coordinated deliveries. Existing research shows that CCCs can improve delivery reliability, reduce inbound vehicle trips, and lower transport-related impacts in urban construction projects (Muñuzuri et al., 2005; Russo et al., 2021). They have been widely studied as a logistics solution for improving material delivery efficiency, with consistent evidence of reduced vehicle trips and emissions through coordinated last-mile logistics (Russo et al., 2021).

Most CCC studies focus explicitly on inbound material flows, evaluating performance in terms of delivery efficiency, cost savings, and emission reductions associated with supplier-to-site logistics. These analyses typically assess CCC performance using indicators such as vehicle kilometres travelled, delivery frequency, and load factors, often in comparison with conventional direct-to-site delivery models (Muñuzuri et al., 2005).

By contrast, the application of CCC to outbound logistics, and particularly to C&DW flows, remains largely unexplored (Rubio et al., 2019). Existing CCC literature rarely considers reverse logistics or the potential role of CCC in enabling source-separated waste collection under spatially constrained site conditions. Where waste is mentioned, it is typically treated as a secondary or operational issue rather than as a core component of logistics system design (Guerlain et al., 2019).

As a result, there is a lack of analytical tools and empirical studies that evaluate CCC-enabled reverse logistics for C&DW at the project level. In particular, the literature does not provide structured methods for comparing conventional mixed-waste handling with integrated CCC-based waste strategies under real inner-city constraints.

Research Gap

Despite useful insights from both strands of literature, a practical project-level gap remains. On the one hand, C&DW assessment studies predominantly rely on LCA and LCC approaches that are insufficiently tailored to

project-specific, scenario-based decision-making in spatially constrained environments (Finnveden et al., 2009). On the other hand, CCC research has largely focused on inbound logistics, with limited attention to outbound waste flows and reverse logistics applications (Russo et al., 2021).

What is still missing is a project-level method for comparing conventional mixed-waste handling with CCC-supported reverse logistics under the same site conditions. Empirical studies that make this comparison in spatially constrained inner-city settings are still limited. Accordingly, this study develops an ex ante, project-level decision-support framework that explicitly links outbound waste-handling strategies to inner-city logistical constraints and evaluates their economic, environmental, and social implications during the finishing stage of inner-city construction projects. This gap directly informs the framework and method presented in the following section.

Decision-Support Framework and Method

Framework Overview

The framework is used to compare alternative outbound C&DW logistics strategies during the finishing stage of inner-city construction projects. This stage is characterised by high material diversity, frequent logistics operations, and severe spatial constraints, which together complicate conventional waste-handling practices.

The framework adopts a scenario-based comparative logic, enabling project stakeholders to evaluate alternative waste-management strategies under identical project conditions. Two distinct strategies are defined:

- Baseline scenario, representing conventional mixed-waste handling practices commonly observed in spatially constrained inner-city projects (Haag and Jünger, 2023).
- Integrated scenario, representing a coordinated waste-handling strategy enabled through a Construction Consolidation Centre (CCC) with reverse logistics integration (Paddeu, 2018).

The decision context is explicitly project-level and ex ante. The framework is intended to be applied during the procurement and planning phase, when waste-handling strategies can still be adjusted without disrupting ongoing construction activities. The primary stakeholders supported by the framework include contractors, project managers, CCC operators, and, indirectly, municipal authorities responsible for regulating urban freight and construction logistics (Melkonyan et al., 2022; Sobotka and Sagan, 2021).

This setup allows the baseline and integrated scenarios to be compared on the same economic, environmental, and social indicators under the actual spatial conditions of each case (Maxner et al., 2025).

Key Performance Indicator (KPI) Framework

To support multi-criteria decision-making, the framework evaluates outbound C&DW management strategies using a structured set of Key Performance Indicators (KPIs) (Figure 1). The KPIs are limited to indicators that are decision-relevant and operationally estimable during procurement-stage planning and are grouped into three dimensions—economic, environmental, and social—as summarised in Table 1, together with their definitions and units. The framework is intended as a project-level, ex ante comparative assessment of finishing-stage outbound waste logistics rather than a full cradle-to-grave LCA/LCC.

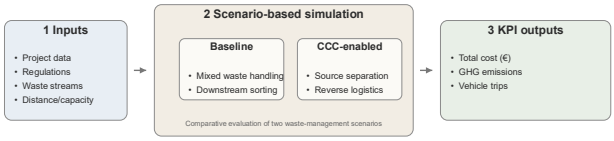

Figure 1: Decision-support framework for outbound C&DW logistics

Table 1: KPI Framework Overview

Dimension	Indicator	Unit	Description
Economic	Transport cost	€	Waste transport costs
Economic	Container handling	€	Container rental and handling
Economic	Sorting & labour	€	On-site sorting labour
Economic	Recovery revenue	€	Income from recyclables
Economic	CO_2 cost	€	Monetised carbon emissions
Environmental	Transport emissions	kg CO_2-eq	Freight-related emissions
Environmental	Sorting emissions	kg CO_2-eq	Waste treatment emissions
Social	Vehicle trips	number	Proxy for urban disturbance

Economic dimension

Economic performance is evaluated as a project-level cost–benefit balance for outbound C&DW logistics, enabling ex ante comparison across scenarios (Brusselaers et al., 2024; Yuan, 2013). Where relevant, carbon pricing is applied to express greenhouse gas emissions as a monetised externality within the economic comparison (Greenstone et al., 2013). Physical emissions are reported separately in the environmental dimension; the CO_2 cost term is included only to support integrated scenario comparison and does not replace the environmental assessment.

Environmental dimension

Environmental performance is assessed using greenhouse gas emissions associated with transport and mixed-waste sorting processes, allowing consistent comparison across logistics configurations (Butera et al., 2015; Hossain et al., 2017; Bayram and Greiff, 2023). Greenhouse gas emissions were selected as the primary environmental indicator because they can be estimated consistently using available project-level inputs, whereas broader impact

categories would require a level of process detail beyond the scope of this ex ante project-level assessment.

Social dimension

Social performance is captured through vehicle trips as an operational proxy for urban disturbance associated with waste logistics movements, providing a transparent basis for project-level comparison under typical data constraints (Çolak et al., 2016). Congestion, noise, and traffic-related disturbance are difficult to quantify directly at project level, whereas trip frequency offers a simple and comparable indicator of logistics intensity in dense urban contexts.

Scenario-Based Simulation Logic

The decision-support framework evaluates performance using two explicitly defined simulation scenarios. Both scenarios are modelled using identical project inputs to ensure comparability.

Baseline scenario

The baseline scenario represents conventional C&DW handling practices commonly applied in inner-city construction projects:

- Waste is collected in a single mixed container.
- No on-site waste separation is performed.
- Waste collection is reactive, triggered when the container is full.
- Waste is transported directly to recycling facilities, where mechanical sorting is required.

This scenario reflects a common fallback practice where limited site space and constrained layout conditions reduce the feasibility of stable on-site source separation (Tsegay et al., 2023).

Integrated scenario

The integrated scenario models a coordinated outbound waste-handling strategy enabled through a CCC with reverse logistics integration:

- Waste is separated on-site using multiple small, material-specific containers.
- Empty containers are supplied (and swapped when needed) via the same coordinated inbound delivery trips from the CCC, i.e., no dedicated trips are assumed solely for container provision.
- Inbound material deliveries and outbound waste collection are coordinated.
- Vehicles delivering materials to the site collect full waste containers on return trips.
- Weekly logistics planning is used to improve the coordination and utilisation of construction transport operations (Brusselaers et al., 2024).

By integrating inbound and outbound logistics, the integrated scenario aims to enable source separation without substantially increasing transport demand.

Decision-Support Tool Implementation

The framework is implemented as a project-level decision-support tool (DST) for the ex ante evaluation of alternative outbound waste-handling strategies. The tool uses project-specific inputs, including project type and size, site constraints, finishing-stage waste-generation parameters, distances to CCCs and recycling facilities, and cost, emission, and carbon-pricing parameters (Greenstone et al., 2013; Çolak et al., 2016; Katsela et al., 2022).

The tool simulates baseline and CCC-enabled scenarios under identical case conditions and converts the outputs into comparable economic, environmental, and social KPIs. Assumptions and parameters remain explicit and adjustable, enabling transparent scenario testing prior to implementation (Melkonyan et al., 2022).

Case Studies and Results

Case Study Description

The decision-support framework was applied to three inner-city construction projects in the Netherlands, selected to represent varying degrees of spatial constraint while involving comparable finishing-stage logistics challenges. The cases include two projects in Utrecht and one in Amsterdam, all involving intensive finishing-stage activities under constrained site conditions (Tsegay et al., 2023).

The Renaissance project in Amsterdam represents a highly constrained inner-city context, characterised by extremely limited on-site storage space, strict access windows, and intensive interaction with surrounding urban functions. These conditions severely restrict conventional waste-handling practices during the finishing stage.

The Tivoli project in Utrecht is a heritage renovation located in a dense historic urban area. While spatial constraints are slightly less severe than in the Renaissance case, the project faces access regulations, heritage protection requirements, and restricted on-site container placement, imposing both spatial and regulatory limitations on waste-handling decisions.

The Beneluxlaan project in Utrecht serves as a comparatively less constrained urban case. Although still embedded within the urban fabric, the project benefits from improved access conditions and marginally greater on-site space, providing a contrast for assessing how strategy performance varies with the degree of spatial constraint.

Across all three cases, the finishing stage constitutes the primary focus of analysis due to its high waste-stream heterogeneity and operational complexity. For each project, two waste-handling strategies were evaluated: a baseline scenario representing conventional mixed-waste handling and an integrated scenario based on CCC-enabled reverse logistics.

Table 2: Characteristics of analysed case studies

Case	City	Project type	Site constraint	Finishing complexity
Renaissance	Amsterdam	Redevelopment	Very high	High
Tivoli	Utrecht	Heritage renovation	High	Medium–high
Beneluxlaan	Utrecht	New construction	Moderate	Medium

Economic Performance Results

Economic performance is evaluated based on project-total finishing-stage waste-handling costs for each case study. Cost components include container rental and handling, transport operations, sorting and labour activities, disposal fees, and revenues from recovered materials, consistent with the framework defined in the previous section. Absolute cost levels differ substantially across the three cases because the reported results reflect project totals rather than normalised values; they therefore support within-case scenario comparison more directly than cross-case benchmarking. Figure 2 illustrates the project-total cost difference between the baseline and integrated scenarios for each case.

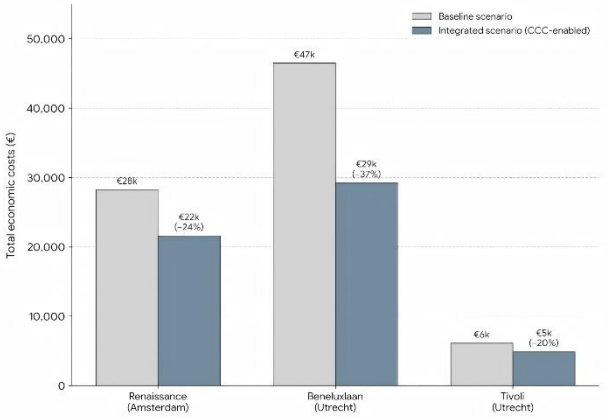

Figure 2: Project-total finishing-stage waste-management costs by case and scenario

In all three cases, the CCC-enabled scenario was less costly than the baseline mixed-waste handling strategy. Total cost reductions range from approximately 20% to 37%, depending on project characteristics and spatial constraints. Differences in absolute cost levels should be interpreted in relation to project-specific scale, finishing-stage scope, and site conditions rather than as like-for-like benchmarks between the three cases. The largest relative savings are observed in the most spatially constrained cases, where baseline logistics are characterised by high transport frequency and handling inefficiencies.

Cost breakdown analysis indicates that savings are primarily driven by reduced transport inefficiencies and increased revenues from material recovery. Although the integrated scenario introduces additional sorting and coordination activities, these costs are outweighed by efficiencies achieved through consolidated logistics operations. In contrast, the baseline scenario exhibits higher downstream disposal and sorting costs due to the treatment of mixed waste streams.

Overall, the economic benefits of CCC-enabled reverse logistics were strongest in cases where limited space and inefficient mixed-waste treatment made the baseline arrangement particularly costly.

Environmental Performance Results

Environmental performance is evaluated based on project-total transport- and mixed-waste-sorting-related CO_2 emissions associated with finishing-stage waste handling (Butera et al., 2015; Bayram and Greiff, 2023). These emissions are calculated consistently across the baseline and integrated scenarios using the parameters defined in the decision-support framework and are intended primarily for within-case comparison rather than cross-case benchmarking. Figure 3 illustrates the difference in project-total transport- and sorting-related CO_2 emissions between the two scenarios in each case.

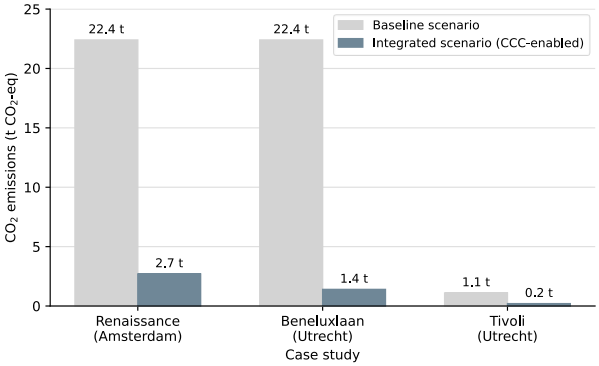

Figure 3: Project-total transport- and sorting-related CO_2 emissions by case and scenario

In all three cases, the integrated scenario produced substantially lower transport- and sorting-related CO_2 emissions than the baseline, with total reductions of roughly 85% to 94%. The dominant contributor to this reduction is the avoidance of energy-intensive downstream sorting processes associated with mixed-waste handling.

Transport-related emissions are also lower in the integrated scenario due to coordinated inbound and outbound logistics enabled by the CCC. Although logistics operations may occur more frequently, improved vehicle utilisation and reduced reliance on dedicated waste transport trips lead to lower overall emissions within the defined project-level assessment boundary (Wu et al., 2023).

Environmental performance gains are particularly pronounced in projects where baseline practices rely heavily on mixed containers and downstream mechanical sorting. In such contexts, source separation enabled through CCC-based reverse logistics offers significant emission avoidance potential.

Social Impact Results

Social impacts are evaluated using the number of vehicle trips as a proxy indicator for urban disturbance, including traffic congestion, noise, and safety risks in dense urban environments (Li et al., 2024).

In contrast to the economic and environmental results, the integrated scenario is associated with a moderate increase in modelled vehicle trips, ranging from approximately 8% to 15% across the three cases. This increase is primarily linked to the more frequent collection of smaller, source-separated waste containers during the finishing stage. Figure 4 shows the modelled number of vehicle trips under the baseline and integrated scenarios for each case.

However, this increase should be interpreted with care. Under the integrated scenario, waste collection is coordinated with inbound material deliveries, meaning that some outbound waste movements may be combined with return legs that would otherwise occur without payload. The vehicle-trip indicator should therefore be understood as an operational proxy reflecting handling rhythm and logistics intensity, rather than as a direct count of net-new urban freight movements. In the baseline scenario, fewer trips may be observed, but these are typically less coordinated and may involve less efficient vehicle utilisation and longer on-site dwell times.

This points to a clear trade-off: the integrated scenario improves cost and emissions performance, but it can also increase the frequency of on-site waste-handling operations. This trade-off highlights the importance of coordination between project-level waste-handling decisions and broader urban logistics planning in highly constrained inner-city environments.

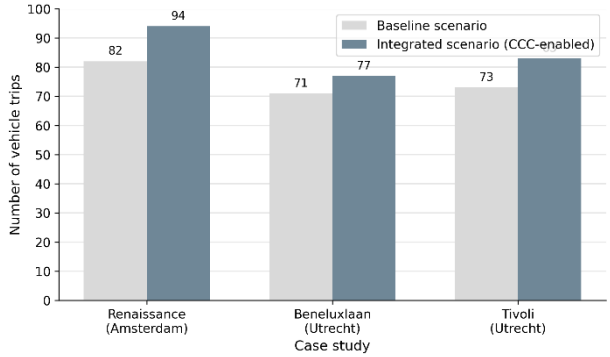

Figure 4: Number of vehicle trips associated with outbound C&DW logistics under baseline and CCC-enabled scenarios

Sensitivity Analysis

To test the robustness of the case-study findings, a threshold-based sensitivity analysis was conducted, focusing on dominant economic and project-constraint parameters. Specifically, we identified (i) the break-even mixed-waste recycling cost at which the baseline strategy becomes economically comparable to the CCC-enabled scenario, and (ii) estimated tipping points for key project constraints, including project size and available on-site storage area, at which the relative performance of the integrated strategy changes.

Across the analysed cases, the CCC-enabled scenario remains environmentally favourable across the tested ranges, while economic performance is more sensitive to market and constraint factors. As summarised in Table 3, the baseline strategy would require a substantial reduction in mixed-waste recycling costs (23.6–30.7%) to become economically comparable to the integrated scenario. In addition, the viability of the integrated strategy is shaped by project scale and available on-site staging capacity, indicating that CCC-enabled reverse logistics should be interpreted as a context-sensitive rather than universally optimal solution.

The thresholds reported in Table 3 are case-specific and should therefore be interpreted as indicative break-even conditions rather than transferable benchmark values.

Table 3: Case-specific sensitivity thresholds: indicative break-even recycling cost and project-constraint tipping points

Case	Break-even recycling cost (€/m³)	Required reduction (%)	Economic scale threshold (m²)	Environmental scale threshold (m²)	On-site storage threshold (m²)
Renaissance	147	25.1	1880	900	100
Tivoli	150	23.6	1900	1850	20
Beneluxlaan	136	30.7	1800	900	25

Discussion

Scalability and Transferability

The framework should not be read as a source of universally applicable threshold values. Its value lies instead in offering a comparison logic that can be adapted to projects with different spatial constraints. In this study, these constraints are operationalised mainly through on-site staging capacity and accessibility conditions, which shape feasible container configurations, handling frequency, and collection feasibility in the baseline and integrated strategies.

Across the three cases, performance differences are driven by how these constraints interact with project-specific scale and duration. Tighter sites restrict material-specific containers and increase swap frequency, whereas less constrained sites allow more stable source separation. The resulting cost and emission outcomes should therefore be interpreted as contingent on local spatial and logistical conditions rather than fixed benchmarks.

Even so, the analytical structure can still be applied to other projects, provided that case-specific inputs are retained. By combining scenario-based comparison with a consistent KPI set, the framework supports ex ante assessment across projects while allowing case-specific inputs to vary.

Sensitivity and Key Enablers

The sensitivity analysis shows that the economic performance of CCC-enabled reverse logistics depends mainly on a small number of market and project-constraint variables. As summarised in Table 3, its economic advantage is particularly sensitive to downstream mixed-waste treatment conditions: the

baseline strategy would require a substantial reduction in mixed-waste recycling costs (approximately 23.6–30.7%) to become economically comparable to the CCC-enabled scenario. This indicates that, under typical market conditions, the economic case for integrated reverse logistics is relatively robust, although it may weaken under unfavourable pricing environments (Wu et al., 2023).

Project scale constitutes a second decisive factor. The tipping-point analysis (Table 3) indicates scale thresholds around 1800–1900 m², below which the fixed coordination requirements of CCC-enabled logistics are less likely to be amortised. Smaller or short-duration projects may therefore struggle to realise economic benefits despite potential emission reductions. The analysis further shows that on-site staging capacity acts as a practical feasibility constraint: where available storage space falls below the identified thresholds, the achievable degree of source separation and the operational rhythm of container swaps may be restricted.

Beyond these quantitative sensitivities, institutional and organisational conditions remain key enablers. Effective implementation depends on coordination among contractors, CCC operators, and municipal authorities, particularly with respect to delivery windows, vehicle access regulations, and on-site handling arrangements. In addition, mechanisms such as carbon pricing may strengthen the relative performance of integrated logistics by internalising transport-related emissions that are otherwise excluded from project-level decision-making (Katsela et al., 2022).

CCC-enabled reverse logistics is therefore better understood as a conditional solution: it performs well in some inner-city settings, but not under all project conditions. The proposed framework provides a structured means to identify when integrated outbound waste logistics constitutes a robust and defensible choice under real inner-city constraints.

Limitations

This study has several limitations. It is based on three Dutch case studies, limiting geographical and regulatory generalisability. It provides a project-level, ex ante comparison of finishing-stage outbound waste logistics rather than a full cradle-to-grave LCA/LCC. Social impacts are approximated through vehicle trips, and mixed-waste sorting emissions and other operational parameters rely partly on secondary assumptions. Results are therefore most robust for within-case comparison rather than direct cross-case benchmarking.

Conclusions

This study developed a framework for comparing outbound C&DW strategies during the finishing stage of inner-city construction projects. Using a baseline mixed-waste scenario and a CCC-enabled reverse-logistics scenario, it examines how cost, emissions, and urban disturbance change under different site conditions.

The case-based comparisons suggest that CCC-enabled reverse logistics may improve cost and emission performance under the analysed conditions, while also increasing logistics intensity in some cases. The main contribution is not a universal prescription, but a practical way to judge when integrated outbound waste logistics is feasible and worthwhile under specific spatial and organisational conditions.

Future research

Future research could extend the framework in several directions. BIM-based waste estimation could improve the automation and accuracy of project-level waste forecasting (Guerra et al., 2019).

Real-time logistics data could support more dynamic decision-making during project execution (Brusselaers et al., 2024).

In addition, coupling the tool with urban transport simulation models may help capture network-level effects, while expanding the social assessment could account for worker-related impacts such as handling burden, safety, and usability. Together, these extensions would improve the framework's relevance for circular decision-making in dense urban construction contexts.

DATA DRIVEN DECISION SUPPORT FRAMEWORK FOR PRODUCT LEVEL REUSE PRIORITISATION AND BARRIER DIAGNOSIS

Qi Han, Jintian Xu, Dujuan Yang, T. van Tongeren
Eindhoven University of Technology, The Netherlands

Abstract

This paper proposes a three-stage workflow to prioritise reusable building product groups in Dutch demolition outflows, addressing the gap between impact potential and implementation feasibility. Stage 1 screens 139 groups using an impact proxy combining mass outflow and the environmental cost indicator, shortlisting ten candidates. Stage 2 applies a five-criteria multi-criteria analysis with weights from eight experts using the Best–Worst Method, where supply–demand balance dominates (0.296) and sustainability ranks lowest (0.137). Stage 3 links ranking to barrier diagnosis through a masonry case, identifying contamination, certification, and coordination challenges. The workflow supports identifying high priority product groups for early-stage reuse planning.

Introduction

Problem context

The construction sector remains a major contributor to material demand and embodied environmental impacts, which makes improving circular performance a priority in the transition toward a circular economy (Kirchherr et al., 2017). Yet, reuse implementation in practice remains limited, particularly at the demolition stage where large volumes of potentially reusable products leave the building stock and are often downcycled or disposed of (Arora et al., 2020).

This study focuses on demolition outflows from Dutch residential and utility buildings (B&U). In this context, environmental relevance is quantified computationally as mass outflow × MKI, where MKI (Milieu Kosten Indicator) is a Dutch aggregated environmental cost indicator and impact values are operationalised using the A1 indicator set as implemented in the national database (Nationale Milieudatabase (NMD), 2025). This framing enables a consistent comparison of heterogeneous product groups by combining (i) how much material becomes available at the end-of-life and (ii) to what extent environmentally relevant that material is under the same indicator system.

However, identifying environmentally relevant product groups does not automatically translate into reuse uptake. Practical decision-making is often constrained by fragmented information about what leaves the building stock, under what conditions, and whether reuse is feasible, timely, and economically viable within real project constraints (Bellini et al., 2024). This results in a persistent gap between circular ambition and operational reuse uptake in the built environment (Planbureau voor de Leefomgeving (PBL), 2025).

Related work and research gap

This section focuses on decision-support approaches for product-level reuse prioritisation in the built environment, rather than reviewing circular economy literature more broadly.

Research has extensively documented barriers to circular construction and product reuse, including technical constraints, market uncertainty, and institutional and behavioural factors (Kanters, 2020; Wuni, 2022). Two limitations are particularly relevant for this study.

First, high environmental relevance does not imply high reuse feasibility. Product groups with high mass outflow × MKI can still face major implementation barriers such as contamination, certification requirements, liability concerns, and misaligned supply and demand (Giorgi et al., 2022). This implies that computational decision support must separate “impact potential” from “implementability” rather than assuming they overlap (De Wolf et al., 2024).

Second, existing approaches often lack an explicit, reproducible computational pipeline that turns heterogeneous demolition outflow data and expert knowledge into transparent prioritisation outputs. In particular, reuse prioritisation requires combining impact-based signals with feasibility-related dimensions, such as cost barriers, risk barriers, supply–demand balance, and technical feasibility, rather than relying on impact alone (Yu et al., 2023). To address this, the study applies an MCA structure with five criteria—cost, risk, supply–demand balance, technical feasibility, and sustainability impact—and derives criterion weights from eight expert interviews using the Best–Worst Method (BWM) (Rezaei, 2015).

This means that environmental relevance alone is not enough to identify reuse potential. Instead, prioritisation requires explicitly accounting for implementation-oriented criteria such as cost, risk, technical feasibility, and supply–demand balance alongside impact-based indicators.

Computing-oriented circularity research in the built environment increasingly treats the existing building

stock as a quantifiable "secondary resource" that can be measured, forecast, and prioritised through data pipelines rather than narrative assessments (Arora et al., 2021). At the city/building-stock scale, computational approaches typically combine stock modelling with environmental accounting to estimate future availability of recoverable components and associated impact reduction opportunities (Röck et al., 2021). Such pipelines support "where-to-focus" decisions by identifying high-leverage materials/components before stakeholders invest in detailed feasibility studies (Wuyts et al., 2022).

However, much of the stock/potential modelling literature remains oriented toward estimating quantity and theoretical circularity potential, while practical implementation still depends on socio-technical constraints (e.g., dismantling feasibility, market absorption, regulatory permission) (Röck et al., 2021). This calls for a workflow that links data-driven screening to decision criteria such as cost, risk, technical feasibility, and market balance, instead of assuming that high potential also means easy implementation (Van Den Berg et al., 2023).

Multi-Criteria Analysis (MCA) is widely used in construction and demolition contexts because circular decisions are inherently multi-dimensional: environmental benefits must be assessed alongside cost, risk, feasibility, supply chains, and stakeholder acceptance (Banias et al., 2010; Bajwa et al., 2025). Methodologically, MCA offers a transparent aggregation structure—criteria, weights, and scores—that can be audited and updated as assumptions or stakeholder inputs change (Bajwa et al., 2025). Within circular construction research, barrier- and driver-oriented studies often operationalise implementation constraints into evaluative criteria, creating a bridge between qualitative insights and decision models (Kanters, 2020).

In C&D waste and circular practice assessments, MCA has been applied to compare strategies, prioritise interventions, and structure complex trade-offs across stakeholders (Swarnakar and Khalfan, 2024). Yet, a recurring limitation is that MCA is frequently applied after a case or material is selected, rather than being computationally coupled with an upstream, data-driven filtering step that justifies why a given product group deserves priority attention from a system-wide list (Wuyts et al., 2022).

A central methodological challenge in MCA is how to elicit reliable criterion weights, especially when expert time is limited and decision contexts are complex (Peykani et al., 2026). The Best–Worst Method (BWM) has been proposed as a robust multi-criteria weighting approach that reduces the number of pairwise comparisons while improving consistency (Rezaei, 2015). Compared to more comparison-heavy weighting methods, BWM structures expert judgement around two anchors (best and worst criteria), which is easier to communicate and reproduce in a computational workflow (Rezaei, 2016).

For computing-in-construction venues, the relevance of BWM is not only that it yields weights, but that it supports an auditable pipeline: expert inputs can be stored, checked for consistency, and re-run when either the criteria set or the stakeholder group changes, enabling iterative refinement and sensitivity testing (Peykani et al., 2026).

Combine a quantity factor (e.g., mass outflow or material availability) with an impact factor (e.g., environmental burden per unit) to identify candidate materials/components with both sufficient scale and meaningful sustainability leverage (Arora et al., 2020). This logic aligns with urban mining perspectives that frame cities and building stocks as measurable repositories whose recovery potential can be quantified and prioritised (Ghisellini et al., 2022). Building-stock studies further show that "future supply" assessments become more actionable when they are resolved into component/product categories that map onto real recovery processes and market channels (Orenga Panizza and Nik-Bakht, 2024).

In the Dutch context, impact-based filtering can leverage the national environmental cost indicator (MKI) and associated databases/tools to operationalise environmental relevance in a standardised way (Nationale Milieudatabase (NMD), 2025). Sectoral material-flow datasets provide product-group resolution for construction-related inflows/outflows, enabling computational shortlisting across many product groups before deeper feasibility analysis begins (EIB; Metabolic, 2022). The key methodological opportunity is to connect stock flow quantification with decision support prioritisation in one framework, rather than treating them as separate analytical exercises (Wuyts et al., 2022).

Two research gaps are especially relevant here. First, urban mining and stock-flow studies provide useful system-level signals on material availability and environmental impact, but they rarely translate these signals into prioritisation approaches that reflect practical feasibility, such as cost, risk, technical constraints, and supply–demand balance (Röck et al., 2021). Second, barrier and driver studies explain why reuse remains difficult, but they are less often incorporated into an explicit decision workflow. In practice, this means that few studies combine quantitative screening, weighted multi-criteria ranking, and structured barrier diagnosis in a single approach that can support intervention design (Wuni, 2022).

To address these gaps, the study treats reuse prioritisation as a decision-support task that combines impact screening, MCA-based ranking, and barrier diagnosis: product groups are first filtered using impact-based signals, then prioritised using MCA with explicit weighting, and finally connected to a demonstrative barrier diagnosis to show how quantitative ranking can guide targeted implementation strategies (Van Den Berg et al., 2023).

Existing reuse metrics and stock-based assessments are useful for identifying material availability, environmental relevance, or theoretical recovery potential, but they often

stop before implementation conditions are examined. By contrast, this study does not propose another single reuse score. It combines impact-based screening with implementation-oriented multi-criteria ranking and a case-based barrier diagnosis. The key distinction is therefore methodological rather than purely metric-based: the workflow is designed to move from environmental relevance to ranked action candidates and then to an explanation of why high-potential product groups may still face barriers in practice.

Research question

The study addresses the following main research question:

RQ: How can high-potential product groups for reuse be computationally identified from Dutch B&U demolition outflows using mass outflow × MKI, and how can key implementation barriers be diagnosed to inform targeted circular interventions?

Contributions

This study makes three contributions. First, it develops a three-stage workflow for product-level reuse prioritisation that combines impact-based filtering, weighted multi-criteria analysis, and case-based barrier diagnosis. Second, it operationalises public Dutch demolition-flow and environmental-impact data together with structured expert elicitation, making the ranking logic explicit and updateable when new data become available. Third, it shows how ranking outputs can support intervention-oriented diagnosis rather than stopping at score comparison alone, using masonry brickwork as an illustrative case.

Methodology

Research design

This study uses a mixed-method design to identify, rank, and further examine reusable product groups in Dutch demolition outflows. The design combines public product-group flow data, environmental impact data, and two rounds of semi-structured interviews. The first interview round supports Stage 2 by eliciting implementation-oriented judgement for MCA weighting and selected product-level scoring. The second round supports Stage 3 by examining how the highest-ranked product group performs in practice through stakeholder interviews along the brick value chain. This design was chosen because product-level reuse cannot be assessed from environmental relevance alone; it also requires evidence on implementation conditions, actor perspectives, and sector-specific bottlenecks.

Workflow overview

The study develops a three-stage workflow to identify, rank, and further examine reusable product groups in Dutch demolition outflows. The workflow combines impact-based screening, multi-criteria ranking, and barrier diagnosis to support product-level comparison under real implementation constraints (Swarnakar and Khalfan, 2024).

In this paper, ‘computational’ means that product groups are assessed through explicit indicators, weighted aggregation, and reproducible ranking rules (Papamichael et al., 2023).

As illustrated in Figure 1, the framework consists of three sequential stages. First, an impact-based filtering stage is applied to identify product groups with high environmental relevance based on demolition-related material outflows and environmental impact indicators (Atta and Bakhoum, 2024; Nationale Milieudatabase (NMD), 2025). Second, a multi-criteria prioritisation stage evaluates the shortlisted product groups by explicitly accounting for economic, technical, and supply–demand considerations using a structured decision-analysis method (Rezaei, 2015). Third, a case-based barrier diagnosis is conducted for the highest-ranked product group to demonstrate how the framework supports the identification of dominant implementation barriers (Giorgi et al., 2022; Wuni, 2022).

Each stage uses explicit indicators and scoring rules. This makes the workflow easier to reproduce and adapt to other datasets (Yang et al., 2023). The framework is not intended to optimise a single material or project case, but to support early-stage circular construction planning under data constraints (Papamichael et al., 2023).

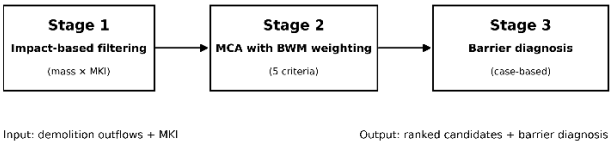

Figure 1: Overview of the computational prioritisation workflow

Stage 1 – impact-based candidate filtering (data-driven)

The first stage aims to reduce the initial set of demolition-derived product groups to a manageable number of candidates that are environmentally relevant for reuse considerations (Wuyts et al., 2022). The analysis is based on a dataset comprising 139 distinct product groups identified within the Dutch residential and utility building stock (EIB; Metabolic, 2022; Nationale Milieudatabase (NMD), 2025).

Each product group is characterised by two quantitative indicators:

(i) the annual mass outflow generated during demolition activities, and

(ii) an aggregated environmental impact indicator, expressed as the Environmental Cost Indicator (Milieu Kosten Indicator, MKI), which reflects life-cycle environmental burdens (Nationale Milieudatabase (NMD), 2025).

An impact score is derived by combining these two indicators, enabling the identification of product groups that exhibit both substantial material quantities and high environmental relevance (EIB; Metabolic, 2022). To

avoid bias towards a single material category, the selection procedure includes both overall high-impact product groups and the highest-ranking representatives within major material classes (EIB; Metabolic, 2022).

As a result, the initial set of 139 product groups is reduced to a shortlist of ten high-impact candidates, which are subsequently evaluated in greater detail in the following stage. The shortlist combines the highest-impact product groups with category representatives to avoid a shortlist dominated by a single material family.

Stage 2 – multi-criteria prioritisation

While the first stage identifies product groups with high environmental relevance, it does not capture constraints related to practical implementation (Byers et al., 2024). Therefore, the second stage applies a multi-criteria decision analysis (MCA) to assess the feasibility of reuse across the shortlisted product groups (EIB; Metabolic, 2022).

Five evaluation criteria are defined to capture key dimensions influencing reuse implementation:

(1) economic barriers,

(2) technical feasibility,

(3) sustainability/impact,

(4) risks related to uncertainty and liability, and

(5) supply–demand balance.

Each product group is scored on a five-point ordinal scale for each criterion using evidence from the literature and expert judgement (Peykani et al., 2026). Criterion weighting and product-level scoring served different purposes. Weighting was used to capture broader implementation priorities across the five reuse criteria, whereas product-level scoring of cost and risk required more specific familiarity with particular product groups. To reflect the relative importance of the criteria, weights were derived using the Best–Worst Method (BWM), which provides a structured form of preference elicitation (Rezaei, 2016).

Criterion weights were obtained from eight semi-structured interviews with relatively independent experts in circular construction and reuse. The interviewees were selected to provide cross-sector perspectives rather than product-specific advocacy. In the BWM step, each expert identified the most important and least important criterion and then compared the remaining criteria to these two anchors on a 1–9 scale. Individual weights were calculated and averaged to obtain the final weight set. Product-level scoring of cost and risk was restricted to interviewees who indicated sufficient familiarity with specific product groups, to avoid speculative ratings at that level. To test robustness, the weighting step was recalculated by excluding one expert at a time. This allowed the ranking to be checked for sensitivity to individual expert input.

The overall prioritisation score for each product group is calculated using a weighted additive model:

$$S_i = \sum_{j=1}^{n} w_j \cdot x_{ij}$$

where S_i denotes the aggregated score of product group i, w_j represents the weight of criterion j, and x_{ij} is the normalised score of product group i under criterion j (Jato-Espino et al., 2014).

This procedure allows different product groups to be compared using the same logic, while keeping environmental relevance separate from implementation feasibility (Byers et al., 2024). Criterion weighting used all eight expert interviews, whereas product-level scoring of cost and risk was restricted to interviewees who indicated sufficient familiarity with specific product groups.

Stage 3 – barrier diagnosis

Stage 3 examines why the product group ranked highest in Stage 2 may still face implementation bottlenecks in practice. Brick masonry is used as the demonstration case. A qualitative analysis is conducted to examine its value-chain structure and identify dominant barriers affecting reuse implementation. The diagnosis draws on five stakeholder interviews across the brick value chain and uses literature-derived barrier categories as a coding frame to identify constraints related to coordination, certification, contamination control, and process organization (Wuni, 2022). The purpose of Stage 3 is analytical explanation rather than statistical validation: it links the ranking output to observed implementation barriers and shows how prioritisation results can support intervention-oriented diagnosis (Rakhshan et al., 2020; Wuyts et al., 2022).

Data sources and reproducibility

The workflow combines public quantitative datasets with interview-based expert judgement. Product-group outflow data were taken from the EIB/SGS-Search mass-flow dataset for Dutch residential and utility buildings, while environmental impact values were retrieved from the Dutch National Environmental Database (NMD) using MKI-based product matches. Data cleaning, product-group merging, thresholding, and impact calculations were implemented in Microsoft Excel using explicit rules and formula-based operations. Public input datasets, decision rules, and scoring procedures are described in the methodology. Interview responses are not reported in full because of ethics and anonymity requirements, but the interview protocol, weighting procedure, and sensitivity checks are summarised in the paper.

Evaluation logic

The framework is evaluated as a demonstration rather than as a full external validation exercise. Its usefulness is assessed in three ways: first, whether Stage 2 meaningfully reorders the Stage 1 shortlist once implementation-oriented criteria are introduced; second, whether the weighting results remain stable under leave-one-out recalculation; and third, whether the masonry

case reveals barriers that are not visible in impact screening alone. Together, these checks show whether the workflow produces distinct, interpretable, and implementation-relevant outputs.

Results

Impact screening results

This section presents the results from the three stages of the workflow. Stage 1 yields a shortlist of high-impact product groups, Stage 2 produces a reuse-oriented prioritisation ranking, and Stage 3 uses masonry brickwork for demonstration only to illustrate the quantitative–qualitative linkage between computational prioritisation and barrier diagnosis (Hopkinson et al., 2019).

After applying the predefined merging rules, the initial product-group list was reduced from 139 to 115 groups. Candidate filtering first applied a mass-flow threshold, retaining groups with relative mass outflow ≥ 0.5%; groups in the 0.5–0.1% band were re-examined for possible merging effects, but no additional merges qualified. The average relative mass outflow of the Top-5 groups was more than 29× that of the 24th group, supporting the assumption that contributions below the threshold can be neglected. For shortlisted groups, environmental impact was computed as mass outflow × MKI, where MKI values were retrieved from the Dutch National Environmental Database (NMD) and multiplied by the corresponding outflow mass to obtain an impact proxy in euros (€). To avoid dominance by stone-like products in the Top-5, the shortlist also includes the highest-impact representatives from steel, wood, glass, mixed and plastics; see Figure 2.

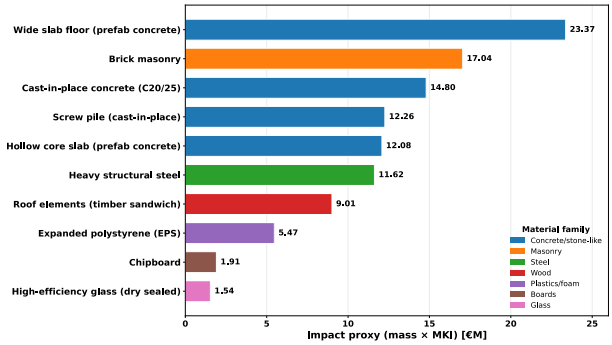

Figure 2: High-impact candidate groups based on impact proxy (mass × MKI)

MCA ranking results

Stage 2 applied MCA to the ten shortlisted product groups. Expert elicitation indicated that supply–demand balance was the most influential criterion (average weight 0.296), more than twice the weight assigned to sustainability/impact (average weight 0.137), underscoring the role of market viability in enabling reuse. This weighting structure provides quantitative evidence that implementation readiness can dominate environmental relevance in computational reuse prioritisation. While all experts contributed to criteria weighting, only a subset provided sufficiently confident and consistent product-level scores for cost and risk; therefore, product scoring draws on those inputs, while the final aggregation uses the combined weights across experts. The resulting MCA ranking shows a clear top tier: brick masonry achieved the highest total score (4.04/5), followed by heavy structural steel (3.29/5), while the third-ranked option (hollow core slabs) scored notably lower (2.78/5). A saturation test indicated that the Top-2 positions remain stable under different expert combinations; see Figure 3.

All eight experts were included in the criterion-weighting step, as they indicated sufficient confidence in judging the relative importance of the five MCA criteria. However, only four experts were retained for product-level scoring of cost and risk. The remaining interviewees reported insufficient familiarity with specific product groups to provide reliable comparative ratings at that level. This separation was intentional: criterion weighting captured broader implementation priorities, whereas product-level cost and risk scoring required more detailed knowledge of particular materials and products.

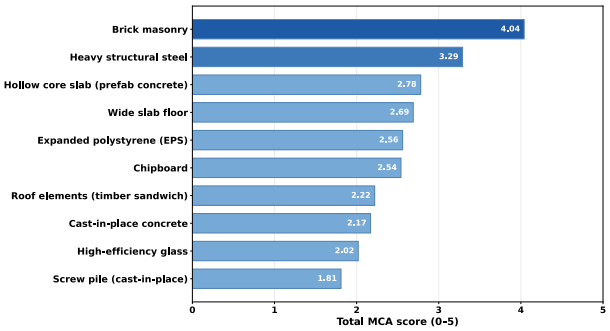

Figure 3: MCA-based reuse prioritisation ranking

Barrier diagnosis results

Although heavy structural steel ranks highly, its end-of-life value retention and established recycling/reuse practices suggest a smaller incremental knowledge gap. By contrast, masonry brickwork is typically downcycled (e.g., crushed for road base), indicating a larger opportunity for value retention if direct reuse can be enabled. Together with its top MCA score and supporting qualitative insights, masonry was selected as the demonstration product group.

To reduce over-interpretation of absolute values, Table 1 is presented as an illustrative comparison. Using estimates reported for an industry tool, direct reuse of brickwork yields an MKI reduction of approximately €24/t, whereas steel reuse yields about €60/t (general reuse) or €80/t (reuse as structural material). However, given masonry's much larger mass flow, the system-level impact of increasing brick reuse is estimated to be 2–3× higher than that of heavy structural steel when scaled by national outflow volumes.

Table 1: Illustrative MKI savings and potential impact reduction (brick vs. steel)

Product	MKI (€/t)	MKI saving (€/t)	Current impact (M€)	Potential impact saving (M€)	Relative savings (%)
Heavy structural steel	120	60	11.62	5.81	50.0
Heavy structural steel (structural reuse)	120	80	11.62	7.74	66.7
Brick masonry	26.3	24	17.04	15.55	91.3

The demonstration barrier diagnosis indicates that the most constraining bottlenecks for brick reuse relate to cleaning and contamination control (including mortar separation), quality consistency and certification, and the time/coordination costs associated with selective deconstruction and matching supply to demand. Corresponding leverage points include selective deconstruction to increase recoverable quality, standardised quality control and certification schemes, and reorganising testing/grading processes across supply-chain nodes to reduce schedule conflicts (Knoth et al., 2022). Based on these constraints, the paper outlines possible intervention directions, such as standardised quality assessment and improved demolition–demand coordination, to show how the ranking results can support practical action.

Discussion

The results indicate that product-group prioritisation for reuse cannot be inferred from environmental relevance alone. While the Stage 1 shortlist is dominated by high-mass, stone-like products, Stage 2 shows that implementation-oriented criteria—especially supply–demand balance—can substantially reorder priorities. This is reflected by masonry brickwork ranking first despite comparatively weaker scores on cost and technical feasibility, suggesting that market fit can outweigh near-term process constraints in determining reuse readiness (Wuni, 2022). This aligns with broader observations that circular implementation is shaped by interacting economic, technical and institutional drivers and barriers rather than single-factor optimisation (Tura et al., 2019). Importantly, the dominance of supply–demand balance over environmental impact in the weighting structure illustrates that reuse prioritisation should not be treated as a single-criterion screening exercise. This suggests that reuse potential should be assessed through both environmental relevance and implementation conditions, rather than environmental relevance alone.

The value of the workflow lies not only in identifying high-impact candidates, but in showing how rankings change once implementation conditions are introduced. In this study, the shift from Stage 1 to Stage 2 demonstrates that environmental relevance alone is not sufficient for prioritisation, while Stage 3 shows why even highly ranked options may still face coordination, certification, or contamination-related barriers. In this sense, the paper offers a proof-of-concept that ranking and diagnosis provide more decision-relevant insight than impact screening alone.

Implications for practice

The barrier configuration observed for brick reuse suggests that scaling requires interventions that simultaneously address (i) quality assurance and certification, (ii) time alignment between demolition and new-build demand, and (iii) process innovations for cleaning and contamination control. Existing reuse toolkits and sector protocols can support standardisation efforts, but their effectiveness depends on embedding them in procurement and early planning routines (SGS Search; Cirkelstad, 2021). In parallel, digital marketplaces and matchmaking platforms may reduce supply–demand uncertainty by enabling earlier visibility of upcoming demolition streams and reusable stock (DigiC, 2024). These implications also matter for computing in construction: reuse is not only a material challenge, but also a coordination challenge involving data availability, timing, and cross-organisational alignment (Knoth et al., 2022).

Limitations and robustness considerations

Several limitations should be noted. First, Stage 1 relies on the availability and consistency of product-group MKI values; while this supports comparability, it also makes results sensitive to database assumptions and boundary definitions (Nationale Milieudatabase (NMD), 2025). Second, the MCA scoring uses ordinal scales and expert judgement, which introduces subjectivity and may vary with expert composition and sector familiarity. Third, the current implementation does not propagate uncertainty from mass-flow estimates, impact factors and scoring into the final ranking; future work could incorporate uncertainty analysis to quantify ranking stability under data and judgement variance. Finally, Stage 3 is deliberately illustrative; it demonstrates linkage to barrier diagnosis but does not validate the effectiveness of specific interventions or business arrangements.

Research and implementation directions

Future development can proceed along three directions. (1) Data enrichment and automation: linking product-group datasets to spatially resolved building-stock models and material-passport data streams to improve timeliness and granularity (Wuyts et al., 2022). (2) Decision-support extensibility: integrating additional objectives (e.g., logistics distance, storage constraints, and risk-adjusted costs) while maintaining the same computational backbone. (3) Governance and standardisation alignment: connecting prioritisation outputs to emerging sector standards and assessment protocols to reduce liability concerns and enable procurement uptake (NEN, 2023).

Together, these directions position the framework as an extensible computational layer that can support circular decision-making across multiple products and contexts.

Conclusions

This paper develops a three-stage workflow for product-level reuse prioritisation in Dutch demolition outflows and shows that reuse potential cannot be inferred from environmental relevance alone. After screening 139 product groups, masonry brickwork emerges as the highest-ranked option, as implementation-oriented factors—especially supply–demand balance—outweigh environmental impact in expert weighting. The masonry case further demonstrates that scaling reuse depends on contamination control, certification, and coordination between demolition and processing.

The main implication is that reuse planning should combine environmental relevance with implementation conditions and use ranking outputs to guide targeted interventions. Although demonstrated on Dutch data and a single case, the contribution lies in the workflow rather than the specific product group, making it transferable to contexts with comparable mass-flow and environmental-impact data. While environmental relevance is operationalised using MKI from the NMD in the Dutch case, alternative indicators—such as monetised LCA metrics or EPD-based impact values—can be adopted in other jurisdictions. The MCA structure is likewise adaptable, provided that criteria and weights are aligned with local market and regulatory conditions (Honic et al., 2021; Giorgi et al., 2022).

Abstract

Recent instability in gas markets has strengthened demand for district heating (DH) solutions. However, design heat loads in DH systems continue to rely on outdated design guidelines that no longer represent the current heat demand. Using high-temporal-resolution data down to 2 seconds from smart heat meters and building information, this study identifies development trends in Danish residential buildings and assesses current design heat loads. The results indicate short-duration peak loads with relatively low heat power, suggesting a potentially over-dimensioned design heat load. These preliminary findings highlight the need for further investigation and may inform future improvements of DH design guidelines.

Introduction

The European Union's REPowerEU roadmap aims to eliminate Russian gas and oil imports by 2027 and to strengthen Europe's energy self-sufficiency (European Commission, 2025). This new initiative to phase out natural gas in building heating systems is driving increased international demand for district heating (DH) technologies. Owing to its high flexibility and capacity to integrate a wide range of energy sources, DH can play a key role in reducing dependence on fossil fuels. The DH sector is currently transitioning toward fourth-generation district heating (4GDH), which is characterized by substantial reductions in average supply and return temperatures, typically around 55/25 °C (Lund et al., 2014). At present, DH supplies 12% of the total building heating demand in the European Union, although significant differences exist among member states (Kranzl et al., 2021). In Denmark, where DH currently accounts for about 50% of the building heating demand, the share is expected to increase to 75% as part of the national strategy for decarbonizing the entire energy system (Mathiesen et al., 2021).

The anticipated growth of Danish DH networks introduces new design challenges because existing guidelines are based on literature and empirical results from the 1980s, when large-scale DH deployment in Denmark was common, and may not reflect the requirements of modern DH systems (Lund et al., 2018). The integration of low-temperature heat sources can impose constraints on the achievable supply temperature levels in current DH networks. In the presence of high return temperatures from end-users, the resulting reduction in temperature difference may create hydraulic bottlenecks in the distribution network. These effects can limit operational flexibility and increase system complexity. Moreover, the future competitiveness of DH compared to individual heating solutions strongly depends on minimizing capital investments in network infrastructure (Holmstedt Hansen et al., 2018) and system components, which are directly influenced by design requirements. Therefore, in-depth knowledge of current heat load demand in the building stock is essential for optimally planning and designing new and renovated DH networks.

In dwellings, the design heat load is typically based on domestic hot water (DHW) production via a heat exchanger (HEX), as this requires the highest instantaneous temperature increase. A Danish study with low temperature DH in terraced houses (Thorsen et al., 2011) showed that the peak heat load for DHW production with a HEX was 20% lower than the design value of 32.3 kW from the Danish Code of Practice for Water Supply Installations (DS 439) (Dansk Standard, 2009) and the Danish reference book Varme Ståbi (Andreasen et al., 2021). Another Danish study (Ramboll, 2013) based on single-family houses (SFHs) connected to existing DH networks showed that the measured peak heat load for DHW with HEX in summer ranges from 12 to 29 kW. However, these studies were constrained by the small number of buildings investigated and the relatively low temporal resolution of the available data. As a result, it was not possible to draw general conclusions or to support a revision of existing design guidelines.

In this context, the Energy Efficiency Directive (European Commission, 2023), launched in 2012, has accelerated the deployment of remotely readable energy meters and submeters at the building level, thereby enabling increased digitalization and opening new opportunities for further investigation using larger datasets and higher temporal resolution data.

The planning and design of new DH networks must consider the different building types and the construction years of the building stock, as this also influences the space heating (SH) demand. In the study by (Kristensen and Petersen, 2021), yearly heating use per heated floor area from different building types in a DH utility was

analyzed by construction year period. The author showed that, for residential buildings, age groups after 1961 had lower annual heating use, down to less than half for the newest age group. Thus, this study only indicates that newer buildings use less heating energy, and not whether the heat load is also reduced.

Novelty

The novelty of this study lies in the use of remotely readable DH smart heat meters (SHMs) to measure the combined heat load for SH and DHW at high temporal resolution in residential buildings. The heat load was recorded at temporal resolutions ranging from 3 minutes down to 2 seconds, allowing the dynamics of heating systems to be analyzed and the actual magnitude of peak heat demand to be revealed. An aspect not always captured in previous studies, many of which are based on hourly measurements. By linking some of these measurements with building registry data, this study establishes an initial methodological structure for assessing building heat demand at scale.

The study's results and conclusions, based on high temporal resolution measurements, are preliminary and based on a small data set. Nevertheless, this creates a basis for revisiting current DH design guidelines and exploring whether prescribed design heat load values can be improved.

Method

The methodology section presents the data sources and analytical workflow applied in this study. It describes the collection and preprocessing of SHM data and explains how building characteristics obtained from the Danish Building and Dwelling Register (BBR; in Danish: Bygnings- og Boligregistret) (Vurderingsstyrelsen, 2025) are used to contextualize the measurements. Design heat load values from existing standards and guidelines are employed as reference benchmarks to evaluate the observed heat demand. The analysis is limited to residential buildings, which constitute the largest share of the Danish building stock.

Design heat load

The design heat load for a building in the Danish design guidelines is calculated as the maximum of the SH or DHW heat load. The SH is designed with an outdoor-indoor temperature set of -12/20 °C and no heat gains. The heat load for DHW preparation can be provided by a HEX or a storage tank. For a single dwelling, the instantaneous design heat load for DHW preparation with HEX is by far the highest. According to the current version of DS 439, it can be as high as 32.3 kW and is based on the maximum heat load required for simultaneous draw-off from a kitchen sink and a shower (Dansk Standard, 2024).

Data collection

The SHM measures the total DH energy use delivered to a building, combining SH and DHW, or separately if two meters are installed. In this study, only SHMs measuring the combined energy use were used, as this is the most common solution. The data were collected hourly, every 3 minutes, and every 2 seconds. Two approaches were used to extract the data, either remotely or on-site.

1) The remote reading is performed using long-distance wireless M-Bus, in which strategically placed concentrators in the utility network communicate with the SHM. The readings are set to hourly by default, but the frequency can be increased to every 3 minutes. Data collection is conducted remotely without access to the building.
2) The on-site reading is performed with an optical eye, Figure 1A, which is mounted on the SHM and communicates via a serial infrared two-way communication. The optical eye is typically used to access the meter's settings. However, with an Arduino and an SD card, a data logger was created, and meter readings are logged every 2 seconds. Access to the building is required to install the data logger. Figure 1B shows an installation of a data logger.

The data collection is conducted in accordance with the General Data Protection Regulation (GDPR). In Denmark, DH utilities and SHM manufacturers have an assigned GDPR agreement with the building owner to collect remote readings. For the on-site readings, the authors have a signed GDPR agreement with the building owner. All data is handled anonymously.

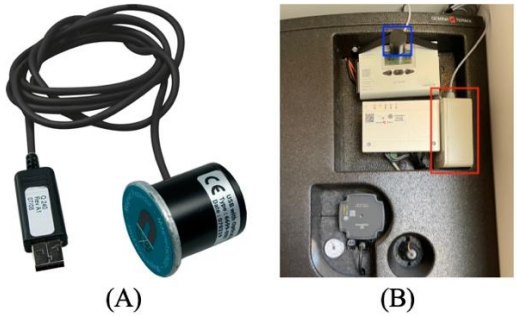

Figure 1: A) Optical eye. B) Optical eye (marked blue) and data logger (marked red) installed on an SHM in campaign 2.

Data preprocessing

Data from remote SHM readings can typically face two problems: first, timestamps may not be aligned to exact clock hours; second, there may be missing data points in the dataset. The reason for both problems is the stability of the remote connection between the SHM and the concentrators located in the utility. A concentrator is a device that collects SHM data and assigns timestamps to the data rows. Depending on the signal strength, location of the installation, and distance from each SHM to the concentrator, there is a deviation between the value's actual timestamp and the assigned timestamp. The signal strength differs between all SHMs in the utility, and changes over time for each individual SHM, depending on interference from electromagnetic signals, and temporally physical blocks e.g. cars and people. If the signal strength is too poor, data can be lost.

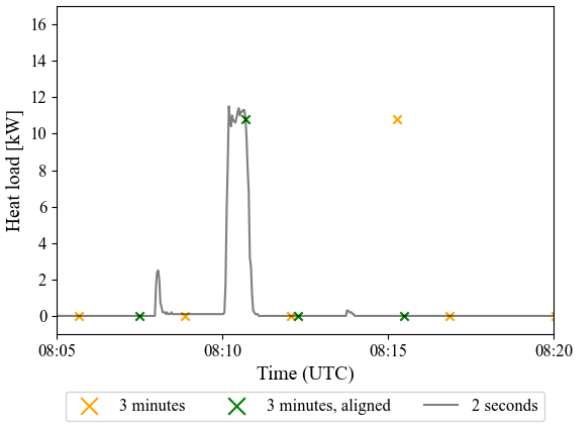

Figure 2: Example of graphical time alignment of 3-minute to 2-second values for one SHM. The 3-minute values in this plot were moved 274 seconds back in time.

The operations to address these problems depend on the use of the data in this paper. For the hourly data, two main operations were performed to address these problems: aligning the original data into regular one-hour data and filling the missing values using linear interpolation. For the 3-minute values, timestamps were manually aligned for each SHM by graphically comparing them with the 2-second data. This is done for the given time of each plot in this paper, as the time deviation can easily change. The observed time difference is a maximum of 5 minutes. In Figure 2, an example of a graphical time alignment for 3-minute remote readings is shown.

Using BBR for building classification

The hourly SHM data in Campaign 1 is combined with the BBR data for each building to compare average and maximum heat loads across residential building categories, age groups, and heating seasons. The BBR includes information about all buildings in Denmark in a publicly available database, e.g., building use category (residential, commercial, industrial, etc.), building area, construction and renovation years (Vurderingsstyrelsen, 2025). In this study, the BBR data set was delivered by the DH utility with anonymized SHM numbers and addresses.

A SHM can measure the total DH use for a building or parts of the building (i.e., one SHM can cover either one apartment in a TH/MFH, or one TH/MFH with several apartments). Since the data was anonymized, it was not possible to group heat meters by building. For simplicity, it was assumed that one SHM supplies one building. For each building, the construction year, heated floor area, and building use code were aggregated into the SHM data. Using the heated floor area, the hourly average heat load was normalized by area. The building's construction year was used to classify buildings into age groups to divide the heat load data in subsequent analyses. The age groups were based on the widely used TABULA project (Wittchen and Kragh, 2012) and the study by (Kristensen and Petersen, 2021), where the age groups were defined by shifts in building construction practices or changes in the Danish building regulations (BR). One additional age group (2018-2020) was added in this paper, as BR18 was implemented in 2018. The building use code defines the building category. From the main category Residential in the BBR, three building groups were created for this paper: single-family house (SFH), terraced house (TH), and multi-family house (MFH). Table 1 provides an overview of the BBR building use code and subcategories included in the defined building groups. The subcategory 130 in the TH group is being phased out and replaced by 131 and 132. However, subcategory 130 was included as there are still buildings listed with the building code in the BBR database.

Table 1: The BBR building subcategories included in the building groups for this paper. (Vurderingsstyrelsen, 2025)

Building group	Subcategories' building use code and description
SFH	120 Detached SFH
	121 Semi-detached SFH
	122 Detached SFH in low-density urban area
TH	130 Row, chain, cluster, or double house (*being phased out*)
	131 Row, chain, and cluster house
	132 Double houses
MFH	140 Multi-story building, multi-family house, or two-family house

Measurement campaigns

The SHM datasets are based on two separate measurement campaigns conducted in two municipalities in Nordjylland, Denmark, and using different data collection methods. The details of the two measurement campaigns are listed in Table 2.

Table 2: Details of the two conducted measurement campaigns.

	Period	No. SHM	Temporal resolution	Variables
Campaign 1	Feb'22 – Mar'22 & Jul'22 – Sep'22	4118	Hourly	Cumulative heat energy (kWh)
Campaign 2	Jul'25 – Dec'25	4	3-minutes, 2-seconds	Heat load (kW)

Campaign 1 includes data from 4118 SHM at hourly resolution, from which the measured cumulative heat energy was used. The data was collected in two separate periods, a heating period (Feb'22 to Mar'22) and a non-heating period (Jul'22 to Sep'22). The stacked plot in Figure 3 shows the distribution of the buildings divided into age and building groups. SFH is the most dominant building type, consistent with the results in (Kristensen and Petersen, 2021). Of the total building stock in the DH utility, the age groups 1961-1972, 1973-1978, and 1979-1998 each account for 19.7%, 15.0%, and 25.4%, respectively. As described in the method, the number of buildings was assumed to be per SHM. However, the

large construction of terraced houses in 1979-1998 may be due to the installation of an SHM per dwelling rather than per building. The age group Before 1851 only includes one SFH and was excluded from further analysis.

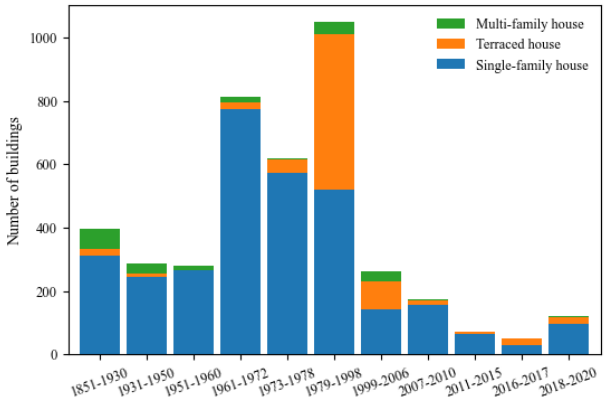

Figure 3: Number of buildings in the three building groups, sorted in age groups. 3168 SFHs, 743 THs, and 206 MFHs.

After analyzing the hourly data in Campaign 1, a need for higher temporal resolution to capture the dynamics of the heat load was evident. Campaign 2 was conducted in another municipality, where the frequency of remote readings was increased to every 3 minutes, and on-site data loggers were installed to measure the actual heat load and capture the short-term peaks. Campaign 2 includes data from four SFHs in the two age groups: 1961-1972 (two buildings) and 1973-1978 (two buildings). The data was collected from 15th July to 31st December 2025 and includes both a heating and a non-heating period. For this analysis, the instantaneous heat load values from the SHM were used.

Results and discussions

The results from the two measurement campaigns are presented and discussed with a focus on heat load characteristics. First, hourly data from Campaign 1 are used to illustrate the distribution of average and maximum heat load at the network level for residential buildings. Second, high-resolution measurements from Campaign 2 are analyzed to assess the magnitude of heat load in four SFH during both heating and non-heating periods. With a temporal granularity down to 2 seconds, this allows the dynamic behavior and true peak values of the heat load to be captured. Finally, a preliminary analysis of the 2-second and 3-minute data in Campaign 2 is conducted for one SFH over one day, during both heating and non-heating periods. 2-second data is focused on, as it shows the actual heat load profile and captures all the peaks from DHW draw-offs, compared to the 3-minute data. However, the 3-minute values are plotted to evaluate the limitations and potential of different temporal resolutions.

Hourly average and maximum heat load on network level – Campaign 1

Using the hourly measurement in Campaign 1, the average heat load for each building over the heating and non-heating periods is determined and normalized by the building's heated floor area. The distribution of the hourly average heat load is shown in Figure 4 as box plots grouped by building group and age group. There is a significant difference in the number of buildings in each building group. For terraced houses and multi-family houses, conclusions should be drawn with care, as some age groups have fewer than 10 buildings. In this case, a few buildings with poorly adjusted DHW or SH systems could easily skew the results, making them outliers. For the SFH group, there is a significant drop in average heat load from age group 1951-1960 to 1961-1972, consistent with the introduction of the first Danish BR in 1961. The BR61 set requirements for the transmission losses in the building envelope. In BR85, a requirement for maximum building energy demand was introduced, which partly can explain the drop in 1979-1998. The average heat load in buildings constructed after 1999 declines with a small gradient across age groups, matching the tightening of the energy demand in the BRs. When comparing the average heat load for SFHs in Figure 4 with the energy use results in (Kristensen and Petersen, 2021), the age groups show the same declining trend and comparable magnitudes. It

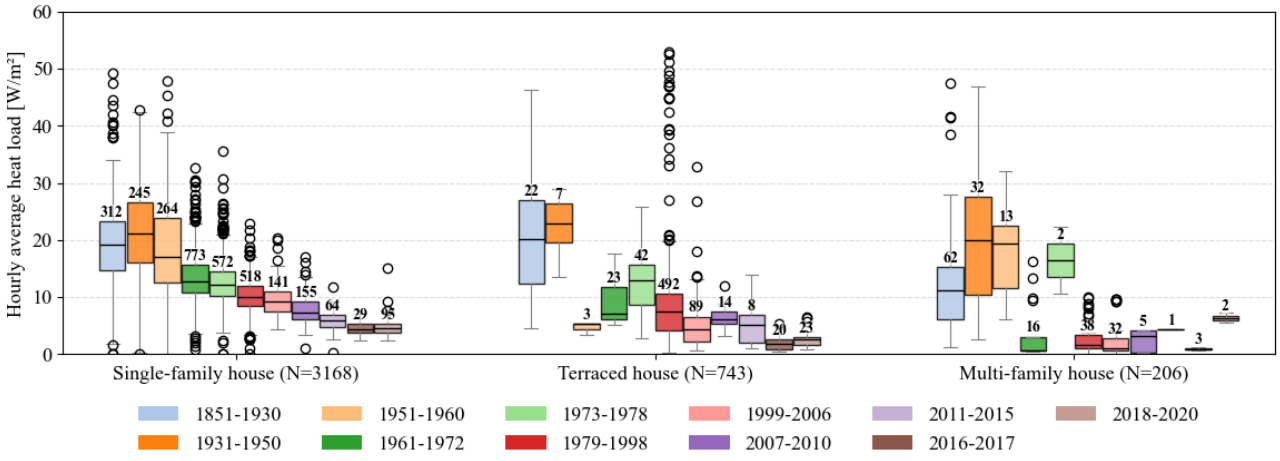

Figure 4: Hourly average heat load normalized per area for all residential buildings in Campaign 1, including the heating and non-heating periods. The boxes show the interquartiles (25th and 75th percentiles) and the median, while the whiskers show the 5th and 95th percentiles. The number above each box plot is the number of buildings in the age group.

should be noted that in the BBR data set, the renovation year for the building is indicated if it has been renovated. This is not considered in this analysis, as renovations can be minimal or radical, and a level of renovation is not indicated in the BBR. Additionally, the BBR data is not error-proof as the long list of inputs is manually entered, which can lead to incorrect entries due to misunderstandings of specific terms. To accommodate this, two outliers in the age group 1931-1950 in the TH building group that skew the general trend are removed from the dataset.

The connection of SFHs is large in Danish DH networks, and the following focuses on this group. For each SFH in Campaign 1, the maximum registered hourly heat load in the non-heating period (July to September) and the maximum registered hourly heat load in the heating period (February to March) are found. In Figure 5, the distribution of maximum hourly heat loads for the heating and non-heating periods is shown as box plots by age group. Obviously, the heating period has a higher maximum load than the non-heating period. An interesting observation for both periods is that, from 1999 onward, the median of the maximum load has increased, and the distribution within each age group is wider. During the heating period, one reason could be the rebound effect (Brøgger et al., 2018; Sorrell et al., 2009), where tenants in low-energy buildings increase the room temperatures to perceive higher thermal comfort. Another reason could be the increased installation of rainshowers in new buildings, which typically have high water flow rates. The use of rainshower affects the heat load throughout the year, but is most evident during the non-heating period, when the heat load for SH is minimal. This should be considered as a hypothesis, as the authors of the paper do not have statistics on rainshowers versus normal showerheads in new buildings.

From Figure 5, it can also be observed that the box plot of the maximum hourly heat load of the five age groups from 1931 to 1998 in the non-heating period is visually very similar. This happens due to two facts. First, the heat energy has a resolution of 1 kWh, making the resolution for heat load 1 kW. Second, box plots summarize the data using the median and quartiles rather than individual values. Since the observed maximum heat load for these age groups is largely concentrated around 4 kW, the resulting medians and quartiles are very close to each other, leading to box plots that appear nearly identical.

Since the data from the first measurement campaign are available only at an hourly resolution, consumption behavior at timescales below one hour cannot be resolved, and a fair comparison with the design heat load specified in the Danish guidelines cannot be made. A higher temporal resolution was therefore required and was adopted in the second measurement campaign.

Actual heat loads in four SFH – Campaign 2

With a relatively small data set in Campaign 2, the focus was on making a preliminary evaluation of the design heat load from DS 439, using the 2-second data. The four SFHs

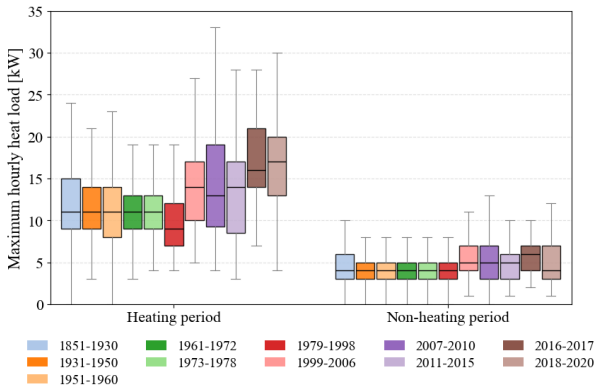

Figure 5: Maximum hourly heat load for single-family houses for both heating and non-heating periods. The boxes show the interquartiles (25th and 75th percentiles) and the median, while the whiskers show the 5th and 95th percentiles.

are connected to the local DH network, and each has a substation with two HEXs for SH and DHW. These houses were selected for the measurement campaign because they have a similar heat load distribution, were constructed according to the BRs, with requirements for transmission losses in the building envelope, and were built before the first requirement for building energy demand. The box plots in Figure 6 show the total measured instantaneous heat load for each SFH, grouped by month. The total heat load is the combined heat load for DWH and SH. The boxes represent the interquartile range (25^{th}-75^{th} percentiles) and the median. The upper whiskers are, as a conservative choice, extended to the 99.9^{th} percentile to include most heat loads for DHW draw-offs while excluding extreme values. The majority of the data in the four SFHs is far below the design heat load of 32.3 kW. The highest 99.9^{th} percentile of the four SFHs is 22.1 kW occuring in SFH2 in December. Of the total data for SFH3, the share of outliers exceeding the design heat load is $2.5x10^{-4}$%. This corresponds to 20 occurrences of a 2-second value exceeding the design value over a 6-month period. These extremely rare and short-term peaks indicate that the design guidelines most certain over-dimensioning the design heat load. The degree of over-dimension cannot be concluded by this preliminary study, and an analysis of more SFHs is needed. The last part of the results section shows an examination of the heat load profile and a discussion about the peaks that exceed the design heat load in SFH3. To understand the outliers, it is necessary to examine the duration of the peaks and the reasons they occur.

Heat load profile and peak analysis in one SFH – Campaign 2

With data at a high temporal resolution of 2 seconds, the actual heat load profile of a building can be visualized and analyzed to better understand the dynamics of DH supplied to a single building. The 3-minute data is also with lower temporal resolution. SFH3 is selected for examination as it has outliers above the design heat load. The SFH is inhabited by a retired couple. The total DH included in the plots to discuss the potential of using data

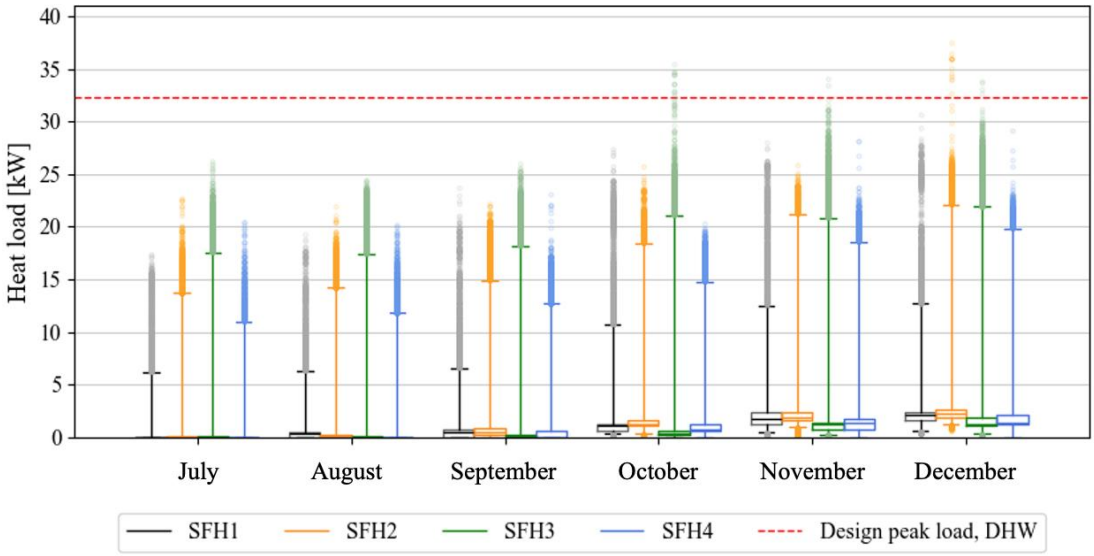

Figure 6: Box plots of the 2-second heat load from the four SFHs in campaign 2, grouped per month. The top-whisker of the box plot is the 99.9th percentile. The design heat load for an SFH is plotted.

load for DHW production and SH is analyzed for one day in the non-heating period (31st of July) and one day in the heating period (16th of November). The 31st of July is chosen as it has the highest peak in the non-heating period, and the 16th of November because it has a high peak, together with a period of low outdoor temperature.

For Thursday, the 31st of July, the heat load profile is plotted in the time range 06:00 to 20:00 in Figure 7. Multiple short peaks occur throughout the day, which aligns well with the occupancy of retired tenants at home using DHW. Two clusters of peaks were located around 7:30 and 17:30, which could be a morning shower and doing the dishes. When there is no peak, the load is 0 W, indicating no need for SH. The plot in Figure 8 is a zoom-in on the time range 09:11 to 09:16 on the same day. It shows the highest peak of 26.3 kW on that day and for the entire month. The interesting outcome is that for this specific peak, the duration is only 12 seconds above 25 kW and 20 seconds above 20 kW.

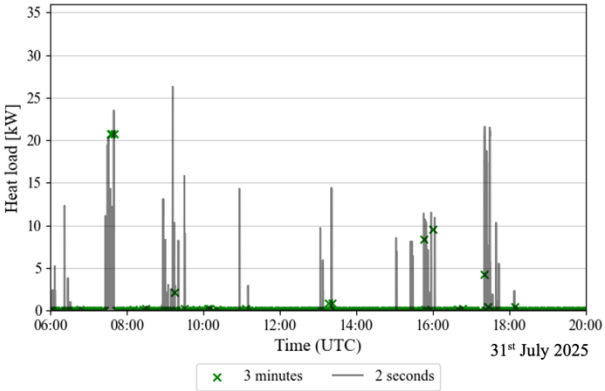

Figure 7: Time series of the heat load over one day in the non-heating period for Campaign 2's SFH3. Remote readings (3 minutes) and on-site readings (2 seconds).

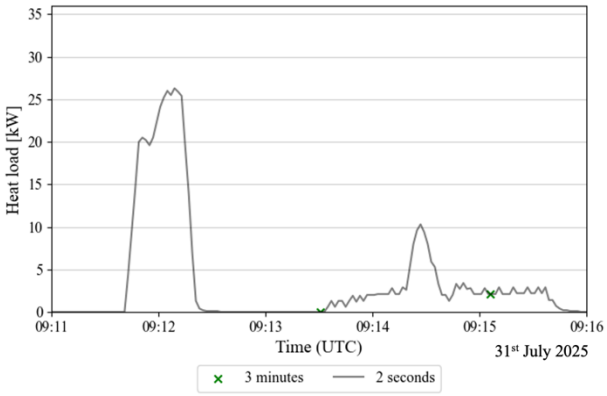

Figure 8: A zoom in on the highest peak in Figure 7.

For Sunday, the 16th of November, the heat load profile is plotted in Figure 9, and a zoom-in on the time range 12:38 to 12:43 is shown in Figure 10. On this day, the peaks also occur throughout the day, but when there is no peak, the base load is between 0.5 and 2.5 kW, covering the heat demand for SH. The highest heat load of the day, see Figure 10, is 33.3 kW. However, the peak duration is significantly short, with only 2 seconds above 32.3 kW. The measurement period for Campaign 2 does not cover the coldest period in Denmark, which typically occurs in January-March, and therefore not the highest SH demand. However, the base load for SH is relatively small compared to peak loads from DHW draw-off and is not anticipated to have a significant impact on the maximum heat load.

Figure 8 and Figure 10 show that the heat load peaks are high for a significantly short time duration. The highest peak in Figure 10 is anticipated to be the start of a DHW draw-off event. The peak has a high spike and drops suddenly to a lower level. This is likely due to the highly reactive thermostatic valve in the HEX, which opens quickly when a DHW draw-off starts and, when the DHW supply temperature is reached, closes more to adjust to the necessary DH flow. These types of control are the main

reasons for the outliers, 0.1% of the measurements, shown in Figure 6. The peaks for DHW draw-off are higher during the heating period than during the non-heating period. The reason for this is, on one hand, due to a higher supply temperature from the DH utility, and on the other hand, due to a colder domestic cold water supply.

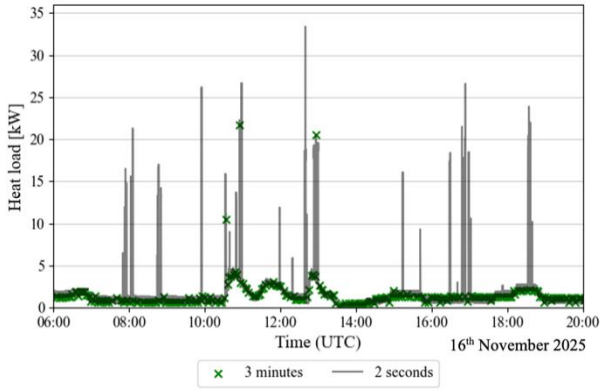

Figure 9: Time series of the heat load over one day in the heating period for Campaign 2's SFH3. Remote readings (3 minutes) and on-site readings (2 seconds).

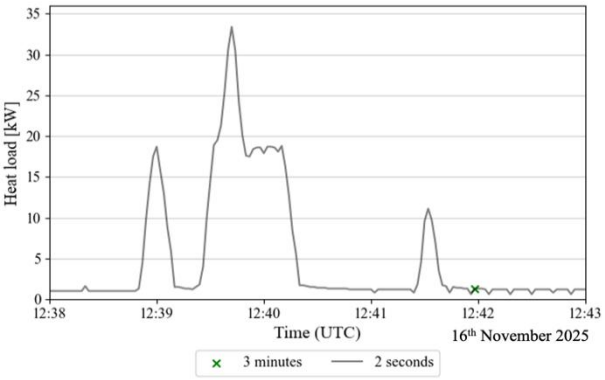

Figure 10: A zoom in on the highest peak in Figure 9.

This suggests that the current design guidelines should not be based on these outliers, which most likely do not affect the tenants' perception of DHW comfort. Nonetheless, there is a need to further investigate, using a larger dataset, the optimal design heat load of a HEX for a single dwelling that ensures tenants' DHW thermal comfort while avoiding the over-dimensioning implied by current design guidelines.

Finally, the 3-minute values are compared to the 2-second values. The 3-minute readings do not capture the maximum peak as seen in Figure 7-10. However, some of the load values in the DHW draw-offs are captured, e.g., in Figure 9 around 11:00 and 13:00. This suggests that, given a sufficiently long observation period, heat loads approaching the maximum peak are likely to be captured. Furthermore, by applying a statistical approach, the maximum peak heat load could be estimated together with an associated level of uncertainty. The use of slightly lower high-resolution data (e.g., 3-minute instead of 2-second values) to identify heat load peaks would allow a larger number of buildings to be analyzed, as data collection can be performed remotely without requiring physical access to the dwellings. This significantly reduces both the time and cost associated with further investigations. The present study reports only preliminary results based on a limited number of single-family houses and therefore does not allow for definitive conclusions. Further in-depth investigations covering a larger sample of SFHs with high temporal resolution are recommended.

Conclusion

Design heat loads in district heating systems continue to rely on design guidelines from the 1980's, which no longer reflect current building heat demand. Many previous studies are based on hourly measurements that shed light on the trend in heating demand, but they do not capture the short-term dynamics of the heat load profile. This work links building registry data with hourly measurements in one measurement campaign and identifies single-family houses for this municipality as the most important building use category for investigating the actual heat load profile. In the second preliminary measurement campaign, the heat load is measured on readable smart heat meters, with a high temporal resolution down to 2 seconds, to capture the actual heat load profile and analyze the magnitude and duration of the peaks. The high temporal resolution allowed a fair comparison to the design guidelines.

This investigation focuses on single-family houses to compare the design heat load of a district heating substation, where domestic hot water is prepared via a heat exchanger, which typically represents the highest instantaneous heat demand. Over a 6-month measurement period across four single-family houses, the majority of measured 2-second heat loads were significantly below the design value. The highest measured 99.9th percentile during a month was 31.6% below the design heat load. The extreme few outliers that exceeded the design heat load were further visually investigated. The outliers occur on 2 seconds when the thermostatic valve for domestic hot water preparation overshoots the opening and immediately reduces it again. This operation is expected to have no impact on tenants' perception of DHW thermal comfort.

The outcome highlights the need for further investigation into the optimal design heat load of a HEX for a single dwelling that aligns with tenants' perceptions of DHW thermal comfort and avoids over-dimensioning in the current guidelines.

EDGE COMPUTING FOR FEDERATED LEARNING–ENABLED ENERGY MANAGEMENT AND MONITORING SYSTEMS

Mustapha Habib, Youssef Elomari, and Qian Wang
Building Technology and Design, Department of Civil and Architectural Engineering,
KTH Royal Institute of Technology, 11428 Stockholm, Sweden.

Abstract

Despite growing digitalization of energy management systems (EMS) in buildings and local networks, integrating data-driven monitoring and control remains challenging. Edge computing offers enhanced local processing that can be embedded in existing EMS infrastructures. Within the European HYSTORE project, two edge-computing use cases were developed: a network-level platform enabling coordinated EMS operation using building thermal mass estimates, and a building-level controller supporting advanced monitoring and control of thermal energy storage. Both architectures are evaluated for design, integration, and potential for federated learning, enabling secure, efficient, and privacy-preserving multi-agent control.

Introduction

The growing demand for energy-efficient and sustainable building management systems (BMS) has driven significant advancements in technology. Traditional BMSs often rely on centralized computing architectures, which, while effective for basic monitoring and control, fall short in handling the complexities of modern building energy systems. With the rise of distributed energy resources, renewable energy integration, and dynamic grid interactions, there is an increasing need for more responsive, decentralized solutions. Edge computing has emerged as a promising approach, enabling real-time data processing and decision-making closer to the source of data generation. This paradigm not only reduces latency but also enhances system resilience, making it an ideal candidate for addressing the evolving challenges in building management. Combined with artificial intelligence (AI) and the internet of things (IoT), edge computing offers the potential to revolutionize the way energy is monitored, optimized, and controlled in smart buildings.

A few contributions were proposed to employ edge computing-driven advanced services to upgrade building management. The authors in (C. H. Wong et al., 2021) discuss how AI systems can facilitate real-time analysis, optimization, and enhancement of building services. They demonstrate how AI can improve energy efficiency, enhance occupant satisfaction, mitigate risks, and reduce costs in building management and control systems. However, the authors also highlighted some limitations regarding some applications, including restricted access to large datasets, high initial investment costs, and the need for specialized expertise. Authors in (L. A. Husein et al., 2022) review the integration of IoT and AI technologies for improving BMSs, emphasizing the need for greater academic attention to these applications. While the review highlights the potential of IoT-AI methods, it notes that few studies have implemented these technologies in the building sector, and their full potential remains unrealized. The authors call for more research to address these gaps and advance the adoption of IoT and AI in building energy management. G. Carvalho et al. examine the use of AI, particularly machine learning (ML), to enable computation offloading in edge computing environments (G. Carvalho et al., 2020). AI and ML techniques are shown to address the challenges of computation offloading in these systems, offering more accurate, adaptable, and portable decision-making compared to traditional methods. The authors categorize various ML algorithms and provide an in-depth analysis of their application in Vehicular Edge Computing Networks, exploring the benefits and limitations of offloading tasks in edge computing systems. Key challenges discussed include determining when and where to offload tasks, managing decision-making costs, and minimizing the risk of errors that could undermine edge computing's advantages. A. Bourechak et al. explore the intersection of AI and edge computing across various IoT application domains, providing a comprehensive analysis of AI's role in edge-based applications across eight key areas (A. Bourechak et al., 2023). The paper includes a qualitative comparison of the reviewed works, an evaluation of the challenges and limitations of AI model development and implementation in edge environments, and a discussion on how AI can address these obstacles. In (G. Walia et al., 2024), authors present a detailed review of resource management challenges in Fog/Edge computing, categorizing these into areas such as resource provisioning, task offloading, resource scheduling, service placement, and load balancing. The paper examines AI-based and non-AI-based solutions, evaluating their performance metrics, limitations, and challenges. It highlights future research opportunities, including integrating emerging technologies like serverless computing, 5G, blockchain, digital twins, and quantum computing to enhance Fog/Edge frameworks for IoT applications. Challenges discussed include the

complexity of managing heterogeneous resources and workload requirements, as well as the limitations of current non-AI-based solutions. In another study, B. Muniandi at el. discuss AI-driven energy management systems for smart buildings, emphasizing their ability to optimize energy use, enhance operational efficiency, and promote sustainability (B. Muniandi et al., 2024). Key functionalities include predictive analytics, adaptive control of building systems, and integration with renewable energy sources. These systems also enable smart buildings to participate in demand response programs, reducing costs and supporting grid stability. However, limitations such as data privacy and security concerns, as well as scalability and interoperability challenges across diverse building portfolios, are also underlined.

This study investigates two real-world applications in which edge computing offers significant potential to enhance energy management systems (EMSs) and building energy performance monitoring. The work covers the design, assembly, and commissioning of the proposed edge-computing solutions in two operational scenarios: a micro-district heating and cooling (micro-DHC) network and a residential building. Except the federated learning (FL) application for indoor temperature estimation in a micro-DHC–connected building, this study does not delve into the detailed mathematical formulation of each use case. The focus is instead on outlining and discussing the range of application scenarios in which FL-oriented edge-computing solutions can have a practical and impactful role.

Edge computing solutions: concepts and roles

This section presents the technical specifications of the two edge-computing concepts developed within the framework of the European HYSTORE project, along with the engineering details related to their design and integration into the existing systems.

Engineering basis of the proposed edge solutions

Solution 1: micro-district heating and cooling

Problem statement:

Isolated energy networks such as micro-district heating and cooling (micro-DHC) systems often suffer from limited coordination between buildings, which typically operate independently due to the lack of effective inter-building communication and system-level monitoring. These limitations become critical when complex thermal energy storage technologies, such as thermochemical (TCM) and phase-change-material (PCM) systems (see Fig. 1), are integrated, as they require advanced observer-based estimation and control strategies beyond the capabilities of conventional building management systems (BMSs). To address these challenges, the Montserrat micro-DHC demonstration within the HYSTORE project introduces a centralized edge-computing platform that enables network-wide data access and the deployment of advanced algorithms for state-of-charge estimation and model predictive control, supporting coordinated operation and improved energy management at the system level.

Solution 2: residential building substation

Problem statement:

In this situation, the purpose of the edge computing solution is to upgrade the computing capability of the BMS so it can handle the complex dynamics of eventually installed energy systems by incorporating advanced algorithms for control and monitoring.

With the current system, there has been an issue with the central air-handling unit (AHU) that uses a central heat pump system for heating. In extreme weather conditions, the AHU sometimes faces some challenges in ensuring acceptable thermal comfort. One of the potential solutions was to boost the temperature coming from the central HP system when it is overloaded, because it is providing heat to the other two buildings as well. In the HYSTORE project, the solution is partially or fully achieved by integrating an edge-driven sensible/latent energy system to boost the temperature in the AHU heating battery.

Edge-upgraded BMS:

The edge-driven solution for this use case is to develop two industrial panels, low- and high-level control. Each one is:

Low-level control:

- Direct communication of the LTES sensors.
- Multi-protocol enabled by Python programming.
- Handle the translation of the control commands to a set of actions on the hydronic system actuators.

High-level control:

- Long-term data storage.
- Complex AI-based and advanced control.
- Extend the control to be the energy management of the entire microgrid.

Within the framework of the HYSTORE project, the primary objective of the edge-driven solution is to enable high-level control of a hybrid sensible/latent thermal energy storage, PCM-based LTES (see Fig. 2) system through the implementation of observer-based model predictive control (MPC). By leveraging direct access to the system database, the edge platform can also coordinate the operation of the LTES with a heat pump in the Live-In Lab microgrid, thereby exploiting on-site photovoltaic generation and battery energy storage systems (BESS). The functional flowchart of the proposed edge-based solution to upgrade BMS functionality for indoor heating, which incorporates latent thermal energy storage (LTES), is presented in Fig. 3.

On-site installation, commissioning, and algorithms

This section details the installation procedures for each edge-computing solution and discusses the commissioning challenges encountered during deployment.

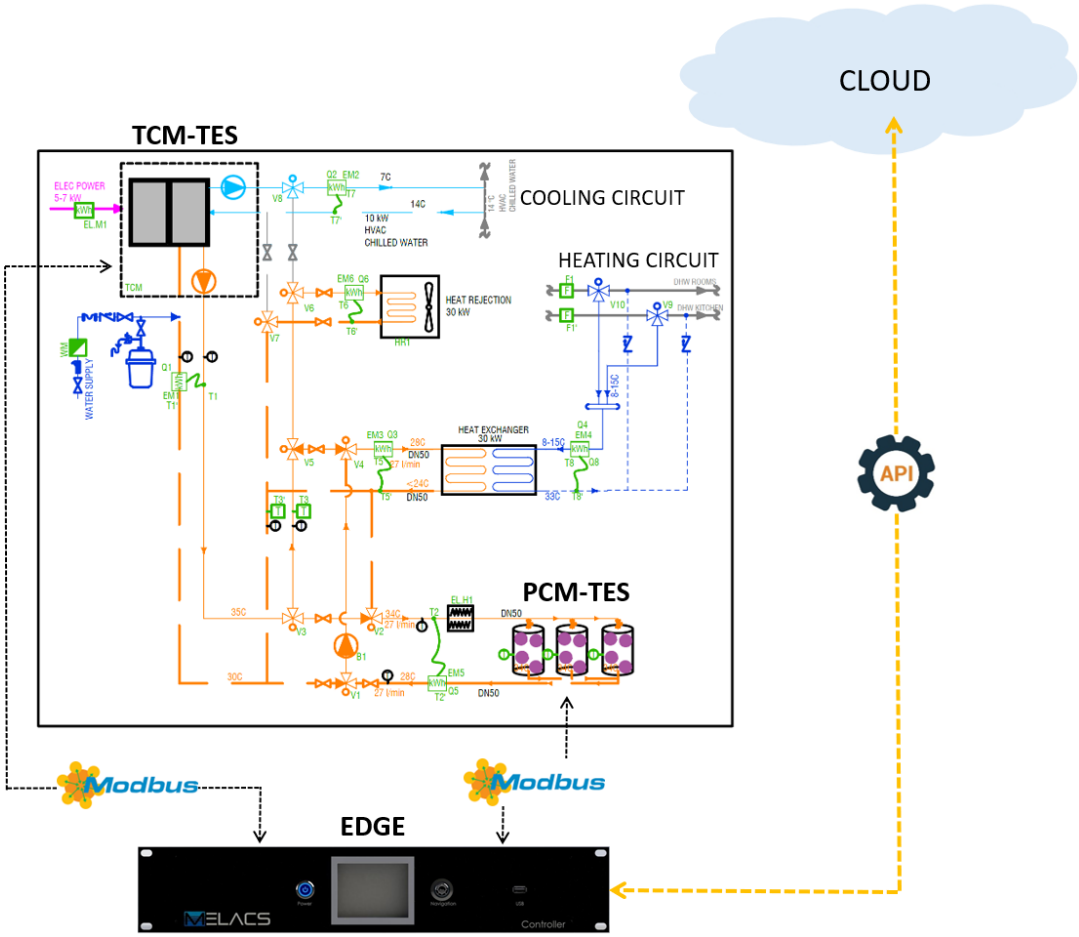

Figure 1: Edge solution as a high-level control for two LTES technologies: PCM and TCM at Montserrat micro-DHC.

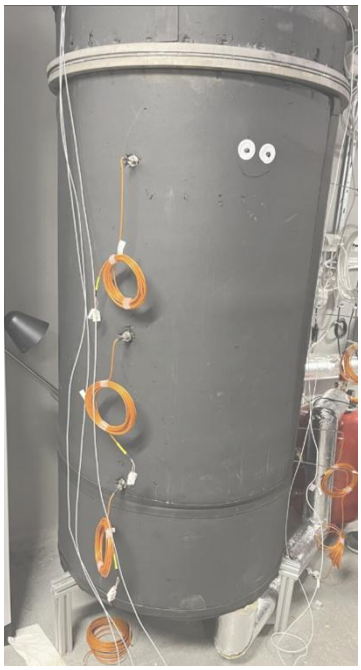

Figure 2: Installation of temperature sensors in the PCM-TES at the KTH live-in lab substation

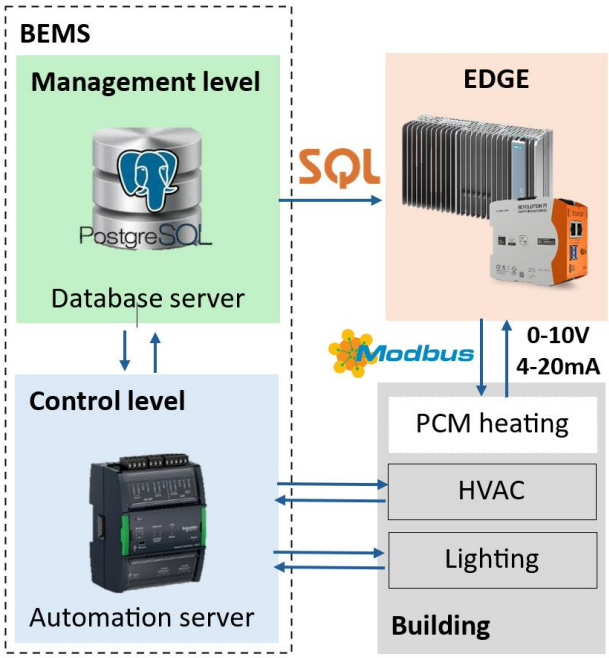

Figure 3: Edge solution as a high-level control for PCM LTES at KTH live-in lab

Solution 1

In Montserrat micro-DHC, a hotel building was selected for the installation of the two thermal energy storage technologies (TCM and PCM), as well as for deploying the second edge-computing solution (see Fig. 1). This choice was driven by the decision to exclude the sensors associated with the two LTES technologies from the central BMS database; as a result, direct physical communication with the devices was adopted. Communication with the various sensors and meters within the micro-DHC, including indoor and HVAC-related measurements from the hotel building, is achieved via the Modbus protocol over the local area network (LAN). Consequently, the edge computer was assigned a static IP address to ensure reliable identification and accessibility by other devices on the network.

Due to time constraints during the on-site commissioning phase of the HYSTORE project, full local communication with all network devices was not possible. To address this limitation, secure shell (SSH) access to the edge computer was configured remotely, allowing continued development and testing of the communication interfaces using Python.

Figure 4: Edge computing solution 1 installed in the hotel substation in Montserrat

Algorithms

In this real-world case, the edge computing platform implemented in Solution 1 serves two primary functions:

- Role 1: Centralized monitoring of the micro-DHC network.
- Role 2: High-level control of complex thermal energy storage (TES) systems.

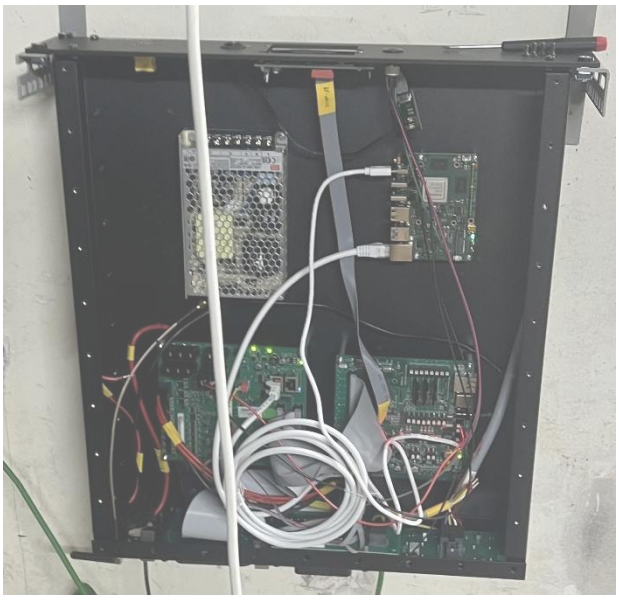

Figure 5: Components of the edge computing solution 1 installed in the hotel substation in Montserrat. It incorporates a GPU-accelerated controller with additional communication cards designed for industrial applications

For Role 1, several functionalities can be envisaged, including anomaly detection systems (ADS), centralized energy management systems (EMS), and coordinated demand-side management (DSM). The presence of a central computing entity communicating with all network components—such as HVAC systems, sensors, meters, and databases—enables a system-level perspective of energy flows and performance. This holistic view supports both network-wide energy management and detailed assessment of building and HVAC performance in heating and cooling generation. Within this scope, the present study focuses on the mathematical formulation of one representative function, which is presented at the end of this section.

For Role 2, a data-driven SoC estimation is implemented using a state observer. The algorithm combines Koopman theory with a linear Luenberger observer (KOOPMAN-LSO) to estimate internal PCM temperatures within the LTES based solely on the heat transfer fluid (water) outlet temperature. This approach has been validated in simulation using real operational data for multiple charging and discharging cycles of compact PCM TES, enabling on-site deployment without the need for intrusive PCM temperature sensors, which are often impractical in real applications.

A similar observer-based strategy will be developed to estimate the SoC of the thermochemical material (TCM) TES, which is co-located with the PCM-TES in the same building substation (see Fig. 1). Accurate SoC estimates allow the edge computer to optimally schedule charging and discharging of both LTES systems, maintaining thermal comfort while minimizing energy consumption. Two candidate control strategies will be tested for this purpose:

- Model predictive control (MPC)
- Reinforcement learning (RL)

Solution 2

In the residential building substation at the KTH Live-In Lab, the installation closely followed the approach used for Solution 1. A static IP address was assigned to the edge panel to enable connection to the LAN and allow real-time data queries from the system database via SQL. This database collects all operational data from the electrical systems, HVAC units, and indoor sensors across the microgrid. Since the edge panel was primarily tasked with managing the charging process of a PCM-TES, it was equipped with a Modbus coupler to allow direct physical wiring of the LTES sensor data to the controller. Additional analog and digital input/output cards were installed to interface with analog sensors and to control actuators, including ON/OFF switches and regulation valves. All remaining data acquisition and control of the heat pump are performed via Modbus TCP/IP.

Algorithms

As stated earlier, the planned role for the edge Solution 2 is to control the charging process of a hybrid latent/sensible using ground-source HP. Two main scenarios will be applied:

- A rule-based control (RBC), where a set of operational modes will be activated if certain conditions are met.
- MPC.

.

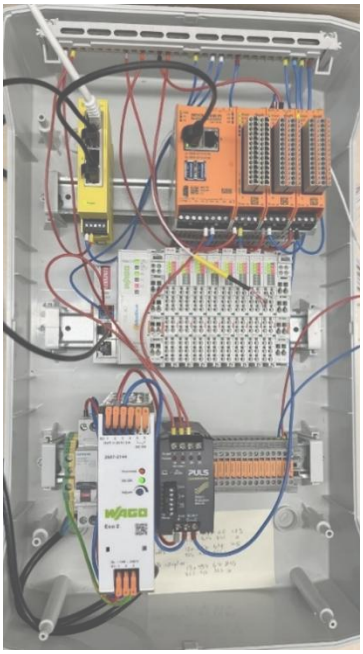

Figure 6: Components of the edge computing solution 2 (low-level control) meant for managing the PCM-TES and acts as an FL client. It incorporates a Python-enabled controller, IO cards, and Modbus coupler with the capacity of integrating 32 4-wire RTD temperature sensors needed to trach the PCM-TES SoC

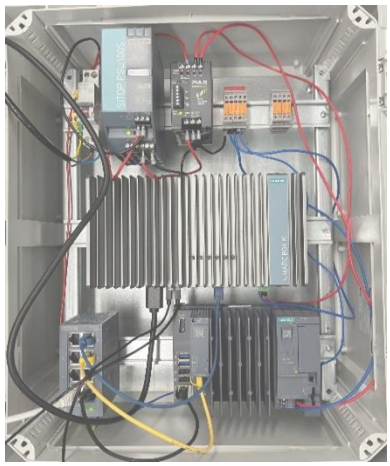

Figure 7: Components of the edge computing solution 2 (high-level control) meant for managing the KTH live-in lab microgrid, along with the different FL clients. It incorporates a high-capability industrial computer for running AI tasks and a PLC to enable communication with the field devices

For the rule-based control (RBC) strategy, a set of predefined operational modes is established, such as heating via the heat pump desuperheater, heating from the PCM-TES, combined operation, PCM-TES charging, and PCM-TES discharging. Each mode corresponds to a specific set of control actions executed by the edge panel through its embedded I/O modules. In this initial stage, the state-of-charge (SoC) of the PCM-TES is estimated using a simple physics-based formulation.

As operational data accumulates during RBC operation and is stored in a time-series database on the high-level control panel, a linear data-driven model of the PCM-TES is subsequently identified. This model enables the implementation of a linear model predictive control (MPC) scheme to maintain the existing heating functionality while achieving cost-effective operation based on dynamic electricity price forecasts and on-site photovoltaic (PV) power generation forecasts.

Federated learning concept

Role 1: microgrid management:

The KTH Live-In Lab can be regarded as a microgrid consisting of a local energy network serving three student residential buildings. The system integrates multiple energy resources, including renewable generation (PV, PVT, and wastewater heat recovery), energy storage systems (battery energy storage systems, sensible thermal energy storage, and geothermal storage), and diverse HVAC technologies, resulting in a sector-coupled energy system that includes heat pumps and air handling units. When operating in island mode, maintaining occupant comfort while optimizing energy utilization requires coordinated control across the three buildings, taking into account heating and domestic hot water demands, the state of charge of BESS and LTES units, renewable energy availability, and dynamic electricity tariffs.

Within this framework, each controllable HVAC system is associated with a federated learning client, implemented at the low-level edge computing layer (an

example is shown in Fig. 5). These clients locally train and update models for load prediction, renewable energy forecasting, and BESS/TES state-of-charge estimation. Only the learned model parameters are transmitted to a central FL server (Fig. 6), which uses them to perform network-level optimization aimed at maximizing renewable energy utilization, preserving thermal comfort, and sustaining islanded operation whenever technically feasible. If required, the server can propagate updated model parameters back to the clients using FedAvg or other aggregation and fitting methods.

Role 2: Indoor temperature / thermal mass prediction:

One of the main advantages of deploying a central monitoring computer in an islanded energy network, such as the Montserrat micro-DHC is its ability to operate as an FL server that coordinates multiple clients distributed across substations and buildings. Each client locally collects indoor temperature and HVAC operational data, trains its own thermal model, and transmits only the learned model parameters to the server. In this study, an RC-model-based observer is developed at each client to estimate indoor temperature dynamics in real time. Only the linear RC model coefficients and the associated observer gains are shared with the FL server, while raw measurements of indoor temperature, heating demand, and HVAC operation remain strictly local, preserving data privacy. Depending on the control objective, the FL server can exploit the received models in two ways. First, it can use the individual observer-corrected models to compute real-time optimal setpoints for each building, enabling coordinated yet decentralized energy management. Second, the server can aggregate the observation-based RC models to construct a global network-level thermal representation, which is then used to derive optimal boiler-side control actions, such as supply temperature and pump operation. This dual use of federated, observation-based models allows the micro-DHC to improve both building-level comfort control and system-level energy efficiency without centralized data collection. The building management system (BMS) collects at each building the following measurements:

- Outdoor temperature T_{out}
- Supply air temperature T_{sup}
- Humidity RH (can be used indirectly)
- Air quality (CO_2 ppm → occupancy proxy)
- Setpoint cooling $T_{sp,c}$
- Setpoint heating $T_{sp,h}$

The dynamic model in this case is based on the state

$$x = T_r$$

Where T_r: room air temperature. Therefore, the continuous-time equation is:

$$C_{eq}\dot{T}_r = \frac{T_{out} - T_r}{\mathrm{R}_{eq}} + Q_{HVAC} + Q_{\mathrm{int}} \qquad (1)$$

Where R_{HVAC} is effective HVAC thermal resistance and Q_{int} internal gains (occupancy + equipment). Thanks to the availability of the air quality sensor data, the heat source emissions related to the occupants (Qin) can be approximated as follows:

$$Q\mathrm{int} = \alpha.(CO_2 - CO_{2baseline}) \qquad (2)$$

Humidity sensor data can be incorporated as a regression term in HVAC heat flow:

$$Q_{HVAC} = \beta_1.(T_{\mathrm{sup}} - T_r) + \beta_2.RH \qquad (3)$$

$$\beta_1 = R_{HVAC}^{-1} = \begin{cases} k_c & T_r > T_{sp,c} \\ k_h & T_r < T_{sp,h} \\ 0 & deadband \end{cases}$$

The input vector is:

$$u = \begin{bmatrix} T_{out} \\ T_{sup} \\ RH \\ \mathrm{CO_2} \end{bmatrix} \qquad (4)$$

Output:

$$y = T_r \qquad (5)$$

Continuous-time state model is:

$$A = -\left(\frac{1}{C_{eq}\,\mathrm{R}_{eq}} + \frac{\beta_1}{C_{eq}}\right) \qquad (6)$$

$$B = \begin{bmatrix} \dfrac{1}{C_{eq}\,\mathrm{R}_{eq}} & \dfrac{\beta_1}{C_{eq}} & \dfrac{\beta_2}{C_{eq}} & \dfrac{\alpha}{C_{eq}} \end{bmatrix} \qquad (7)$$

Discrete state-space representation is:

$$x_{k+1} = A.x_k + B.u_k \qquad (8)$$

Parameters to be identified:

$$\left\{C_{eq},\ \mathrm{R}_{eq},\ R_{HVAC},\ \alpha,\ \beta_1,\ \beta_2\right\}$$

Since no RC model can perfectly capture building energy performance under changing physical conditions, this study proposes incorporating real-time model correction using sensor measurements. A linear Luenberger observer is employed to fuse measured data with model predictions, thereby mitigating the effects of sensor noise, modeling inaccuracies, and external disturbances (e.g., weather variability, occupancy changes, internal heat

gains, and unmodeled HVAC dynamics). The indoor temperature estimate can then be formulated as follows:

$$\hat{x}_{k+1} = A.\hat{x}_k + B.u_k + L(y_k - \hat{y}_k)$$
$$\hat{y}_k = C.\hat{x}_k \quad (9)$$

Local learning objective (client optimization)

Each client independently solves a local prediction-error minimization problem**:**

$$\min_{\theta^i} \sum_{k=1}^{T} \left\| y_k^{(i)} - \hat{y}_k^{(i)}(\theta^{(i)}) \right\| \quad (10)$$

subject to physical constraints on RC parameters (stability, positivity) and local data only.

Federated learning formulation (server-side)

Let: $\theta^{(i)} = \{A^{(i)}, B^{(i)}, L^{(i)}\}$ be the model and observer parameters learned locally. At the communication round r, each client sends $\theta_r^{(i)}$ to the central server

Server aggregation (FedAvg-style)

Federated averaging (FedAvg) computes a weighted average of client parameters:

$$\theta_{global} = \frac{\sum_{i=1}^{N} n_i \theta^{(i)}}{\sum_{i=1}^{N} n_i} \quad (11)$$

n_i is the weight for client $\boldsymbol{i}$, typically number of samples used to train the local model. These aggregated coefficients at the FL server side can be used to represent a global heating demand dynamic of the whole network so it is feasible to optimize the heating energy extracted from the main boilers.

- Let $\theta^{(i)} = \{A^{(i)}, B^{(i)}, L^{(i)}\}$.
- One can compute a global A and B as:

$$A_{global} = \frac{\sum_{i=1}^{N} w_i A^{(i)}}{\sum_{i=1}^{N} w_i}, \quad B_{global} = \frac{\sum_{i=1}^{N} w_i B^{(i)}}{\sum_{i=1}^{N} w_i} \quad (12)$$

- Weights w_i are to be chosen proportional to building thermal mass or typical heat demand.
- No need for L_global, since the observer is only relevant for estimating individual building states.

In the first case, the FL server does not attempt to aggregate building models into a global network representation. Instead, it uses each building's RC model with observer-corrected states to compute real-time optimal setpoints locally. The server sends these setpoints back to the respective clients, allowing each building to regulate its indoor temperature efficiently while respecting occupant comfort and local constraints. Here, the server acts as a coordinator and optimizer, leveraging up-to-date state information to suggest adjustments, but the boiler and network operation are effectively treated as secondary, since the focus is on individual building performance rather than total network-level energy optimization. In the second case, the FL server aggregates the observer-corrected RC models from all connected buildings to construct a global network model. Using this network-level model, the server can simulate how changes in supply temperature, flow rates, or pump operation affect the entire micro-DHC system. With this approach, the server can compute optimal boiler-side control actions that minimize total energy consumption, prevent peak loads, and maintain network stability, while still ensuring buildings receive the heating they need. The observer-based global model allows the server to incorporate real-time deviations in building states, making the control decisions robust to disturbances and heterogeneous building dynamics.

Simulation results

This section details the preliminary simulation results for the edge application of Solution 1. Due to a more streamlined installation and commissioning process, Solution 1 reached the testing phase ahead of Solution 2. Figure 8 illustrates the performance of an RC model in predicting indoor temperatures for a hotel building integrated with a Micro-DHC. Even in its base form – without observer-based corrections – the RC model demonstrates strong predictive accuracy. Future enhancements will involve real-time state observer corrections utilizing micro-DHC heat exchanger data, which will eventually be integrated into an optimal control framework, such as Model Predictive Control (MPC)

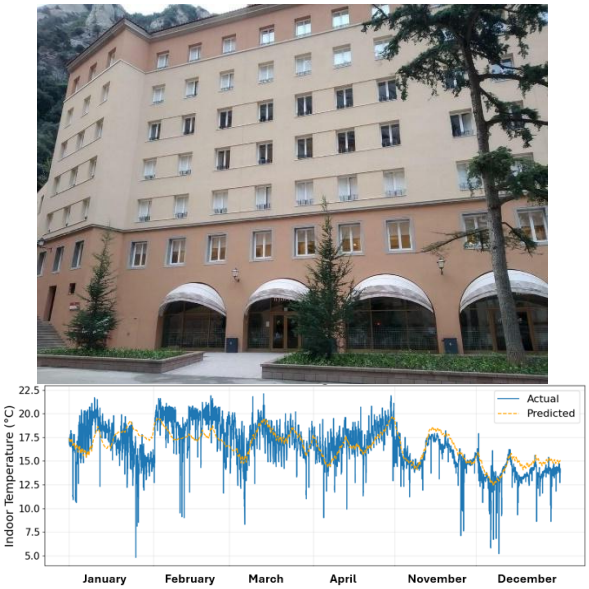

Figure 8: Indoor temperature prediction using trained RC model: (top) the view of the Abat Oliba hotel concerned by the study, (bottom) the seasonal prediction performance for 2023

Fig. 9 illustrates another application featuring an advanced data-driven observer implemented for LTES monitoring. This technique utilizes the KOOPMAN

theory to model the LTES, leveraging collected datasets to construct a linear representation within a lifted observation space. The linearity of this space facilitates the use of a classical Luenberger Observer, which compensates for low-quality measurement data and estimates unmeasured PCM temperature.

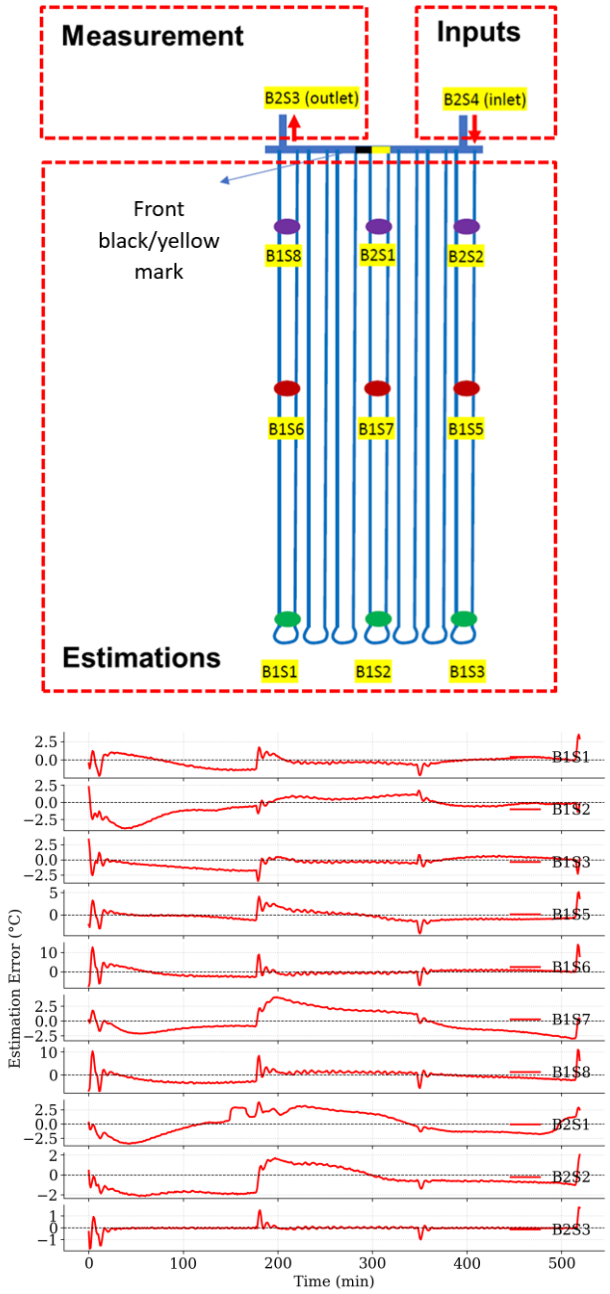

Figure 9: Edge-hosted observer for PCM temperature estimation of LTES (top)sensor placement in the LTES during KOOPMAN model development, (bottom) estimation error for all PCM temperatures

Conclusions

This paper presented two real-world edge-computing implementations developed within the HYSTORE project, targeting coordinated energy management in micro-DHC and residential microgrid environments. In the Montserrat micro-DHC, a centralized edge platform enables network-level monitoring and advanced control of complex thermochemical and PCM thermal energy storage systems using observer-based state estimation and anomaly detection. At the building level, the KTH Live-In Lab implementation demonstrates how similar edge concepts support PCM-TES operation and coordination with heat pumps, photovoltaic generation, and battery storage. Together, these cases show how edge computing can overcome coordination and control limitations of conventional EMSs, enabling observer-driven, privacy-preserving, and scalable control of complex energy systems in isolated energy networks.

A DATA-DRIVEN KOOPMAN-MPC FOR MULTI-ACTUATOR AHU CONTROL

Youssef Elomari[1], Mustapha Habib[1], and Qian Wang[1,2]
[1]Division of Building Technology and Design, Department of Civil and Architectural Engineering, KTH Royal Institute of Technology, 114 28, Stockholm, Sweden
[2]Uponor AB, Hackstavägen 1, Västerås, 721 32, Sweden

Abstract

Air-handling units (AHUs) are major energy consumers in HVAC systems due to their coupled actuators and constrained multi-input multi-output operation. This paper proposes a data-driven Koopman-MPC framework that identifies lifted linear dynamics from building management system (BMS) data using EDMDc, enabling constrained MPC design for nonlinear AHU behavior. The approach is validated on a residential AHU in Stockholm, Sweden. Results demonstrate the feasibility of deploying Koopman-based predictive control using operational data, and a BMS-integrated edge implementation workflow is presented for practical building applications.

Introduction

In recent years, data-driven methods have become increasingly important for the operation and optimization of heating, ventilation, and air conditioning (HVAC) systems (Afram and Janabi-Sharifi, 2014). Air-handling units (AHUs) represent a critical component of building HVAC systems, responsible for conditioning and distributing air throughout building zones. Modern AHUs incorporate multiple actuators, including supply and return fans, mixing dampers, heating and cooling coils, and humidifiers, creating a complex multi-input multi-output (MIMO) control problem (Afram and Janabi-Sharifi, 2014; Matetić et al., 2022). Coordinating these actuators to achieve multiple objectives—energy efficiency, thermal comfort, indoor air quality poses significant challenges for conventional control approaches (Yue et al., 2023). Despite this multivariable and constrained nature, AHU control in many buildings still relies on decentralized proportional–integral–derivative (PID) and rule-based controllers implemented in the building management system (BMS) (Zou, Yu and Ergan, 2020). These strategies are robust and easy to commission, but they do not coordinate multiple actuators or explicitly handle constraints. At the same time, the increasing availability of high-resolution BMS data has accelerated progress in data-driven control methods. Most of the literature has focused on fault detection and diagnosis and on supervisory energy management and operational decision-making at scale (Deshmukh, Glicksman and Norford, 2020; Taheri et al., 2021; Matetić et al., 2022).Several studies have attempted to address AHU optimal control using data-driven methods. Optimization-based approaches using simplified models have been demonstrated for AHU regulation in simulation environments, often relying on reduced polynomial structures that cannot represent all internal AHU interactions(Zou, Yu and Ergan, 2020). Learning-based control has also been explored through deep reinforcement learning trained on operational datasets, reporting improvements relative to baseline operation while maintaining predicted discomfort around 10% using an LSTM-based surrogate (Zou, Yu and Ergan, 2020). Neural-network predictive controllers based on dynamic recurrent models have reported up to 69.9% energy reduction on historical data, while also indicating that nonlinear predictors inside the controller (Asvadi-Kermani et al., 2022). (Zheng, Wang and Wang, 2024) conducted a systematic comparison of model-based and data-driven economic MPC using the BOPTEST framework. Their results showed that data-driven methods achieved energy cost reductions within 5–10% Overall, the literature suggests that data-driven control can deliver substantial gains. However, robust AHU optimal control remains challenging due to nonlinear multivariable dynamics.

Koopman operator theory provides a promising route to address these challenges by representing nonlinear dynamics through linear evolution in a lifted space of observables (Wahba et al., 2023). The lifting map captures the nonlinear structure, while prediction evolves linearly in lifted coordinates, enabling the use of standard linear MPC solvers with explicit constraints. A finite-dimensional approximation of the Koopman operator can be learned directly from operational data using extended dynamic mode decomposition with control (EDMDc), which estimates lifted linear dynamics from measured state–input snapshot pairs (Zawacki and Abed, 2023).

In this paper, we develop a Koopman–MPC framework for coordinated multi-input supervisory control of an AHU using operational BMS data from the KTH Live-In Lab. We identify the Koopman predictor via EDMDc, embed the lifted linear dynamics into an MPC formulation, and regulate supply air temperature and exhaust airflow under actuator constraints. Closed-loop performance is evaluated using a high-fidelity model trained on measured data. We also present an edge implementation workflow compatible with BMS-integrated operation

Methodology

This section presents a Koopman–MPC framework for coordinated multi-input control of an air-handling unit (AHU). A finite-dimensional approximation of the Koopman operator is identified from operational building management system (BMS) data using extended dynamic mode decomposition with control (EDMDc). Closed-loop performance is evaluated using a high-fidelity neural state-space (NSS) surrogate model trained on measured data. Figure 1 summarizes the overall architecture and data flow.

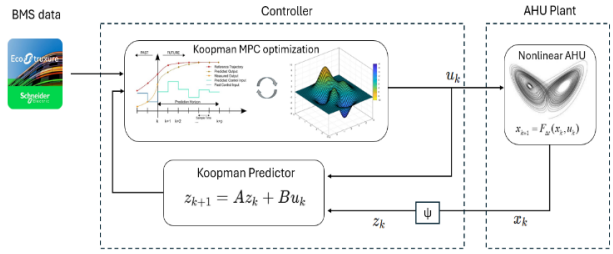

Figure 1: Overview of the proposed Koopman–MPC architecture

System definitions

The AHU is modeled as a nonlinear discrete-time system sampled at interval Δt

$$x_{k+1} = F_{\Delta t}(x_k, u_k)$$

where x_k denotes the system state and u_k the control input at time step k and Δt corresponds to the BMS sampling interval.

Based on available BMS measurements, the state and input vectors are defined as

$$x_k = \begin{bmatrix} T_{\text{sup},k} & F_{\text{sup},k} & T_{\text{rec},k} & T_{\text{exh},k} & F_{\text{exh},k} \end{bmatrix}^{\cdot}$$

$$u_k = \begin{bmatrix} V_{\text{heat},k} & T_{\text{heat},k} & S_{\text{sup},k} & S_{\text{wheel},k} & S_{\text{exh},k} \end{bmatrix}^{\cdot}$$

The control objective focuses on regulating supply air temperature and exhaust airflow, which are defined as the controlled outputs

$$y_k = \begin{bmatrix} T_{\text{sup},k} \\ F_{\text{exh},k} \end{bmatrix}$$

These variables directly affect indoor comfort and energy use and are therefore selected as the primary control targets. This multi-input setup matches the practical control objective. The controller adjusts the heating coil, fans, and heat-recovery wheel in a coordinated way rather than relying on a single actuator.

Koopman-based predictor for MPC

Koopman theory represents nonlinear state evolution through linear evolution of observable functions. For a discrete-time system, the Koopman operator $K_{\Delta t}$ acts on an observable g as

$$(K_{\Delta t} g)(x_k, u_k) = g\big(F_{\Delta t}(x_k, u_k)\big)$$

A practical predictor requires a finite-dimensional approximation. Following the EDMD framework, we select a dictionary of basis functions and project the Koopman operator onto its span.

We define a lifting map ψ that maps the normalized state into a higher-dimensional feature vector

$$z_k = \psi(x_k)$$

where ψ consists of polynomial basis functions selected to capture dominant nonlinearities observed in the data. The lifting map uses normalized measured states and a second-order polynomial dictionary with linear, squared, and pairwise interaction terms. All variables are normalized using the training-data mean and standard deviation. For five measured states, this gives a lifted-state dimension of 21 including the constant term.Using EDMDc, the lifted dynamics are approximated by the linear controlled system

$$z_{k+1} = Az_k + Bu_k$$

$$y_k \approx Cz_k$$

Where matrices A and B describe the evolution of the lifted state under the influence of the control inputs, while C maps the lifted coordinates back to the physical outputs. To identify the Koopman system matrices, snapshot pairs are constructed from the operational dataset

$$Z = \begin{bmatrix} z_1 & \cdots & z_{N-1} \end{bmatrix}, Z^{+} = \begin{bmatrix} z_2 & \cdots & z_N \end{bmatrix}$$

$$U = \begin{bmatrix} u_1 & \cdots & u_{N-1} \end{bmatrix}$$

The lifted system matrices are obtained by solving a regularized least-squares problem

$$\min_{A,B} \left\| Z^{+} - \begin{bmatrix} A & B \end{bmatrix} \begin{bmatrix} Z \\ U \end{bmatrix} \right\|_F^2 + \lambda \left\| \begin{bmatrix} A & B \end{bmatrix} \right\|_F^2$$

Koopman-MPC formulation

At each control step k, MPC optimizes a sequence of future control inputs over a finite horizon. The Koopman–MPC optimization problem is formulated as

$$\min_{\{u_{k+i|k}\}_{i=1}^{N_p}} \sum_{i=1}^{N_p} \Big[(y_{k+i|k} - y_{r,k+i})^{\cdot} Q (y_{k+i|k} - y_{r,k+i}) + (u_{k+i|k} - u_{k+i-1|k})^{\cdot} R (u_{k+i|k} - u_{k+i-1|k}) \Big]$$

Where $y_{r,k+i}$ denotes the reference trajectory for supply air temperature and exhaust airflow. The first term penalizes tracking error, while the second term penalizes aggressive variations in the control inputs.

The optimization is subject to actuator magnitude and rate constraints

$$u_{\min} \le u_{k+i|k} \le u_{\max}$$

$$\Delta u_{\min} \le u_{k+i|k} - u_{k+i-1|k} \le \Delta u_{\max}$$

The Koopman–MPC uses a 15 min sampling time and a prediction horizon of 4 steps. The optimization is solved using sequential quadratic programming (SQP). Following our earlier AHU MPC setup on the same testbed, the baseline weighting is set to $Q = 1$and $R = 10^{-5}[1,1,1,1,1]$.

High-fidelity AHU model

To evaluate the Koopman-MPC under realistic conditions, a neural state-space (NSS) model is used as a high-fidelity surrogate of the AHU dynamics

$$x_{k+1} = f_\theta(x_k, u_k),\ y_k = h_\theta(x_k)$$

where f_θ and h_θ are nonlinear mappings parameterized by neural network weights θ. The NSS model is trained using one-step-ahead prediction on one year of measured BMS data with a 15-minute sampling resolution.

The NSS model is used solely for closed-loop performance evaluation and benchmarking and is not employed for prediction or control within the Koopman–MPC framework.

Case study

The proposed Koopman–MPC framework is evaluated on an AHU installed at the KTH Live-In Lab. The system serves four student apartments and consists of a rotary heat exchanger, variable-speed supply and exhaust fans, and a water-based heating coil, as illustrated in Figure 2. Historical operational data were collected from the building management system (BMS) at a 15-minute resolution over three years. The dataset includes supply and exhaust air temperatures, airflow rates, heating-coil rate and temperature, fan speeds, and wheel speed. These measurements are used to identify the EDMDc Koopman predictor and to train the NSS surrogate model.

Results

This section presents the results obtained using the proposed Koopman–MPC framework applied to the real AHU system use case described in Section 2. The analysis focuses on validating the high-fidelity neural state-space (NSS) model used as a surrogate plant, evaluating the predictive capability of the EDMDc-based Koopman linear predictor, and assessing the closed-loop performance of the MPC controller under realistic operating constraints.

The predictive accuracy of the NSS model was first assessed to ensure that it provides a reliable reference for closed-loop controller evaluation. The model was trained using one-step-ahead prediction on historical BMS data with a 15-minute sampling interval and validated on unseen data segments covering a wide range of airflow rates, heat-recovery operating points, and heating-coil conditions. Figure 3 compares measured and simulated air-temperature trajectories for the supply, recycled, and exhaust air streams. Minor deviations between measured and simulated signals are primarily observed during periods of rapid airflow variation, where sensor dynamics and short-term turbulence effects introduce additional uncertainty. Despite these effects, the overall agreement remains strong. The mean absolute error for supply-air temperature remains below 0.5 °C, while exhaust airflow prediction errors stay within 5 % over the validation period. These results confirm that the NSS model accurately represents the nonlinear behavior of the full-scale AHU and can be used as a high-fidelity surrogate plant for evaluating the proposed Koopman–MPC strategy.

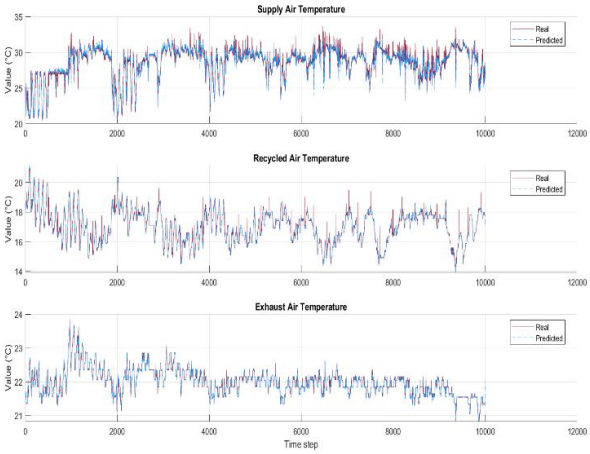

Figure 3: Comparison between measured and NSS-simulated air temperatures (supply, recycled, and exhaust) used for model validation

The multi-step prediction capability of the Koopman-based linear model identified via EDMDc was then evaluated. The lifted predictor is embedded in the MPC to forecast future temperature and airflow trajectories over the prediction horizon. The results show that the Koopman model maintains stable and physically consistent predictions despite the strong nonlinear coupling between airflow, heat recovery, and heating-coil operation. In particular, the predictor accurately captures the influence of airflow modulation on supply-air temperature, which is critical for coordinated multi-input control. As expected, prediction errors increase gradually with horizon length; however, they remain sufficiently small to support reliable MPC optimization.

Figure 4 illustrates the system response during a representative winter operating sequence. The controller successfully maintains both the supply-air temperature and supply airflow close to their respective setpoints while coordinating the heating coil, supply fan, exhaust fan, and rotary heat-exchanger speed. The MPC dynamically adjusts actuator combinations in response to disturbances and load variations, ensuring stable operation without violating actuator magnitude or rate

constraints.

Technical deployment consideration and edge implementation workflow

This section discusses the technical considerations for deploying the proposed Koopman–MPC framework within a building management system (BMS) using an edge computing architecture. While the control strategy is evaluated in a co-simulation environment in this work, the deployment design is presented to demonstrate practical feasibility and compatibility with existing industrial automation infrastructure.

BMS-integrated edge architectures

The proposed Koopman–MPC framework is designed to operate within a BMS-integrated edge control panel. The hardware architecture, illustrated in Figure 5, consists of a programmable logic controller (PLC), an industrial PC (IPC), and a gateway device.

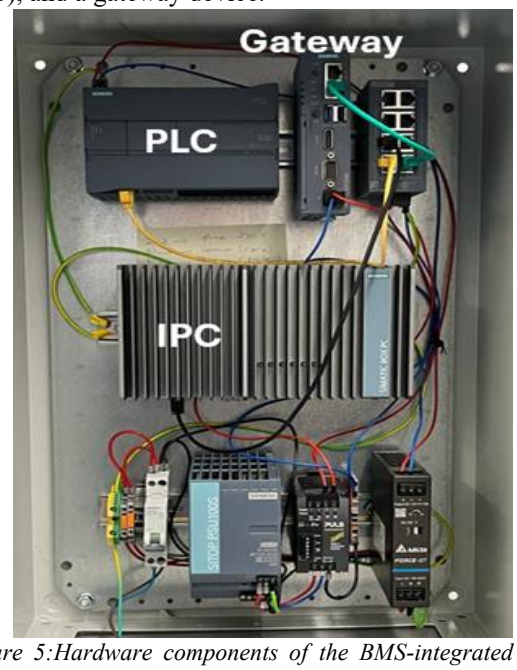

Figure 5:Hardware components of the BMS-integrated edge control architecture considered for Koopman–MPC deployment

The PLC acts as the primary interface with the physical AHU and the BMS. It is responsible for acquiring real-time measurements, enforcing actuator limits and safety logic, and applying control setpoints to the AHU actuators. In the proposed architecture, the PLC retains full authority over final actuation, ensuring safe operation regardless of the control strategy used at higher levels.

The IPC is intended to host the Koopman–MPC algorithm. Its computational resources are sufficient to perform lifted-state prediction and constrained optimization within the control sampling interval considered in this study.

The gateway device enables standardized communication between the PLC, IPC, and supervisory systems. It supports protocol translation between field-level communication (e.g., Modbus) and higher-level interfaces such as OPC UA, facilitating data exchange with the BMS.

Data flow and control integration

The data flow between the AHU, edge devices, and BMS is illustrated in Figure 6. At each sampling interval, the PLC acquires measurements from the AHU and relevant BMS controllers and makes them available to the IPC through the gateway. These measurements constitute the input to the Koopman–MPC algorithm, together with reference setpoints defined at the BMS level.

Based on the received measurements, the IPC executes the Koopman–MPC optimization using the EDMDc-identified linear predictor. The resulting control setpoints are transmitted back to the PLC, where they are evaluated against safety rules, actuator bounds, and operational constraints. If accepted, the setpoints are applied to the AHU actuators; otherwise, the PLC maintains the current operating point or falls back to standard BMS control logic.

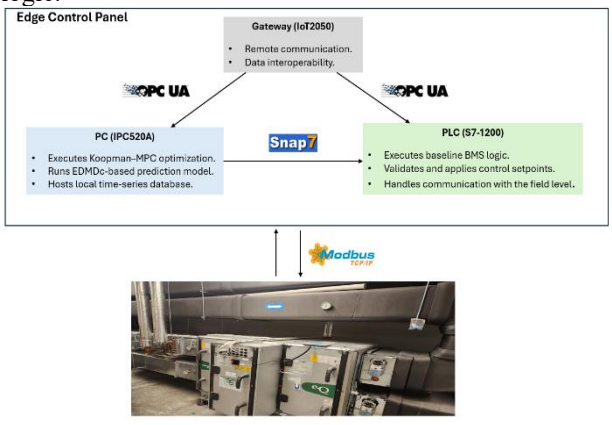

Figure 6:Edge Control Panel architecture used communication protocols for Koopman–MPC integration with the BMS

Conclusions

This paper proposed a data-driven Koopman–MPC framework for coordinated multi-input control of an AHU using operational BMS data. The approach identifies a finite-dimensional linear predictor in lifted space via EDMDc and embeds it in a constrained MPC formulation. The resulting controller targets supply air temperature and

exhaust airflow while coordinating multiple AHU actuators within practical operating limits.

A high-fidelity NSS surrogate trained on measured data was used to evaluate closed-loop performance under realistic nonlinear AHU dynamics. The results indicate that the EDMDc-based Koopman predictor delivers stable short-horizon forecasts of the controlled outputs across representative operating conditions, enabling effective MPC-based regulation.

From a deployment perspective, the workflow is compatible with BMS-integrated edge execution. EDMDc identification and NSS training can be performed offline using historical BMS datasets, whereas online operation requires only state lifting, linear prediction, and constrained optimization at the BMS sampling interval. This separation reduces computational requirements and supports integration with standard automation hierarchies in which PLC-level logic enforces safety constraints and fallback operation.

Future work will focus on experimental validation on the real AHU, with the Koopman–MPC implemented as a supervisory layer in real time and benchmarked against the baseline BMS control. This will enable a quantitative assessment of comfort tracking, actuation behavior, and energy-related performance under comparable disturbance conditions.

CAUSALITY-INFORMED TIME-SERIES FOUNDATION MODELS FOR BUILDING PERFORMANCE PREDICTION

Dennis Grauer and Joern Ploennigs
University of Rostock

Abstract

Time-Series Foundation Models, pretrained on large amounts of time-series data, offer strong zero-shot forecasting capabilities. Recent TSFM versions provide improved support for covariate forecasting. This renders them a promising alternative to address current limitations of data-driven building performance prediction approaches: they are highly dependent on data availability, are mostly case-specific, and often favor correlation over causation. In this paper, we compare the predictive performance of two TSFMs with graph neural network approaches and a statistical baseline. We also present an approach for configuring causal covariates for TSFM predictions from graph representations. All models are evaluated using two real-world building datasets.

Introduction

Given the challenges of climate change, it is imperative to improve the energy performance of buildings. Accurate predictions of indoor environmental quality (IEQ) and building energy use can help identify strategies to reduce the environmental impact of buildings (Ali et al., 2024) while maintaining a healthy indoor environment for occupants. With an increasing number of Internet of Things (IoT) sensors deployed in modern buildings, machine learning (ML) approaches that leverage historical data have emerged as an alternative to traditional physical simulations.

Although these approaches perform well on IEQ and building energy management (BEM) tasks, they face two major challenges. First, models often overfit to spurious correlations in the data due to the high redundancy of sensors in buildings (Chen et al., 2025). For example, it is easier for models to learn correlations among temperature sensors than dependencies on heating and cooling systems. Second, models are often limited by the availability and quality of sensor data (Ogundiran et al., 2024; Semasinghe et al., 2025). Consequently, models in the building domain are highly case-specific because they need to be configured for the available sensor data of each building (Ogundiran et al., 2024). Both issues make it difficult to transfer models between buildings, as they do not sufficiently learn generalizable physical causal relationships but instead capture case-specific correlations.

Recently, Time-Series Foundation Models (TSFMs) such as Chronos (Ansari et al., 2024, 2025), TimesFM (Das et al., 2024), Moment (Goswami et al., 2024), and Moirai (Woo et al., 2024) have emerged as an option to address the data availability challenge. They pose to require less training data, as they are pretrained on a variety of time-series datasets from different domains, similar to the transformer architectures of Large Language Models (LLMs) that are trained on large amounts of natural language data. This enables them to make zero-/few-shot forecasts by leveraging a short context window of previous time steps. With increased support for co- and multivariate forecasting in newer model versions, TSFMs promise to incorporate external factors and to predict multiple time series simultaneously.

In this paper, we investigate whether their out-of-the-box performance provides a suitable alternative for short-term forecasting tasks related to Indoor Environmental Quality (IEQ) and Heating, Ventilation, and Air Conditioning (HVAC) loads. We compare the predictive performance of (i) two state-of-the-art TSFMs, (ii) the Autoregressive Integrated Moving Average (ARIMA) model as a strong statistical baseline for time-series forecasting, and (iii) Graph Neural Networks (GNNs) combined with sequence-to-sequence learning methods as a simple way to encode physical causal relationships into machine learning models. By evaluating forecasting accuracy across four tasks, split across two real-world building datasets and varying forecasting horizons, we aim to explore not only the applicability of TSFMs in general but also whether they can be combined with causality-informed approaches such as GNNs. To this end, we *propose a causality-informed TSFM approach* that automatically configures TSFM features from graphs. Our evaluation is conducted on two publicly available datasets: a residential building with sparse HVAC data coverage and no occupancy ground truth, and an office building with diverse HVAC operational data and indoor environment measurements across multiple thermal zones.

This paper is structured as follows. We start with a review of related work on Time-Series Foundation Models and data-driven indoor environment and building energy performance prediction. We then describe our methodology by defining the models and forecasting tasks, followed by an introduction to the scenarios. After presenting and discussing the results, the paper concludes with an outlook.

Background and related works

Indoor environment predictions, HVAC and energy efficiency

Indoor environmental quality is a key factor in ensuring occupants' comfort and health. IEQ is largely governed by heating, ventilation, and air conditioning (HVAC) systems, which also account for a major share of energy use in modern buildings. This relevance makes the resulting complex relationships an important subject of research. Data-driven models that learn from historical data without requiring detailed building information have been employed for various tasks in the IEQ and energy-efficiency domain, including data collection and processing, fault and anomaly detection and analysis, HVAC control management, design optimization, and predictive analysis (Ogundiran et al., 2024). In this paper, we focus on the latter by predicting different IEQ variables and HVAC energy use. HVAC-related predictions mainly involve heating and cooling loads as well as energy consumption, which have been tackled by researchers using deep learning methods (Shi et al., 2024; Liu et al., 2023), neural networks (Borowski and Zwolińska, 2020; Irshad et al., 2024), and graph neural networks (Jia et al., 2024a,b). IEQ prediction is a diverse field, including indoor temperature, CO_2, particulate matter, and thermal comfort. While approaches such as neural networks (Cho and Moon, 2022; Tagliabue et al., 2021; Elmaz et al., 2021) and graph neural networks (Zhang et al., 2023) show convincing results, multiple reviews highlight a key limitation: these approaches remain highly case-specific and are sensitive to the availability and quality of data (Li et al., 2025; Latoń et al., 2025; Ogundiran et al., 2024; Semasinghe et al., 2025). This raises the question of whether zero-/few-shot models could provide an alternative that alleviates this limitation.

Time series foundation models

Time-Series Foundation Models (TSFMs) have recently emerged as a zero-shot alternative for time-series tasks. Built on transformer architectures, they are pretrained on a diverse collection of time-series datasets, enabling them to forecast, detect anomalies, and classify time series. The underlying idea is that TSFMs learn generalizable patterns and correlation structures from these datasets. This can enable zero-shot forecasting, as the model only needs to identify patterns that it has encountered before. In addition, TSFMs support transfer learning by fine-tuning them on new datasets and tasks with fewer data, as the model needs to learn the new task but not the patterns from scratch. Beyond univariate forecasting, models such as Moirai (Woo et al., 2024) and the most recent version of Chronos (Ansari et al., 2025) support integrating past and future covariates into forecasting pipelines.

This suggests that TSFMs could be applicable to different prediction tasks in buildings. However, existing studies report mixed results. Mulayim et al. (2025) evaluate TSFMs for building energy management tasks and find limited zero-shot generalization; TSFMs often fail to outperform classical statistical models. Similarly, Lin et al. (2024) show that TSFMs can handle heterogeneous building data if they are well configured. Extending the analysis to spatio-temporal forecasting, Gupta et al. (2025) report that TSFMs perform competitively at high sampling frequencies but degrade in settings with sparse spatial sensor coverage. Overall, these studies suggest that TSFMs do not necessarily work out of the box but require careful parameterization. This motivates our research question: Can incorporating causal relationships improve TSFM performance in building settings?

Methodology

The aim of this paper is to evaluate the accuracy of TSFMs on different IEQ and energy-consumption tasks and to investigate whether causal information can improve performance. To this end, we perform univariate forecasting with TimesFM and Chronos as two state-of-the-art TSFMs, and covariate forecasting with Chronos using past and future covariates. On the GNN side, we compare two different GNN models as well as our newly proposed approach, which uses GNN graph-representation nodes as covariates for Chronos. We compare these deep learning models with the well-established Autoregressive Integrated Moving Average (ARIMA) model (Newsham and Birt, 2010) as a strong statistical baseline.

Since we want to focus on a comparison of data-driven methods, white-box models are excluded from the scope of this paper. GNN models are favored over other deep learning models, as they allow encoding causal relations in a rather simple manor.

The general task is to predict the next values over a prediction duration P from a set of previous values spanning a context duration D. Since we focus on short-term forecasting in this study, we set $P \in \{1\,\mathrm{h}, 2\,\mathrm{h}, 4\,\mathrm{h}, 8\,\mathrm{h}\}$ to provide an overview of general trends in model forecasting capabilities. The context duration D is defined separately for each model. Depending on the case-specific sampling rate f_s (in minutes; see Scenarios), the context window length C and the horizon length H are defined as $C = (60D)/f_s$ and $H = (60P)/f_s$. In compliance with other work in this domain, we use root mean squared error (RMSE) as the evaluation metric.

Graph neural network models

We employ two types of GNN models: (i) a spatiotemporal GNN (GRUGCN) that uses a Gated Recurrent Unit (GRU) layer to capture temporal regression and a graph convolutional layer, and (ii) a two-layer Graph Convolutional Network with no mechanism to capture temporal dependencies. For both models, we define a directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. The node set $\mathcal{V}$ denotes a subset $\{v_1, v_2, \ldots, v_i\}$ of available time-series signals from sensor measurements. Each node is associated with a node-feature vector that contains the previous values $\{x_{t-C}, \ldots, x_{t-1}\}$. The edge set $\mathcal{E}$ denotes a set of directed edges $\{e_1, e_2, \ldots, e_i\}$.

Each edge $e = (v_i, v_j)$ represents a directed connection from node v_i to node v_j. We construct these connections based on domain knowledge of physical relationships between the measured signals and dataset exploration, aiming to obtain a graph that captures causal relationships between sensor measurements. Although ontologies like Brick (Balaji et al., 2016) offer schemes for building metadata, they do not cover physical relations and causalities, making automatic graph construction based on causality a complex problem (Langbridge et al., 2023; Grauer and Ploennigs, 2025), not covered in the scope of this paper.

For both models, the context duration is set to $D \in \{4\,\mathrm{h}, 8\,\mathrm{h}\}$. Since we consider different datasets and prediction targets, each requires careful hyperparameter tuning. To this end, we employ the Optuna framework (Akiba et al., 2019) to optimize the learning rate and hidden size of each model layer.

Time series foundation models and ARIMA

We use TimesFM (Das et al., 2024) and Chronos (Ansari et al., 2025) as state-of-the-art TSFMs in our evaluation. We use the most recent versions available at the time of writing, namely TimesFM 2.5-200m and Chronos 2. While TimesFM only supports univariate forecasting, Chronos 2 can incorporate past and future covariates (real-valued or categorical) to support multivariate forecasting. Its in-context learning (ICL) capability shares information within a group of multivariate time series via a group-attention mechanism. We test the effectiveness of this mechanism by adding graph nodes as past covariates to Chronos. Therefore, we define the causal-covariate forecasting task as follows:

$$\hat{y}_{causal} = Chronos(D_{target}, \mathcal{S}) \tag{1}$$

where D_{target} is defined as the previous time-steps of the prediction target and $\mathcal{S}$ is defined as a subset of $\mathcal{V}$:

$$\mathcal{S} = \{v_i \mid \exists e_{i,target} \in \mathcal{E}\} \quad \forall v_i, v_k \in \mathcal{V} \tag{2}$$

where $e_{i,target}$ denotes an edge directed from node v_i to the target node v_{target}. The full pipeline for configuring causal covariates from graph representations is given in Algorithm 1.

Besides the causal approach, we define two additional Chronos covariate settings: one that uses only two past covariates for each prediction target, and one that adds past covariates as well as known future covariates. While past-only covariates add information to the context window D, future covariates are incorporated over the prediction horizon H. To create realistic scenarios, we restrict future covariates to quantities that can be estimated (e. g., future temperature or dew point using weather forecasts), are controlled by building operators (e. g., air supply rates or heating setpoints), or follow time patterns (e. g., indicators for working hours or day of the week).

TimesFM serves as a comparison to Chronos, as it is designed and trained for univariate time series only. We set $D = 2048$ for both models, as this is the maximum context length used in the first pretraining stage of Chronos (Ansari et al., 2025). Although TimesFM 2.5 supports context lengths of up to 16,000 samples, our exploratory experiments suggest that longer context lengths do not necessarily improve performance while increasing computational cost. For ARIMA, we set $D = 1024$. To simplify forecasting, we use AutoARIMA (Smith et al., 17), which automatically fits the model parameters to the data.

Since the data for the GNN models are split into training and test subsets, TSFM and ARIMA predictions are made only on the test subset to ensure a fair comparison across all model types.

Algorithm 1 Causal-covariate TSFM forecasting

Require: Directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, target node v_{target}, historical data matrix $\mathrm{X} \in \mathbb{R}^{|\mathcal{V}| \times T}$, context length C, horizon H

Ensure: Forecast $\hat{y}_{t:t+H}$ for v_{target}

Scenarios

Residential building

We use the dataset presented by Pandey et al. (2025) to evaluate forecasting performance in residential buildings. The dataset contains sensor data capturing occupant behavior, energy use, and IEQ for eight student dorm units over a period of two years. The data are divided into pre- and post-retrofit periods. During the retrofit, heat pumps were installed alongside a heat recovery ventilation (HRV) system, and the insulation of walls and windows was significantly improved. For our prediction tasks, we use the post-retrofit period, as the HVAC and HRV deployment provides more sensor data for the GNN models. Although energy use for HVAC and HRV is available after the retrofit, other operational signals (e. g., HVAC supply air volume or temperature) are missing. The available sensors include outdoor climate conditions (temperature [°C], solar radiation [W/m²], dew point [°C], humidity [%]), indoor environment variables (relative humidity [%], illuminance, CO_2 [ppm], TVOC [ppb], temperature [lx]), energy use of electrical appliances [kWh], and occupant behavior (door and window state [binary, indicating open or closed]). After data cleaning and preparation, we retain 8.5 months of data sampled at $f_s = 10\,\mathrm{min}$. We use a 70:30 split for training and validation/testing, as recommended for the size of the cleaned dataset (Muraina, 2022). We

aim to predict the following target variables:

- **Indoor relative humidity [%]:** We predict the relative humidity in the living room of the student dorm. Input features for the GNN models and causal-covariate setting include outdoor relative humidity [%], dew point temperature [°C], room temperature [°C], HRV power use [kWh], and window state (0 = closed, 1 = open). Outdoor temperature and dew point temperature are used as both past and future covariates for Chronos.

- **HVAC energy use [Wh]:** We predict the combined energy use of electric baseboard heaters in the dorm and heat pumps. Input features include outdoor temperature [°C], relative humidity [%], dew point temperature [°C], indoor temperature [°C], and indoor relative humidity [%]. Outdoor temperature and humidity are used as past and future covariates.

The graph structures used for the GNNs are shown in Figure 2. Due to sparse operational information on ventilation, the graph remains relatively simple. Moreover, as this is a residential building, humidity and HVAC energy use depend strongly on occupant behavior, daily schedules, habits, and personal preferences. In particular, HVAC energy use is a challenging stochastic prediction task: it exhibits spikes at certain time steps and remains close to zero at others, with no clear seasonality (Figure 1).

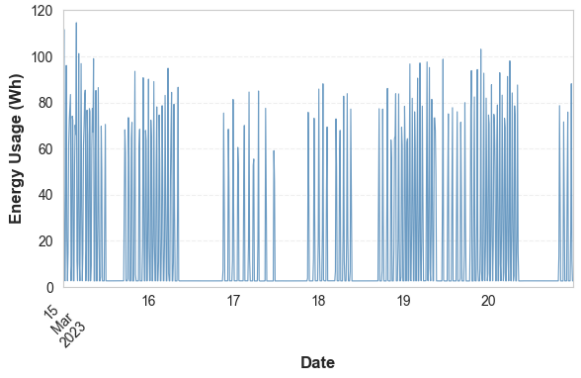

Figure 1: Exemplary HVAC energy usage of student dorm for one week

Office building

We use the Building 59 dataset (Luo et al., 2022) to evaluate forecasting performance in an office building. The records include energy consumption, HVAC operational data, IEQ, and outdoor climate data for a campus building over three years, from January 2018 to December 2020. The IEQ data are separated by thermal zones. For each zone, the zone temperature, cooling and heating temperature setpoints, CO_2 concentration, fan speed for the ventilation air supply, and heating valve position are provided. The building is divided into northern and southern parts, each served by two rooftop units (RTUs). For each RTU, operational data such as supply/return temperature, air flow rates, and setpoints are available. We use data from the southern part of the building, as it provides more detailed measurements. Although the dataset contains a short period of occupancy data, there are no time spans in which both occupancy and indoor-climate data are complete. The following prediction targets are chosen:

- **Zone temperature [°C]:** Zone temperature of an office-space thermal zone. Input features for the graph-based models include temperatures of adjacent zones, outdoor air temperature and humidity, RTU supply-air temperature, and zone fan speeds and heating valve positions. Since office temperatures depend strongly on occupancy, we use a binary indicator for typical working hours (9 am to 5 pm on weekdays) as a past and future covariate for Chronos, alongside outdoor air temperature. The sampling rate is $f_s = 5\,\mathrm{min}$.

- **HVAC energy consumption [kWh]:** HVAC energy consumption is the aggregate of the energy consumption of both RTUs serving the southern part of the building. The graph representation is constructed from each RTU's operational signals (supply/return/mixed-air temperature, supply flow rates), setpoints, fan speeds, heating valve position, temperatures of the thermal zones served by the RTU, and outdoor climate conditions. This yields a complex graph with 115 nodes and 154 edges. For covariate forecasting, we use the working-hours indicator and outdoor air temperature. The sampling rate is $f_s = 15\,\mathrm{min}$, i. e., the original sampling rate of HVAC energy consumption.

Results and discussion

Student dorm - relative humidity

For the task of predicting relative humidity, TSFM and ARIMA significantly outperform the GCN approaches for all horizons (Table 1). With an RMSE below 1 %, these models show superior performance for the shorter prediction horizons of 1 and 2 hours. When the prediction horizon is doubled to 4 and 8 hours, their performance decreases. ARIMA performs at a similar level for the 1-hour prediction but quickly falls behind Chronos and TimesFM as the horizon increases. This is likely due to ARIMA autoregressive stepwise prediction, where errors accumulate for longer horizons. TSFM on the contrary can replicate longer patterns due to the transformer architecture. While adding past-only covariates of outdoor temperature and dew point adds little accuracy, incorporating known future covariates improves performance as the context grows, with particularly strong gains for the 4- and 8-hour horizons. Causal covariates also improve performance but remain behind future covariates.
The GCN model fails to capture the dynamics across horizons and context lengths. Its best performance is achieved

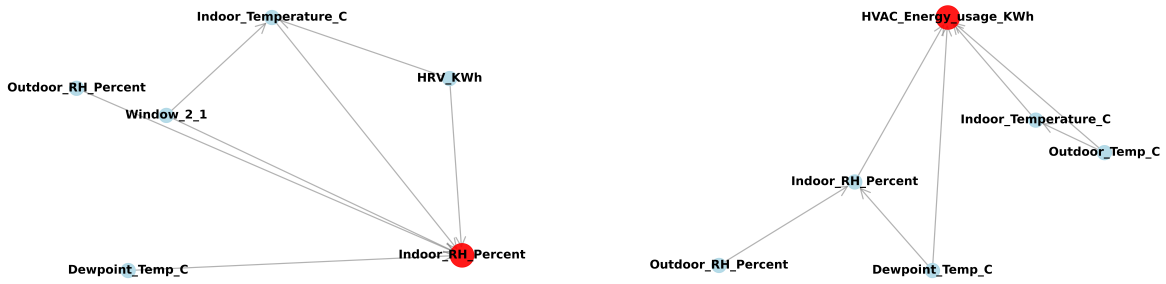

Figure 2: Graph underlying for predictions in the student dorm data set for relative humidity (left) and HVAC energy usage (right).

with the short context length of 4 hours ($C = 24$) for the longest horizon; however, on the 8-hour horizon, performance degrades across all context lengths. The GRUGCN performs best when input and output sequence lengths are equal, yet it still remains behind ARIMA and the TSFMs. These results suggest that TSFMs perform particularly well when predicting variables with a fixed range. Relative humidity, by definition, is bounded between 0 and 100 %; in the test set, values range from 20 % to 57 %, with a mean of 35.1 % and a median of 35.25 %. For machine learning models, the nonlinear relationships between input features can be difficult to learn from scratch, especially given the limited number of samples and meaningful features in the underlying graph.

Student dorm - HVAC energy usage

Predicting HVAC energy use in the student dorm is a challenging task that none of the models in this study can solve sufficiently well (Table 2). Among all models, Chronos with past covariates achieves the best results for the shortest prediction horizon.

When visualizing 1-hour-ahead predictions over two days in the test set (Figure 3), we find that Chronos can predict peaks in energy use with only a small lag, but it underestimates the magnitude of the energy consumed. The GRUGCN model captures only the baseline, also underestimates peaks, and adds noise around periods with an approximately constant baseline slightly below zero.

For the complex temporal patterns of HVAC energy use, the trend of decreasing accuracy for TSFM and ARIMA forecasts is confirmed, whereas GNN-based models perform similarly across all horizons. For the 4-hour horizon, ARIMA performs best, while the GRUGCN model performs best for the 8-hour horizon.

Because peaks in HVAC energy use are driven by unobserved occupant behavior patterns, all model types struggle to make accurate predictions. Although TSFMs outperform the graph-based models on shorter horizons, the non-seasonal and seemingly random patterns undermine their strengths.

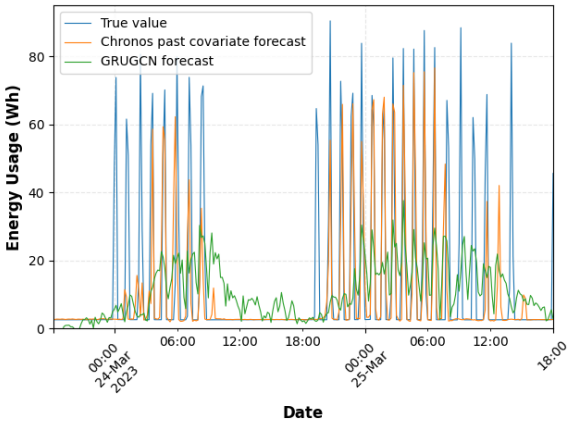

Figure 3: HVAC energy usage of two days in the test set. True value and predictions from GRUGCN with 4 hours context and Chronos past with past covariates for 1 hour horizon are shown.

Office building - zone temperature

Zone temperature in the office building (Table 3) is best predicted by Chronos with causal covariates across all horizons beyond 1 hour. Adding future covariates does not improve longer-horizon predictions at the same scale as in the humidity task: forecasts using only past covariates perform only slightly worse for the 4- and 8-hour horizons, and the RMSE increases with each horizon. The fact that the causal approach performs best for longer horizons

*Table 2: Results for residential HVAC energy forecasting (RMSE in Wh), best result for each horizon is marked **bold***

GCN (8 h)	18.78	18.96	19.41	19.65

(even outperforming predictions that use known future covariates) suggests that Chronos' group-attention mechanism benefits from well-defined causal covariates.

While TimesFM performs best for the 1-hour horizon, it does not appear to scale well for temperature forecasting: it is surpassed by ARIMA for the 2-hour horizon and by both GRUGCN variants for the two longest horizons. Since the sampling rate is doubled compared to the humidity task, TimesFM accuracy decreases substantially for $H > 48$.

As the horizon increases, the GRUGCN model gains ground relative to the TSFMs and ARIMA and surpasses ARIMA for the longest horizon. Compared to humidity forecasting, the gaps between TSFMs and graph-based models shrink. This is likely due to (i) the higher availability of meaningful features for graph learning in the office-building dataset and (ii) the reduced complexity of temperature prediction compared to relative humidity.

Office building - HVAC energy usage

Among the results for HVAC energy-use forecasting in the office building (Table 4), TimesFM stands out by achieving the best predictions for horizons up to 4 hours. While the GNN-based models and ARIMA perform at a similar level, TimesFM outperforms them but still shows a decrease in accuracy for longer horizons: it falls behind all Chronos variants for the 8-hour horizon. Among the Chronos variants, the past-and-future-covariate setting performs best for the longest horizon. We also find that, in this task adding covariates yields smaller gains than in other cases as the target variable depends on a wide range of factors. In particular, the causal-graph variant, which incorporates a large number of covariates, serves as a scalability test for the in-context learning (ICL) mechanism. The strong drop in performance indicates that this approach may not suitable when many covariates are used. The availability of diverse sensor data highly benefits the graph-based approaches, as they perform similarly to the TSFMs and ARIMA up to the 4-hour horizon. Given the complex graph structure, adding a GRU layer to capture temporal patterns does not improve performance, as results are similar to those of the GCN model.

Although HVAC energy data for the office building are still noisy, the patterns are easier to predict because they are governed by observable behavior represented in the graph.

Conclusion and outlook

In this paper, we compare the predictive performance of two state-of-the-art time-series foundation models with ARIMA and graph neural network (GNN)-based approaches. We also present a new approach for configuring covariates based on causal relationships encoded in graph representations. Using two real-world building case studies of residential and office use, we compare forecasting performance for HVAC energy use, thermal-zone temperature, and relative humidity.

The study finds that TSFMs show strong performance on both examined IEQ tasks, surpassing the GNN-based models. By comparing results across datasets with dense sensor coverage and lower data availability, we conclude that TSFMs are a strong alternative to training machine learning models from scratch, particularly in use cases where high-quality data are scarce. As the number of measurements incorporated for graph learning grows, the performance gap between pretrained TSFMs and the relatively simple GNNs used in our experiments shrinks. In cases with high sensor coverage, we show that Chronos' in-context learning capabilities can benefit from causal covariates and perform better than most Chronos runs with only historical data. However, the HVAC use case also

indicates that identifying a refined set of causal variables is important. This suggests that semantic graph models could help identify more effective covariate sets.

Regarding the two TSFMs we compare, Chronos performs best in three out of four experiments and maintains its accuracy better as the prediction horizon increases. Chronos' support for incorporating known future covariates into the prediction horizon shows potential to help maintain performance for longer horizons in the temperature-forecasting task, but does not consistently improve performance across all experiments. As the office-building HVAC results show, it cannot be assumed that covariate forecasting is superior to univariate forecasting in every case. In addition, although covariate support moves beyond purely historical-context forecasting, current prediction pipelines do not incorporate metadata, semantic context, or natural-language inputs, as proposed, for example, by Mulayim et al. (2025).

Overall, while causality-informed TSFMs show promise for building-related forecasting tasks, their performance varies across use cases, and further research is needed to identify the factors that govern their effectiveness. Beyond predictive accuracy, practical deployment also requires interpretability. Although TSFMs have proven valuable for prediction tasks with sparse data, other aspects remain understudied. Trust in predictions in real-world applications is often undermined by the black-box nature of machine learning models (Chen et al., 2023). While ML and GNN models can be augmented with explainability techniques such as GNNExplainer (Ying et al., 2019), the nature of pretraining and learning solely from time-series data and covariates limits TSFM explainability. For future research, we propose augmenting zero-shot TSFMs with semantic context and exploring synergies that combine the strengths of TSFMs with classical machine learning models and semantically explainable causal information.

ADAPTIVE LIFE CYCLE ASSESSMENT AS AN EVOLVING ENVIRONMENTAL KNOWLEDGE STATE FOR DIGITAL BUILDING LOGBOOKS

Kilian Speiser and Jochen Teizer
Technical University of Denmark, Denmark

Abstract

This paper introduces Adaptive Life Cycle Assessment (ALCA) as a time-resolved framework for continuously evaluating building environmental impacts over the lifecycle. Using a conceptual design science approach, the study develops a multidimensional framework integrating prospective and retrospective data and situates it within the Digital Building Logbook (DBL). An illustrative additive manufacturing case demonstrates data flows and feasibility. The results show that ALCA enables continuous updating of accumulated impacts, improves traceability, and supports PDCA-based environmental control. The framework addresses limitations of static and dynamic LCA and provides a governance-oriented approach for lifecycle impact monitoring and regulatory alignment.

Introduction

The building industry is a major contributor to environmental impacts and therefore plays a key role in the transition required to maintain climate stability and planetary habitability (Global Alliance for Buildings and Construction, 2022). Life Cycle Assessments (LCAs) quantify the environmental impacts of buildings and support informed decision-making. This approach helps avoid the unintentional transfer of burdens to other environmental impact categories (Hauschild et al., 2017). In addition, quantification supports the definition of environmental targets, which can guide actions to improve the environmental performance of buildings (International Energy Agency, 2023). Such targets have also translated into quantified thresholds on national levels, where construction projects must hit specific targets, like in Denmark, where only 6.8-8.0 kg CO2 eq are permitted per used m2 and year of a building (Social- og Boligstyrelsen, 2018).

LCA is primarily performed prospectively (ex-ante) but can also be performed retrospectively (ex-post), also referred to as historical LCA (Bruhn et al., 2024; Kristensen et al., 2015). In the remainder of this work, we adopt the terminology for prospective and retrospective LCA proposed by Arvidsson et al. (2024). Aside from the timing of the assessment relative to the product life cycle, time is typically not explicitly resolved in either prospective or retrospective LCAs. Both approaches are generally time-integrated to a reference point (Arvidsson et al., 2024).

LCA is currently performed in the early stages or upon completion and is always time-integrated to a certain point in time (Forth, 2025). A building has a long lifetime with changes through renovations and shifting boundary conditions, meaning that assessments produced early in the project fail to quantify the building's impact once those changes occur. This time-dependency motivates investigation of different LCA approaches.

Dynamic LCA (DLCA) is an approach to LCA that recognizes the changing nature of parameters and processes within assessed systems and incorporates their temporal evolution into the LCA framework. It is therefore time-resolved within the modeling framework, where certain parts can be retrospective and others can consider future events, products, and processes (Arvidsson et al., 2024). In DLCA, temporal evolutions are defined as variations in parameters. Although DLCA explicitly represents time, temporal trajectories are predefined, meaning that the final results are static after LCA completion. Changes in parameters or processes during the product's lifetime are not considered once the LCA is completed. Figure 1 illustrates this limitation: even when time is represented, module contributions remain static once the assessment is produced. In contrast, continuous updating revises module estimates when new evidence becomes available.

Figure 1 suggests that DLCA offers greater opportunities to accommodate time-dependent aspects relevant to the long lifetimes of buildings, but it fails to respond to actual changes over time. The actual impacts after construction, during operation, and renovation are not considered and are based on early predictions, which often significantly deviate from measured energy consumption during operations (De Wilde, 2014). Similar issues occur during the construction phase: as-built LCAs rely on information collected from drawings or Building Information Models (BIM), but significant deviations in the materials used go unnoticed and are hidden from the LCA. This leads to incorrect expectations about environmental impacts.

Ongoing regulatory developments in Europe may provide a framework to address this issue. The Digital Building Logbook (DBL) is defined as a tool to record and assess data, information, and documents that include "maintenance, refurbishment, [...] traceability and characteristics of construction materials, performance

data such as operational energy use [...] and lifecycle emissions" over all phases of a building (Volt et al., 2020). Once such logbooks are available, reported renovation and measured operational energy performance can be used to update prospective LCAs with observed data. In addition, the mandated Digital Product Passport (DPP) can further improve accuracy by enabling instance-specific tracking of building components, so that emissions are linked to a specific installed element rather than to generic impact declarations (European Commission, 2024).

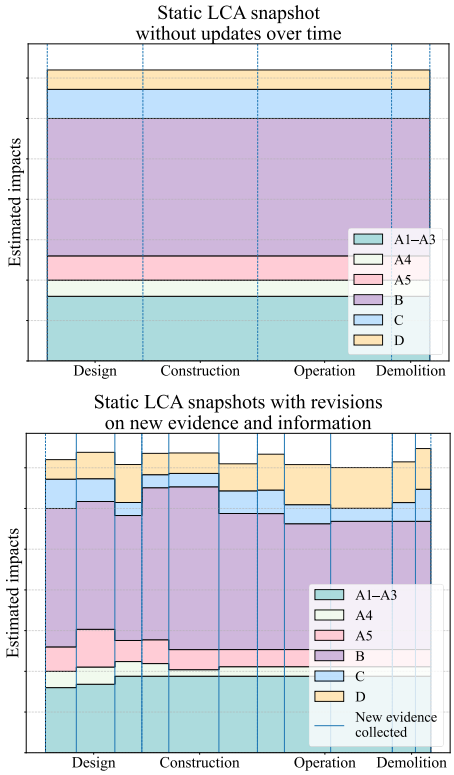

Figure 1: Conceptual comparison of static estimates of LCA and continuous updating based on new evidence. The figure does not show accumulated impacts but the estimates at a given time.

For regulatory environmental impact targets, such as those in Denmark, prospective LCAs are insufficient because they fail to accurately reflect the environmental impacts of buildings as they are actually constructed and operated. The evidence for this gap is well established: as-built deviations systematically alter embodied impacts (Forth, 2025), and the performance gap between predicted and measured operational energy use is widely documented (De Wilde, 2014; IEA, 2023). There is, however, a gap in the conceptual description of how a retrospective LCA can be incrementally developed for buildings over their full lifetime. This would enable more accurate estimates and require stakeholders to act when targets are not met. With the development of DBLs, such updating of impacts could become mandated, but a technical and conceptual description of the information flows and governance structure remains absent.

This work presents the concept of Adaptive LCA (ALCA). It is a time-resolved framework in which LCAs are continuously updated throughout the building's lifetime. Information is updated based on new inputs from either planned changes or retrospective measurements. Previous versions are timestamped and stored, and can become part of the DBL. The paper presents the information dimensions and definitions that align with ALCA and situates it within the information governance context of the Digital Twin Construction (DTC) (Sacks et al., 2020). Additive manufacturing (AM) in construction provides an illustrative context for framework development, as it enables higher traceability of information through sensors and continuous measurements of material use and energy consumption. ALCA is intended as a general framework for buildings; AM is used here as an enabling context that makes information flows more tractable, not as a limiting scope condition.

The paper addresses two research questions:

RQ1: How can a building LCA be conceptualized as a continuously evolving environmental knowledge state that integrates accumulated ex-post impacts and projected ex-ante impacts over the lifecycle?

RQ2: How can ALCA be integrated into a DBL to support traceability, regulatory use, and decision-making?

The paper makes four contributions. First, it introduces ALCA as an evolving environmental knowledge state that integrates accumulated and projected impacts over the building lifecycle. Second, it proposes a multidimensional conceptual framework that formalizes the temporal and epistemic information structure of products and processes within ALCA. Third, it clarifies how ALCA can be integrated into a DBL ecosystem while preserving institutional roles and governance boundaries. Fourth, it uses AM as an illustrative context to show how high-resolution process data, together with DPPs, can reduce uncertainty and improve the instance-specific accuracy of environmental impact declarations.

Research methodology

This paper adopts a conceptual design science research approach (Hevner et al., 2004) to develop the ALCA framework. The framework is derived through three steps. First, limitations in existing LCA approaches, specifically the inability to incorporate observed changes during the building's lifetime, are identified through analysis of established LCA literature and standards (ISO 14040; ISO 14044). Second, the ALCA concept is constructed by synthesizing LCA theory with emerging digital building governance frameworks, including the DBL definition (Volt et al., 2020) and DTC concepts (Sacks et al., 2020). Key framework dimensions (temporal, epistemic, and product-process) are grounded in established LCA terminology and standard practice. Third, the framework is instantiated illustratively in an AM construction context to demonstrate feasibility and to identify key information flows. Evaluation at this stage is argumentative and conceptual: the framework is assessed for internal consistency and alignment with established standards rather than through empirical testing. Empirical validation

in pilot settings is identified as the primary direction for future research.

Conceptual framework for ALCA

ALCA builds on the recognition that retrospective environmental information is increasingly available throughout the building lifecycle. Measurements derived from sensors, construction documentation, operational monitoring systems, and project reports during construction, operation, renovation, and demolition enable systematic observation of realized environmental impacts (Volt et al., 2020; IEA, 2023). Advances in digitization, Internet of Things (IoT) integration, expanded Environmental Product Declaration (EPD) databases, and emerging forms of robotized and AM processes have significantly increased the availability, resolution, and traceability of such data (European Commission, 2024; Schlenger et al., 2025). This development enables the establishment of a closed-loop environmental control logic.

ALCA conceptualizes a building LCA as an incrementally evolving environmental knowledge state. It extends DLCA by not only resolving time within the modelling framework but by updating the assessment incrementally when new information becomes available. ALCA structures the assessment into discrete LCA states. Each state integrates accumulated retrospective (ex-post) impacts and projected prospective (ex-ante) impacts over the remaining lifecycle. At any point in time, one state represents the best available environmental knowledge of the building. When new measured data or planned changes occur, ALCA generates a new timestamped state while preserving the previous version.

ALCA structures environmental knowledge along three explicit dimensions. The temporal dimension distinguishes between retrospective (ex-post) and prospective (ex-ante) impacts across lifecycle phases. The epistemic dimension differentiates primary (measured) data from secondary (estimated or modelled) data. In addition, ALCA separates product-related and process-related impacts to ensure traceability of materials, components, and activities. These dimensions define the information structure required for integration into a DBL, where each LCA state can be timestamped, stored, and audited.

Regarding lifecycle phase characteristics, ALCA's adaptive updating does not apply uniformly across all phases. Module A (product and construction stage) covers activities from raw material extraction through construction completion. Once construction is finished, modules A1-A5 become fully retrospective: no further updating of construction-stage impacts is possible, though their accuracy can be refined with as-built data. By contrast, modules B (use stage) and C (end-of-life) remain partially or fully prospective throughout most of the building's life. The most significant adaptive value of ALCA therefore lies in operational monitoring (module B), renovation cycles (module B4), and end-of-life planning (module C), where continuous updating against realized performance can detect deviations from targets and trigger corrective action. This distinction is important for scoping the practical application and governance responsibilities of ALCA.

LCA methodology steps

According to ISO 14040 and ISO 14044, LCA consists of four phases: goal and scope definition, life cycle inventory (LCI), life cycle impact assessment (LCIA), and interpretation. Information emerges and evolves across all four phases. The goal and scope define the functional unit, system boundaries, assumptions, and impact categories. The LCI quantifies input and output flows across all lifecycle phases of the built asset. In construction projects, these flows correspond to building products and processes. The LCIA translates quantified flows into environmental impacts using selected impact assessment methods and indicators. The interpretation phase evaluates results in relation to regulatory thresholds, project location, and environmental targets.

Although information occurs throughout all phases, the inventory plays a central role. The LCI contains the quantified units and parameters that determine environmental impacts. Changes in quantities, material specifications, process data, or service life assumptions directly affect impact results. Because ALCA incrementally updates environmental knowledge, revisions typically begin at the inventory level and propagate through LCIA and interpretation. The inventory therefore forms the structural backbone of the evolving LCA state.

EPDs provide product-specific LCIA results together with metadata such as reference service life and transport assumptions. However, EPDs cover products only. A building LCA must additionally quantify and assess construction and operational processes, including products that are partially or fully consumed.

Within this methodological structure, data correspond to quantified flows and parameters in the LCI. Information emerges when these flows are characterized through LCIA methods. Knowledge results from interpreting impacts in relation to regulatory requirements and environmental targets. In ALCA, new evidence may require updating inventory data, recalculating impacts, and revising the interpreted knowledge. Each incremental update produces a new LCA state that reflects the best available environmental knowledge at a given time.

Temporal dimension

Prospective and retrospective information both address LCI and LCIA throughout all phases of the building. Prospective information is based on assumptions (design and processes), scenarios (future site conditions), and declared environmental impact data from EPDs. EPD assumptions refer to the declared values and boundary conditions embedded within an EPD dataset, including assumed reference service life, transport distances, and upstream production conditions. As the building progresses through its lifecycle stages, parts of the LCI or LCIA can become historical, meaning that prospective information can be progressively replaced or refined with

retrospective information, such as measured, reported, or verified data, thereby reducing uncertainty.

Retrospective information can address more specific knowledge about units or quantities in the LCI, or more accurate information on impacts in the LCIA (instance-specific EPDs, measured emissions). Additionally, the lifetime of certain elements can be revised based on retrospective evidence.

When updating the LCA using new retrospective information, previous versions are preserved as earlier states. These past projections remain valid representations of former knowledge, enabling learning and retrospective analysis.

Table 1 presents four knowledge states derived from the intersection of two binary dimensions: the temporal dimension (prospective vs. retrospective) and the epistemic dimension (primary vs. secondary). These four states represent analytically distinct combinations relevant to building LCA practice, each characterized by a different uncertainty profile. They are not mutually exclusive within a single ALCA state: a given module may simultaneously draw on both primary and secondary data or combine retrospective and prospective contributions. The four-state structure reflects a minimum necessary set of categories to capture the full range of data quality configurations encountered across the building lifecycle.

Table 1: Temporal-epistemic knowledge states in ALCA

	Secondary (estimated/ modeled)	Primary (measured/ verified)
Prospective	Projected impacts from assumptions • Design-based quantities • Type-level EPDs • Modeled or simulated future scenarios	Empirically grounded projections • Measured baselines • Supplier-specific data • Measured process rates
Retrospective	Reconstructed past impacts • As-built model • Back-calculated activities (fuel/time/waste) • Gap-filled inventories w/o evidence	Observed and measured impacts • Verified quantities (delivery notes, monitored) • Metered process data (energy, telemetry) • Time-stamped records

Epistemic dimension

Information can be measured or estimated. In the context of LCA, these are described as primary (measured) and secondary (estimated). In ALCA, there is no fixed correlation between these and prospective or retrospective information. Instead, primary information reduces uncertainty compared to secondary information. Estimated information refers to assumptions, calculations, simulations, or predictions. Measured information includes raw sensor readings, machine telemetry, verified quantities, and reported data.

Concrete examples of sensor-derived data relevant to ALCA include: electricity consumption of AM robots or construction equipment, directly informing process energy in the LCI; material flow data from weigh cells or volume sensors on concrete pumps, informing material quantities; air quality or particulate sensors on construction sites, informing process emissions; and Building Management System (BMS) data on heating, cooling, and ventilation during operation, replacing assumed operational energy with metered values. Manual data extraction from delivery notes, invoices, and project reports complements sensor data where automated collection is not possible.

The retrospective dimension will still include a significant amount of estimation. For instance, precise on-site fuel consumption tracking does not necessarily linearly translate into specific environmental impact indicators such as NOx. Accurate quantity information in the LCI does not therefore automatically produce accurate impact results; estimation through characterization factors remains necessary. The level of uncertainty, however, should decrease when moving from prospective to retrospective. Yet, uncertainty cannot be eliminated.

Primary and secondary data directly affect the LCI, while LCIA remains largely model-based even when inventory data are measured. LCA interpretation integrates both prospective and retrospective results for decision-making.

Process-product dimension

In addition to temporal and epistemic structuring, ALCA distinguishes between product-related and process-related impacts within the LCI. In standard building LCA practice, although all environmental impacts ultimately originate from physical and chemical processes, they are attributed either to physical building elements (products, with their embodied impacts) or to lifecycle activities such as construction, operation, and demolition. This distinction follows standard LCA practice and enables structured accounting within the inventory.

Product-related impacts refer to impacts embodied in materials, components, and assemblies. These are typically represented through product datasets such as EPDs and quantified as element quantities linked to upstream production processes. Process-related impacts arise from activities such as construction, operation, maintenance, and demolition, and are quantified through activity data, including energy use, transport, equipment operation, and waste handling.

From an ontological perspective, product datasets summarize process-based information into standardized units. While this aggregation enables comparability and practical application, it may obscure instance-specific variations, such as deviations in transport distances, execution conditions, or site-specific energy mixes. Direct process information can therefore reduce uncertainty when available, particularly in adaptive contexts where execution data are progressively observed.

Product impacts are generally object-based and may stabilize once elements are installed, whereas process impacts are activity-based, time-dependent, and execution-sensitive. Within ALCA, both categories coexist in each environmental knowledge state, and updates may affect product quantities, process activities, or both. The distinction serves as a structuring principle within the inventory, enabling clearer allocation, updating, and traceability of impacts across phases.

Conceptual ALCA state

At any given point in the lifetime of a construction project, ALCA is represented by a discrete, timestamped environmental knowledge state. This state reflects the most accurate available environmental knowledge of the building at that moment. It integrates accumulated retrospective impacts and projected prospective impacts across relevant lifecycle modules, preserving traceability of the data and assumptions on which they are based.

Figure 2 represents this multidimensional structure. The three dimensions define the axes of the ALCA knowledge space. The stacked cube representation is scientifically motivated: it visualizes that each lifecycle phase module simultaneously occupies a position along all three dimensions. A given module may involve both prospective and retrospective contributions, draw on both primary and secondary data, and combine product and process impacts. The stacking therefore reflects that no single cell exclusively characterizes a given module; an ALCA state is a composite of multiple co-existing knowledge configurations. When new evidence becomes available, a subsequent ALCA state is generated, preserving prior states for comparison, learning, and regulatory auditability.

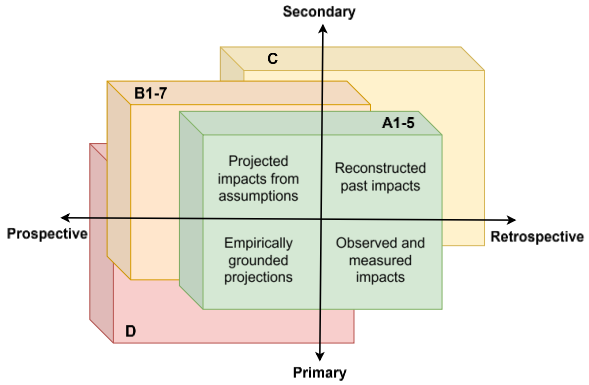

Figure 2: A conceptual ALCA state combining temporal, epistemic dimensions for all building phases.

Continuous PDCA-based control logic

ALCA operationalizes a Plan-Do-Check-Act (PDCA) control logic for environmental performance throughout the building lifecycle. In the planning phase (Plan), prospective LCA defines expected impacts based on design assumptions and scenarios. During execution (Do), construction and operational activities generate retrospective information in the form of measured or reported data, which incrementally replaces earlier assumptions within the ALCA state. Each update produces a revised, timestamped environmental knowledge state, which can be checked.

The checking phase (Check) evaluates the updated ALCA state against environmental targets or regulatory thresholds. If deviations occur, the acting phase (Act) involves mitigation measures such as design adjustments, modified construction methods, or operational interventions. In this way, ALCA transforms LCA from a static reporting instrument into a control mechanism, linking prospective planning with retrospective evidence through structured state transitions.

Regarding operational implementation, several clarifications are relevant. Updates to the ALCA state are triggered by three types of events: phase completion (e.g., end of the fabrication stage), delivery of new monitoring data (e.g., annual metered energy from the BMS), and significant deviations from regulatory thresholds, with specific deviation magnitudes to be defined by regulatory frameworks. Primary responsibility for maintaining the ALCA state lies with the building owner or operator, analogous to existing building maintenance and reporting obligations. Construction teams supply phase-specific process data during active construction stages. Automated data flows from IoT sensors can reduce manual effort significantly, particularly for operational energy monitoring, though manual reporting from delivery notes or invoices remains relevant where automation is unavailable. From a computational standpoint, ALCA does not require substantially new infrastructure: standard LCA calculation engines apply at each state, and the primary technical challenge is data integration and interoperability rather than computational intensity. Building owners and regulatory compliance bodies stand to benefit most from ALCA, as it enables accountable and verifiable impact tracking aligned with regulatory obligations. Design and construction teams also benefit from early deviation detection, which enables timely corrective action before lifecycle thresholds are exceeded.

Additive manufacturing as an enabler for continuous LCA

AM provides a particularly suitable context for illustrating ALCA due to the digital controllability and data richness of AM processes, which directly improve the epistemic quality of LCA inputs. AM processes are typically computer-controlled with integrated logging and are electricity-driven, resulting in accessible and high-resolution energy records. Sensors can additionally track material streams. As a result, material quantities and energy consumption can be recorded at high temporal resolution at the machine level.

Table 2 summarizes generic data characteristics of AM compared to conventional construction. While AM does not eliminate uncertainty it significantly improves the reliability of accumulated impacts during early lifecycle phases. This improvement stabilizes projections of remaining lifecycle impacts and strengthens the basis for continuous evaluation against regulatory thresholds.

Table 2: Generic comparison of data characteristics relevant to Adaptive LCA.

Aspect	Conventional Construction	Additive Manufacturing
Process control	Distributed, manual	Centralized, digital
Quantity tracking	Indirect	Direct or machine-derived
Energy monitoring	Limited	High-resolution, electricity-based
Temporal resolution	Low-medium	High

Impact on LCA uncertainty	High	Reduced (not eliminated)

During the design phase, all information is secondary and prospective. Designers derive quantities and impacts from models and assumptions, covering all lifecycle phases. Some primary historical data from comparable projects may inform baselines, but all future impacts are estimated. Once fabrication starts, modules A1-A3 are progressively updated from estimated to tracked and measured information (see Figure 3). Project teams can integrate instance-specific EPDs for products and measured data for processes. In AM, machine-logged electricity consumption and material flow sensor data can replace estimates directly.

During transport and construction (modules A4-A5), IoT-based measurements replace predicted construction process impacts. Updated as-built BIM models and tracked material quantities progressively substitute simulated impacts. Exact delivery routes or reported fuel use from transport vehicles improve transport accuracy. In AM, robot sensor data provide comparable information for material use and process energy.

During the operational phase (module B), two primary information types become relevant. First, metered energy from BMS progressively replaces estimated consumption for heating, cooling, and ventilation. Continuous prospective projections remain necessary to detect deviations before targets are exceeded. Second, renovation activities must be incorporated with their specific materials, processes, and impacts.

The demolition phase (module C) determines the realized building lifetime, the key parameter assumed at the outset. Only at demolition can final accumulated impacts be determined with certainty. Although corrective action is no longer possible at that stage, stakeholders can transfer results to subsequent projects or apply financial adjustments if targets were exceeded.

DBL integration

In this work, the DBL provides the institutional and technical context for operationalizing ALCA. It functions as an authoritative repository for realized building information, including as-built products and as-performed construction processes, rather than as an analytical or predictive system. This aligns the DBL with the ex-post dimensions of ALCA: measured or reported information provides an auditable baseline of accumulated impacts, while projected future impacts are generated by external analytical services, such as digital twin tools, using DBL data as their factual basis.

The role of DPPs within this architecture is significant. DPPs, mandated under the EU Ecodesign for Sustainable Products Regulation (European Commission, 2024), enable instance-specific documentation of individual building products and components, including material composition, declared environmental impact data, and service life information. Within ALCA, DPPs serve as the link between generic EPD datasets and instance-specific LCA inputs. Where a standard building LCA uses a type-level EPD covering a class of products, DPPs enable attribution of verified environmental data to a specific installed component, e.g., a particular concrete batch used on a specific date, with documented transport distance and energy consumption. This instance-specific traceability directly improves the accuracy of product-related impacts .

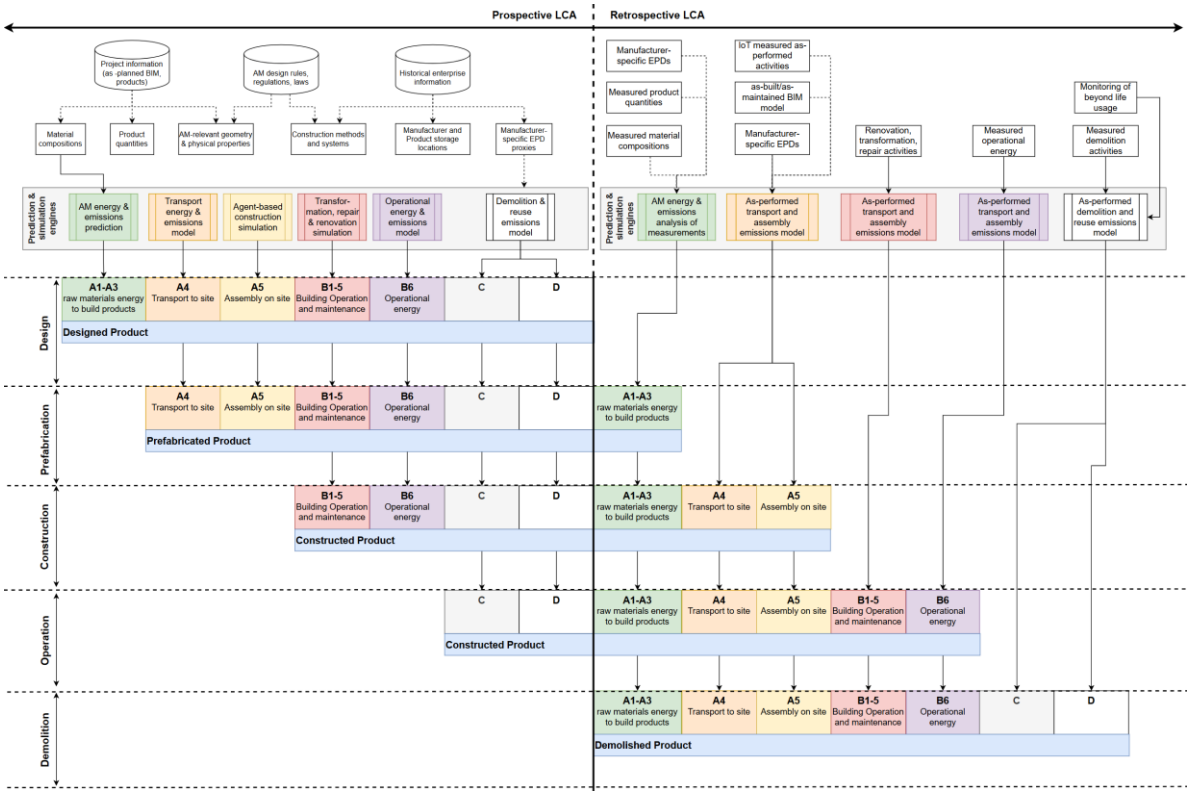

Figure 3: Instantiation of ALCA in an AM construction site.

in the LCI and reduces the uncertainty associated with generic EPD assumptions. As DPP adoption expands under EU regulation, the epistemic quality of ALCA inputs is expected to improve correspondingly, progressively replacing secondary estimates with primary, product-specific data. This connection represents the core mechanism through which the fourth contribution of this paper is realized in practice. The evolution of EPD content within DPP frameworks, particularly the shift from generic type-level declarations to instance-specific performance records, is therefore a key development that ALCA is designed to leverage.

Operationalizing ALCA through the DBL requires interoperable data structures and robust versioning. The DBL should act as an integration layer connecting DPPs, material passports, permit documentation, and LCA state records, rather than duplicating all data. Each update must include timestamps, source links, assumptions, and provenance metadata so that accumulated impacts remain auditable and suitable for regulatory compliance.

This separation clarifies the distinction between the DBL and a DTC. Although the DBL can serve as an information container within a DTC ecosystem, it does not perform reasoning, prediction, or optimization. The DBL stores and exposes information, while external tools provide analytical capabilities. Maintaining this separation preserves institutional clarity and avoids mixing authoritative records with interpretive or predictive models.

Discussion

DBLs and related passport systems should be understood as governance instruments, not merely technical data containers. They formalize documentation obligations, responsibilities, and verification mechanisms across the building lifecycle, giving ALCA the institutional continuity required for regulatory use.

An explicit comparison with DLCA clarifies ALCA's contribution. DLCA resolves time within the LCA model by defining parameter variations as predefined functions, enabling time-specific characterization of emissions and impacts (Arvidsson et al., 2024). However, once the DLCA model is constructed and executed, its results are fixed: the model does not update when actual conditions deviate from modeled trajectories. ALCA differs fundamentally in this respect. Rather than predefined trajectories, ALCA responds to actually observed data, generating new timestamped states as evidence accumulates. ALCA therefore does not replace DLCA; instead, it introduces an adaptive dimension that DLCA lacks. In practice, DLCA methods could be deployed within each prospective ALCA state, while the adaptive state-transition logic of ALCA incorporates retrospective evidence as it emerges. The two approaches are therefore complementary rather than competing.

Regarding standardization, LCA is an ISO-standardized methodology (ISO 14040; ISO 14044), and ALCA does not propose an alternative impact assessment method. Impact categories, characterization factors, and system boundary conventions remain unchanged. What ALCA introduces is a governance framework for managing the updating process: defining when a new state is generated, how prior states are preserved, and how accumulated and projected impacts are combined at any point in time. Developing normative standards for these aspects, including trigger thresholds, state management protocols, and interoperability requirements between DBL systems and LCA calculation engines, represents a necessary step toward regulatory adoption. Engagement with standards bodies such as ISO TC 207 and CEN TC 350, alongside regulatory alignment at the national and EU level, is an important direction for future work.

The conceptual relationship between ALCA and DTC reveals strong theoretical overlap. Both rely on structured information dimensions, iterative updating, and PDCA-based control logic. However, their scopes differ: DTC focuses primarily on construction process monitoring and optimization, whereas ALCA addresses lifecycle environmental impact accounting across all phases. ALCA can therefore be understood as a specialized environmental subsystem within a broader DTC ecosystem, accessing shared semantic information while specifying environmental data requirements that other subsystems must provide. Ontology-based semantic frameworks developed in DTC research (Schlenger et al., 2025; Speiser et al., 2025) offer a promising direction for future integration, particularly to enable consistent cross-system interpretation of environmental data. Extending such frameworks toward environmental impact accounting is acknowledged as future research rather than a current contribution of this paper, as it presupposes empirical validation of the ALCA framework itself. Generative and agentic AI can support experts in including relevant knowledge into such systems (Speiser et al., 2026).

The separation between DBLs as authoritative repositories and digital twin services as analytical engines has important governance implications. Verified ex-post information becomes part of the regulatory record within the DBL. Predictive simulations and scenario analyses remain external and do not automatically acquire authoritative status. This preserves institutional clarity and prevents conflation of observed performance with modeled projections. Regulators can assess compliance based on accumulated and verifiable impacts, while project teams use predictive tools to anticipate deviations and implement mitigation measures within a PDCA logic.

The framework remains conceptual and has undergone argumentative rather than empirical validation. While AM illustrates the feasibility of high-resolution monitoring, application in conventional construction, operational phases, renovation cycles, and end-of-life processes requires further investigation. Long building lifetimes limit full lifecycle validation, but prefabrication facilities and AM environments may serve as short-term testbeds. Standardization of semantic structures, interoperability requirements, and regulatory alignment remain open research challenges. Moreover, although ALCA progressively reduces epistemic uncertainty, it

cannot eliminate inherent predictive limits in future lifecycle modules.

Conclusions

This paper introduced ALCA as a time-resolved framework for treating building LCA as a continuously evolving environmental knowledge state. ALCA combines accumulated ex-post impacts with projected ex-ante impacts across lifecycle phases and structures this information through temporal, epistemic, and product-process dimensions. By generating discrete, timestamped states as verified data become available, ALCA reframes building LCA from a static reporting exercise into an ongoing process of environmental knowledge revision.

The paper further showed how ALCA can be anchored within a DBL ecosystem. The DBL provides an authoritative repository for verified ex-post information, while DPPs improve the instance-specific accuracy of product-level LCA inputs and external digital twin services support projection and decision-making. This separation preserves governance clarity while enabling continuous monitoring and PDCA-based intervention.

The framework remains conceptual and requires empirical validation in pilot settings. Future work should develop interoperable semantic structures, test ALCA across construction and operational contexts, and define normative requirements for adaptive LCA updating.

Declaration of AI in the writing process

During the preparation of this work, the authors used generative AI to proofread text and improve clarity. After using this service, the authors reviewed and edited the content as needed and take full responsibility for the content of the published article.

NO CARBON LEFT BEHIND: TOWARDS TRACEABLE BIOGENIC CARBON IN CONSTRUCTION VALUE CHAINS

Edwin Zea Escamilla, Alexander N. Walzer, and Markus Knecht
University of Applied Sciences and Arts Northwestern Switzerland
FHNW, Muttenz and Windisch, Switzerland

Abstract

Biobased construction materials store atmospheric carbon, yet current life cycle assessment and environmental product declaration practices represent biogenic carbon as aggregated indicators with limited traceability across value chains. This limits transparency, attribution, and credibility of carbon-related claims. This paper explores how blockchain-enabled system principles can address these deficiencies by treating biogenic carbon as a persistent, traceable state linked to material flows. Through an exploratory mapping onto bamboo value chains, we identify how such ledger-based logic can formalize carbon continuity, prevent double counting, and support auditable life cycle transitions. The paper contributes a conceptual framework for carbon ledger approaches in construction.

Introduction

Biobased construction materials such as bamboo and wood are increasingly promoted as key contributors to climate mitigation strategies in the built environment (Rincón et al., 2023). Their relevance stems from their ability to sequester atmospheric carbon during growth and to temporarily store this carbon in buildings and infrastructure (Bundi et al., 2024). As embodied carbon gains prominence alongside operational emissions, the question of how biogenic carbon is accounted for has become central to sustainability assessments in construction.

Current life cycle assessment (LCA) frameworks provide standardized methods to quantify environmental impacts, including biogenic carbon flows (Hellweg & i Canals, 2014). However, in practice, biogenic carbon is typically represented as an aggregated balance at product, building, or system level (Tellnes et al., 2017). Information about origin, transformation, ownership, temporal storage, and end-of-life fate is progressively abstracted away as materials move along value chains (Sayın et al., 2025). This abstraction limits transparency, complicates verification, and creates uncertainty when biogenic carbon is used to support climate claims or compensation mechanisms (Dwyer & Mowry, 2022).

These limitations are particularly pronounced in global and heterogeneous value chains, such as those associated with bamboo-based construction materials. Bamboo is harvested, processed, transformed, and assembled across multiple actors and locations, often with limited digital continuity between stages. While the material itself is inherently traceable in physical terms, the associated carbon information is not.

In parallel, digital technologies in construction have primarily focused on design coordination, simulation, and operational performance, while the underlying logic of carbon accounting has remained largely unchanged, reflecting broader institutional misalignments between technological innovation and adoption in the construction sector (Walzer et al., 2025). However, blockchain and distributed ledger technologies have emerged in other sectors as mechanisms to ensure traceability, immutability, and transparency of data across decentralized systems (Alotaibi et al., 2024). Their potential to address persistent traceability challenges in construction has been widely discussed, yet their relevance for biogenic carbon accounting remains largely unexplored. Further, improved traceability and verification are increasingly linked to the credibility of emerging green finance and carbon market instruments (Schletz et al., 2020).

Therefore, this paper adopts an exploratory perspective to investigate how blockchain-inspired system logics could support traceability and transparency of biogenic carbon in biobased construction materials, using bamboo as a representative case. Rather than proposing a finalized technical solution, the paper examines conceptual mismatches between current carbon accounting practices and material realities, and explores how distributed ledger principles could help bridge these gaps.

This study asks: *How can blockchain-inspired system principles be operationalised to guarantee traceable, auditable biogenic-carbon accounting across heterogeneous bamboo value-chains?*

Methods

The exploration follows a scoped and purposive analytical review suitable for an emerging research field, rather than a full systematic literature review. Relevant literature is selectively sampled to identify conceptual patterns and limitations in current biogenic carbon accounting practices, and the analysis is structured around three analytical steps:

(i) identification of traceability gaps in current biogenic carbon accounting practices,
(ii) abstraction of blockchain-relevant principles applicable to these gaps,

(iii) exploratory mapping of these principles onto bamboo-based material value chains,
(iv) formalization of these insights into a conceptual framework for traceable biogenic carbon accounting

First, common biogenic carbon accounting practices were reviewed with a focus on how carbon information is generated, aggregated, and transferred across life cycle stages. Particular attention was given to points where carbon attribution becomes ambiguous, such as material transformation, component assembly, reuse, and end-of-life treatment. This review was informed by existing LCA-based studies on bamboo construction materials and by current Environmental Product Declaration (EPD) and reporting conventions.

Second, blockchain technologies were not treated as a specific software implementation, but as a set of system principles. These include distributed state management, immutable transaction histories, unique identifiers, and rule-based state transitions. The analysis deliberately avoids technological specificity in order to focus on conceptual compatibility rather than implementation feasibility.

Third, bamboo-based construction materials were used as an exploratory case to test how these principles could be mapped onto real material flows. Bamboo value chains are characterized by biological growth phases, multiple processing steps, and a wide range of end-of-life scenarios. Conceptual data entities representing biogenic carbon quantities were defined and linked to material batches or components. Hypothetical life cycle events (such as processing, assembly, reuse, and disposal) were then interpreted as state transitions that would require transparent and verifiable updates of carbon information.

Fourth, the insights derived from the exploratory mapping were formalized into a conceptual framework for traceable biogenic carbon accounting. This step translates the identified system principles and observed material-flow dynamics into a structured entity–transaction model, in which biogenic carbon is represented as a persistent accounting state linked to material representations. Core conceptual elements, including Carbon Units, Material Tokens, and a defined set of life cycle transactions, were specified to capture how carbon information is created, transformed, transferred, and retired over time.

In addition, a set of invariants was introduced to ensure internal consistency, including conservation of carbon, single attribution, traceable aggregation, explicit state transitions, and auditable history. This formalization step consolidates the preceding analytical steps into a coherent system logic that can support transparent, continuous, and verifiable carbon accounting across heterogeneous value chains.

Results analysis and discussion

Review of current biogenic carbon accounting practices and points of ambiguity

Our ongoing analysis indicates that current biogenic carbon accounting practices are internally consistent within individual assessments, yet they exhibit structural limitations once carbon information is expected to remain traceable across multiple life cycle stages and actors. In most LCA-based studies on bamboo construction materials, biogenic carbon is quantified at the point of material production using established inventory data and is reported as an aggregated balance per functional unit (Tellnes et al., 2017). At this initial stage, carbon uptake and storage are clearly defined and methodologically unambiguous.

As materials progress through processing, assembly, and use phases, however, carbon information is progressively abstracted. Processing steps redistribute material mass through yield losses, residues, and by-products, but the associated carbon is commonly reallocated using averaging or allocation rules that do not preserve links to the original biomass source. During component assembly and at building level, carbon indicators are further aggregated into single values, which are suitable for comparative reporting but obscure the provenance and also the distribution of biogenic carbon within multi-material systems. In reuse scenarios, carbon storage is typically addressed through scenario-based assumptions rather than through documented continuity of material histories, while end-of-life treatments rely heavily on generalized modeling choices that are applied retrospectively (Silvia et al., 2025).

Dynamic life cycle assessment (LCA) has been increasingly explored to account for the temporal dynamics of biogenic carbon flows. However, existing approaches vary widely in their methodological choices, including system boundaries, time horizons, and modelling of carbon sequestration and release, reflecting a lack of consensus and leading to substantial variability in results (de Jong et al., 2026). This methodological diversity, together with increased data and modelling requirements, introduces additional complexity and challenges in interpretation (de Jong et al., 2026). While dynamic LCA can provide more temporally consistent representations in certain contexts, its added value remains case-dependent and it is not part of established standardized LCA practice, which today remains predominantly static. The contribution of this paper is complementary to this insight: rather than focusing on temporal modelling, it addresses the continuity and traceability of biogenic carbon across value chains.

These patterns reveal that biogenic carbon is repeatedly recalculated at successive system boundaries rather than transferred as a conserved and persistent quantity. While this approach aligns with the logic of conventional LCA, it limits transparency when carbon information is interpreted across parallel assessments or over extended time horizons. The resulting ambiguity is not primarily a consequence of missing data, but also of accounting structures that prioritize internal coherence over cross-stage continuity. As a result, attribution becomes increasingly dependent on assumptions embedded in models rather than on verifiable material trajectories.

Our findings suggest that the principal challenge in biogenic carbon accounting lies less in improving quantification methods and more in developing

mechanisms that can preserve attribution, continuity, and auditability as materials move through complex value chains. Addressing this challenge requires system logic capable of explicitly managing carbon state transitions over time, which motivates the exploration of blockchain-inspired principles discussed in the following sections.

Blockchain-inspired system principles relevant to biogenic carbon traceability

Our analysis indicates that, when abstracted from specific software implementations, blockchain technologies can be understood as a set of system principles that directly address several of the structural weaknesses identified in current biogenic carbon accounting practices (Nair et al., 2024). When viewed through this lens, these principles show a high degree of conceptual compatibility with the traceability and transparency gaps discussed in the previous section.

We find that distributed state management is particularly relevant for biobased material value chains, where carbon-related information is generated, modified, and interpreted by multiple actors over time (Komdeur & Ingenbleek, 2021). In contrast to centralized databases or document-based reporting, a distributed state model allows all participants to reference a shared and consistent representation of carbon states. Importantly, this does not require full decentralization of governance or the absence of authoritative oversight. Rather, it ensures that updates to carbon information are synchronized across actors and assessment contexts, reducing the risk of divergent interpretations arising from parallel data silos.

Immutable transaction histories directly respond to the loss of provenance observed in conventional accounting workflows. In current LCA and EPD practices, carbon information is typically recalculated and overwritten as materials progress through successive life cycle stages. As a result, earlier assumptions and allocations are no longer accessible once new results are reported. By contrast, an immutable transaction logic preserves previous states while recording subsequent changes, enabling carbon information to remain auditable over time. This makes it possible to trace later interpretations (such as reuse or end-of-life outcomes) back to earlier decisions and methodological choices, rather than treating each assessment as an isolated snapshot in time.

Our analysis suggests that unique identifiers are a prerequisite for persistence. Assigning persistent identifiers to biogenic carbon quantities, rather than only to products, components, or documents, allows carbon information to remain associated with material flows even when physical elements are transformed, aggregated, or separated. This directly addresses the attribution loss observed during processing and component assembly, where carbon is currently redistributed through averaging and aggregation without preserving its original linkage to biomass sources.

Rule-based state transitions emerge as a further critical principle. In the reviewed accounting practices, decisions regarding carbon release, continued storage, or substitution effects are often embedded implicitly in scenario assumptions or applied retrospectively at reporting stages (He et al., 2024). Blockchain-inspired systems allow such decisions to be formalized as explicit rules governing state transitions. For example, conditions under which biogenic carbon remains stored, are transferred to a new use phase, or are considered released at end-of-life, can be defined and documented consistently. This shifts carbon accounting away from static reporting toward a dynamic, state-based representation that better reflects material trajectories over time.

Taken together, our results suggest that the relevance of blockchain technologies for biogenic carbon accounting lies less in automation or decentralization per se, and more in their capacity to formalize continuity, conservation, and transparency of carbon information, consistent with prior findings that digital construction technologies derive value primarily from decision support rather than from automation alone (Graser et al., 2021). By focusing on system logic rather than implementation, the proposed analysis illustrates how blockchain-inspired principles could complement existing LCA frameworks while addressing limitations that cannot be resolved through methodological refinement alone.

Exploratory mapping of blockchain principles onto bamboo-based material flows

Our exploratory mapping of the identified blockchain-inspired principles onto bamboo-based construction materials both illustrate the suitability and the constraints of these logics when confronted with real material flows. Bamboo value chains are particularly illustrative because they span biological growth, heterogeneous processing pathways, and highly variable use and end-of-life scenarios, which together expose where carbon information is currently lost, reinterpreted, or rendered non-verifiable. At the earliest stage, biogenic carbon is associated with biological growth in managed or semi-managed bamboo systems (Buonocore, 2023). In our mapping, this carbon is represented as a conceptual data entity linked to a defined biomass batch, for which uptake is temporally and spatially constrained. At this stage, the carbon state is relatively stable and attribution is comparatively unambiguous. Introducing a persistent identifier at this point enables the carbon quantity to remain referenceable independently of later transformations, thereby establishing a continuous accounting anchor across the subsequent value chain.

As bamboo undergoes processing such as cutting, splitting, flattening, or lamination, the physical material is divided into multiple output streams, including products, residues, and losses (Liu et al., 2024). Treating these steps as explicit state transitions makes the redistribution of biogenic carbon visible, rather than implicitly reallocating it through mass-based averaging. In our mapping, each processing event updates the carbon state by allocating portions of the original carbon entity to new identifiers associated with derived batches or components. This differs from conventional practice, where carbon is often reassigned at the level of the new product without preserving a traceable link to the originating biomass and the yield structure that produced it.

During component assembly, bamboo-derived elements are frequently combined with other biogenic and non-biogenic materials to form components and systems. In our framework, assembly is treated as a reversible aggregation of carbon entities rather than as a terminal reporting step. Carbon information remains linked to individual components even when aggregated for reporting purposes, preserving the option to disaggregate carbon states during selective disassembly, repair, or reconfiguration. This is particularly relevant for bamboo construction systems where replaceability and modular interventions are common, yet the carbon implications of partial replacement are difficult to represent within conventional building-level aggregation.

Reuse scenarios reveal an important advantage of the state-based approach: When a bamboo component is removed from its initial application and reintroduced elsewhere, conventional LCA practice typically represents this through scenario assumptions or crediting approaches that are external to the component's documented history. In our mapping, reuse is recorded as a state transition that extends the storage duration of the existing carbon entity. This avoids re-estimation and reduces the risk of re-claiming the same stored carbon across multiple assessments, while making reuse effects explicit, time-stamped, and auditable (Zea Escamilla et al., 2020).

End-of-life events further demonstrate the relevance of rule-based transitions. Disposal pathways such as incineration with or without energy recovery, landfilling, recycling, or cascading use represent qualitatively different carbon outcomes and are sensitive to timing. Our mapping shows that these end-of-life assumptions often dominate carbon conclusions, yet are rarely documented with sufficient granularity to be verifiable. Encoding end-of-life as a verifiable transition clarifies when and why biogenic carbon is considered released, substituted, or retained, and it links those outcomes to explicit events rather than to generic scenario choices applied after the fact.

Overall, the bamboo case indicates that blockchain-inspired principles can be meaningfully aligned with the material logic of biobased construction systems when life cycle events are represented as state transitions acting on persistent carbon entities. This approach makes allocations, assumptions, and boundary choices more transparent by externalizing them into recorded transitions. At the same time, our analysis suggests that the usefulness of such systems depends less on technological sophistication than on the clarity of the accounting rules, the definition of permissible transitions, and the governance mechanisms used to validate critical events, particularly those at origination and end-of-life.

Importantly, although the specific form of life cycle events such as end-of-life is not known in advance, their occurrence is inevitable. These events are treated as potential state transitions that are recorded as they occur, allowing carbon information to be updated incrementally rather than predefined through fixed scenarios.

Conceptual framework for traceable biogenic carbon accounting

Building on the ambiguities identified in current biogenic carbon accounting practices and our exploratory mapping of blockchain-inspired principles, we propose a conceptual framework intended to support traceable and transparent carbon accounting for biobased construction materials. The framework is not presented as a software architecture. Instead, we formalize a system logic that can complement LCA-based methods by preserving continuity of biogenic carbon information across life cycle stages, actors, and assessment contexts.

The central premise of the framework is that biogenic carbon should be treated as a persistent state associated with material flows, rather than as a static attribute recalculated at each assessment boundary. To operationalize this premise, we distinguish between (i) carbon information as a persistent accounting entity and (ii) physical material representation as a batch- or component-level entity. These are linked through explicit state transitions that correspond to life cycle events. In doing so, we aim to externalize allocation decisions and scenario assumptions into auditable updates rather than allowing them to remain implicit in isolated assessments.

At the core of the framework is a limited set of conceptual entities and transactions that define how biogenic carbon information is created, redistributed, transferred, and retired over time. Table 1 summarizes these elements.

Table 1: Conceptual entities and transactions in the proposed framework

Category	Concept	Description
Entity	Carbon Unit (1 tCO_2eq)	Persistent representation of a quantified amount of biogenic carbon, including metadata on origin, material type, and data quality
Entity	Material Token	Representation of a physical material batch or component, referencing one or more Carbon Units
Transaction	Origination	Creation of Carbon Units associated with biomass growth and initial material production
Transaction	Transformation	Allocation, splitting, or aggregation of Carbon Units following material processing steps
Transaction	Assembly / Disassembly	Reversible aggregation or separation of Material Tokens without loss of carbon provenance
Transaction	Transfer of custody	Change of responsible actor while preserving carbon state and history
Transaction	End-of-life	Terminal or transformative update of Carbon Units reflecting release, substitution, or continued storage

Within this framework, life cycle events are interpreted as state transitions acting on Carbon Units rather than as opportunities for re-estimation. Processing steps redistribute carbon quantities explicitly by allocating portions of existing Carbon Units to derived Material Tokens. In the context of digital ledgers, a token is a cryptographically secured data object that represents a specific right, asset, or quantity and can be transferred, subdivided, and verified without a central intermediary (Marijana & Bernhard, 2025). Assembly aggregates material representation without erasing carbon provenance, thereby preserving the possibility of later disaggregation during repair, reuse, or selective dismantling. Reuse extends the storage duration of existing Carbon Units through documented transitions rather than through retrospective scenario reinterpretation. End-of-life events close or transform carbon states based on documented treatment pathways, making the timing and nature of carbon release or substitution explicit.

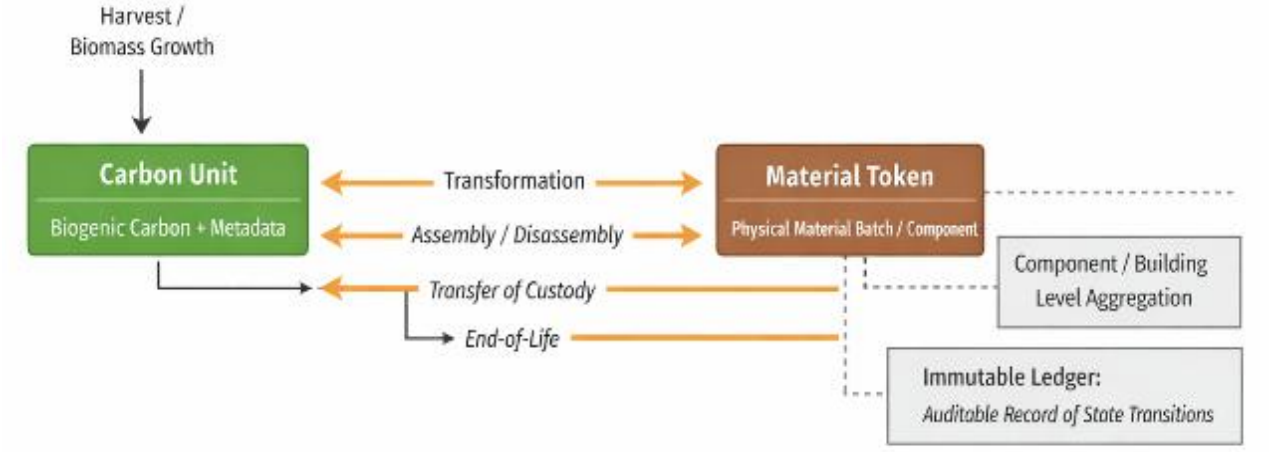

Figure 1: Conceptual entity–transaction diagram for traceable biogenic carbon accounting

To ensure internal consistency and prevent common accounting failures, we define a small set of invariants that govern all transactions (Knecht, 2025):

- First, conservation of carbon requires that the sum of biogenic carbon quantities across derived Carbon Units does not exceed the originating amount, except where methodological adjustments are explicitly recorded as such. This prevents the carbon leakage observed during processing and yield-loss allocation.
- Second, single attribution requires that a Carbon Unit can exist in only one active accounting state at a given time, preventing parallel claims on the same stored carbon. It therefore eliminates the double-counting risk highlighted when bamboo components are aggregated into downstream products.
- Third, traceable aggregation requires that aggregated indicators at component or building level are derived from referenced Carbon Units rather than entered independently. This addresses the loss of provenance that occurs when component-level data are rolled up to building-level totals.
- Fourth, explicit state transitions require that changes in carbon status (e.g., reuse, release, substitution) are represented as transactions rather than implicit assumptions. By doing so, it replaces the implicit scenario assumptions used for reuse and end-of-life modelling.
- Fifth, auditable history requires that state changes preserve previous states, enabling retrospective verification of carbon trajectories and the assumptions that shaped them. This provides the traceability needed to resolve the "black-box" recalculations typical of conventional LCA workflows.

The framework deliberately avoids prescribing specific technologies or governance models. Distributed ledger technologies are relevant insofar as they provide a shared, append-only record of state transitions across multiple actors, thereby supporting consistency and auditability in decentralized value chains. However, the conceptual contribution lies in formalizing continuity, accountability, and conservation of biogenic carbon information, rather than in decentralization or automation per se.

By framing biogenic carbon as a traceable state linked to material flows, the proposed framework addresses the transparency, double counting, and attribution challenges identified in the introduction. It also provides a structured basis for subsequent work on verification, governance, and integration with digital construction environments (for example, see Walzer et al., 2024), while remaining compatible with established LCA and EPD practices.

Figure 1 presents the framework as an entity–transaction system linking Carbon Units (persistent biogenic carbon states with metadata) to Material Tokens (physical batches or components).

Carbon Units are created at origination and persist throughout the system, while Material Tokens can be split, combined, assembled, or disassembled. Life cycle events are represented as transactions that update carbon states according to predefined rules while preserving an

auditable history. Aggregated carbon indicators are then derived from referenced Carbon Units rather than recalculated independently.

The diagram emphasizes conservation, explicit state transitions, and traceability across actors and life cycle stages, without prescribing a specific technological implementation.

Conclusions

Our objective in this paper was to explore how blockchain-inspired system principles could contribute to improved traceability and transparency of biogenic carbon accounting in biobased construction materials, with a particular focus on bamboo value chains. Rather than proposing a definitive technical solution, we set out to examine whether the structural challenges identified in current LCA- and EPD-based practices could be addressed through an alternative accounting logic that preserves continuity of carbon information across life cycle stages.

Our analysis shows that existing biogenic carbon accounting practices are effective for quantification within defined system boundaries but are limited when carbon information must remain attributable and verifiable as materials move through complex value chains. The review and discussion revealed that aggregation during processing and assembly, scenario-based treatment of reuse, and generic end-of-life assumptions progressively detach carbon indicators from their material origins. These limitations do not primarily stem from insufficient data or methodological inconsistency, but from accounting structures that repeatedly reinterpret carbon at successive assessment boundaries rather than transferring it as a conserved quantity.

By abstracting blockchain technologies into a set of system principles, we demonstrated that distributed state management, persistent identifiers, immutable transaction histories, and rule-based state transitions are conceptually well aligned with these challenges. When applied to bamboo-based material flows, these principles enable biogenic carbon to be represented as a persistent state linked to material batches and components and updated explicitly through documented life cycle events. The exploratory mapping showed that such an approach can make processing allocations, reuse effects, and end-of-life outcomes more transparent by externalizing assumptions that are otherwise embedded implicitly in conventional accounting models.

The conceptual framework proposed in this paper builds on these findings by formalizing biogenic carbon as a traceable accounting entity governed by a small set of invariants, including conservation, single attribution, and auditable history. In doing so, it outlines how a carbon ledger logic could complement existing LCA frameworks without replacing established standards. The potential of such a framework does not lie in automation or decentralization per se, but in its capacity to support consistent carbon attribution across actors and over time, thereby reducing the risk of double counting and increasing the credibility of carbon-related claims (Knecht & Stiller, 2023).

Our preliminary results suggest that ledger-based representations of biogenic carbon could provide a robust foundation for future carbon accounting and reporting mechanisms in the built environment. In particular, they offer a structured basis for component-level traceability, for handling reuse and cascading use scenarios, and for linking carbon outcomes to documented material trajectories rather than to abstract scenarios. At the same time, the exploratory nature of this work shows the need for further research on governance, verification, and integration with digital construction workflows, as well as on the institutional conditions under which such carbon ledgers could be adopted.

Overall, this study contributes to ongoing discussions on digitalization and sustainability in construction by reframing biogenic carbon accounting as a state-based, traceable process. By doing so, it opens a pathway toward carbon ledger approaches that can support transparent, verifiable, and scalable carbon accounting for biobased materials within and beyond the bamboo sector.

HOUSEHOLD-LEVEL ENERGY POVERTY ASSESSMENT IN IRELAND: A COMPARATIVE ANALYSIS OF INDICATOR-BASED APPROACHES

Afshin Saeedian[1], Lorna Fitzsimons[1], James McGrath[2], Arash B. Naamrudi[1], Reihaneh Aghamolaei[1]

Abstract

Energy poverty measurement at the household level is sensitive to indicator choice and data availability. This study evaluates energy poverty in Dublin using a set of expenditure-based, income-sensitive, and needs-based indicators with a Building Energy Rating (EPC) dataset. Household income uncertainty is addressed through scenario-based income assumptions, enabling estimation of indicator-specific thresholds and escape income levels. Results reveal divergence in household classification across indicators, driven largely by structurally high energy costs linked to dwelling characteristics. The findings highlight the limitations of single-indicator approaches and demonstrate the value of comparative, household-level frameworks for informing targeted energy poverty interventions in data-constrained contexts.

Introduction

Energy poverty is increasingly recognised as a multidimensional condition arising from the interaction of low household income, high energy costs, and poor dwelling energy efficiency, which together restrict access to essential domestic energy services. This concept extends beyond traditional fuel poverty that focuses primarily on heating affordability, and instead encompasses the broader set of energy services required for an acceptable standard of living, including space heating, water heating, lighting, and appliance use (Boardman 1991; González-Eguino 2015; Bouzarovski et al. 2014; Bouzarovski and Simcock 2017; Thomson et al. 2017; Scarpellini et al. 2019; Shahzad et al. 2022).

Across Europe, energy poverty has emerged as a growing policy concern, driven by a combination of rising energy prices, ageing building stock, and persistent income inequality. Recent estimates suggest that a substantial share of households experience difficulties in maintaining adequate indoor thermal comfort or meeting essential energy needs, with impacts extending beyond energy affordability to health, well-being, and social inclusion (European Commission et al. 2024; Thomson et al. 2017; 2017). In Ireland, these challenges are particularly pronounced due to a housing stock characterised by low energy efficiency, high dependence on fossil fuels for space heating, and comparatively slow rates of deep retrofit, increasing the exposure of households to energy cost shocks (ESRI et al. 2022).

Despite growing policy attention, the identification and measurement of energy poverty remain contested. Existing approaches rely heavily on single-dimensional indicators, such as fixed expenditure thresholds or income-based rules, which are often unable to capture the combined effects of affordability constraints and dwelling-related energy needs. Indicators such as the 10% rule or income-only measures may misclassify households that under-consume energy due to affordability pressures, or overlook those living in energy-inefficient dwellings with structurally high energy requirements (Hills 2011; Palma et al. 2024; Wojewódzka-Wiewiórska et al. 2024; Al Kez et al. 2024). As a result, the scale and nature of energy poverty can vary substantially depending on the indicator applied, raising concerns regarding robustness, comparability, and policy relevance.

In the Irish context, the measurement of energy poverty is further constrained by data availability and scale. While national surveys provide valuable insights into income and self-reported deprivation, they lack the spatial and technical resolution required to assess dwelling-specific energy needs. Conversely, the EPC database offers detailed information on building characteristics and modelled energy demand at the household level, but does not contain direct information on household income. This separation between economic and technical data has limited the ability to evaluate energy poverty consistently across indicators and at fine spatial scales, creating a methodological gap between policy monitoring and building-level intervention design.

Building on these conceptual and methodological debates in the energy poverty literature, the following section outlines the data sources and analytical framework used to operationalise and compare multiple energy poverty indicators at the household level in Dublin.

Methodology

The methodology consists of three main stages: (i) preparation and preprocessing of EPC data, (ii) Application of leading energy poverty indicators on a common analytical baseline, and (iii) household-level result generation and cross-indicator comparison for the Dublin residential stock.

Step 1: EPC dataset preparation and preprocessing

This study uses a cleaned and validated Irish EPC dataset for residential dwellings in Dublin as the primary technical evidence base. Each record represents an individual dwelling and includes dwelling descriptors, delivered energy by end use, heating fuel types, and energy performance ratings. The analysis is conducted at dwelling (household proxy) level.

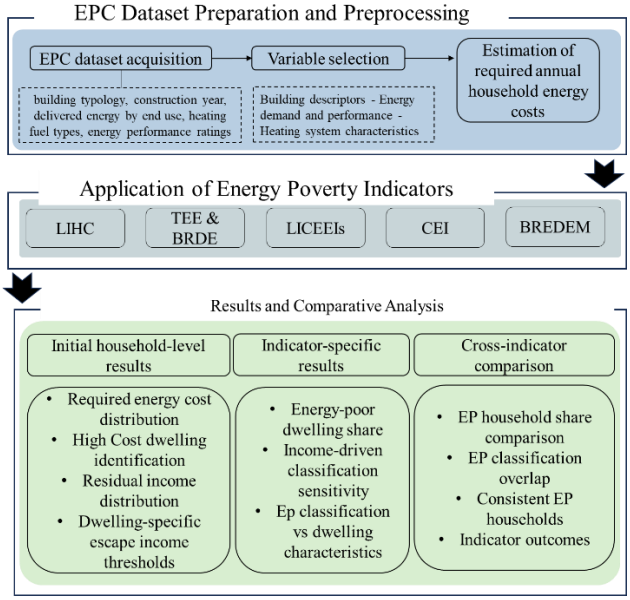

Figure 1: Methodological workflow for household-level energy poverty assessment using EPC data.

Variable selection and analytical dataset construction

To ensure methodological transparency and reproducibility, the full EPC dataset was reduced to a minimum set of variables required to apply the selected energy poverty indicators and to compute annual required energy costs. The retained variables were grouped into three categories: 1. Dwelling descriptors (unique dwelling identifier, dwelling archetype, Year of Construction, and BER Rating), 2. Delivered energy by end use (kWh/year) (space heating, water heating, lighting, fans and pumps, and other electricity uses where available), and Fuel type metadata (Main Space Heating Fuel and Main Water Heating Fuel).

These variables form the common input layer for all subsequent indicator implementations.

Estimation of required annual household energy Costs

Annual required household energy costs were estimated by converting delivered energy to cost using fuel-type-specific unit prices. Space-heating and water-heating costs were calculated by multiplying delivered energy (kWh/year) by the assigned unit price of the corresponding heating fuel. Electricity costs were computed by aggregating electricity-related end uses (lighting, pumps/fans, and recorded electricity consumption where available) and applying the electricity unit price. The total annual required energy cost for each dwelling was then calculated as:

$$C_i = C_i^{space} + C_i^{water} + C_i^{elec}$$

where C_i is the total required energy cost for dwelling i. This cost measure is treated as a required energy cost proxy derived from EPC data, enabling consistent comparison of structural energy burden across dwellings prior to introducing any income assumptions.

The resulting dataset provides a harmonised dwelling-level input layer comprising building descriptors, delivered energy by end use, fuel type information, and an estimated annual required energy cost, which together underpin the implementation of all subsequent energy poverty indicators.

Step 2: Application of energy poverty indicators

Following the preparation of a harmonised EPC-based analytical dataset and the estimation of required annual household energy costs, energy poverty was determined using a suite of leading indicators identified from the literature. To ensure comparability, all indicators were applied on a common technical baseline and evaluated consistently at dwelling (household proxy) level.

Given the absence of household income information in EPC data, income uncertainty was addressed through a scenario-based assumed-income framework, rather than income imputation or spatial proxies. This approach enables transparent sensitivity analysis and avoids introducing hidden bias into indicator application.

Income representation and poverty threshold

Household income was represented using a discrete set of assumed annual income levels spanning low to high income ranges. These income scenarios were applied uniformly across all dwellings, allowing assessment of how energy poverty classification responds to changes in income while holding building characteristics constant.

Low-income status was defined using the national at-risk-of-poverty threshold for Ireland, corresponding to 60% of the median equivalised disposable income. For the purposes of this study, the 2024 poverty line of €17,998 was adopted. This threshold was used consistently across all indicators incorporating income or residual income criteria.

Low income high costs (LIHC)

The LIHC indicator was implemented following the residual income formulation widely adopted in EU and UK methodological guidance. A dwelling was classified as energy poor if it simultaneously satisfied:

- High-Cost condition: Required annual energy cost exceeds the median energy cost of the Dublin sample (€2,129).
- Low Income condition: Residual household income after paying required energy costs falls below the poverty threshold (€17,998).

Formally, for dwelling i with assumed income Y and required energy cost C_i, energy poverty occurs when:

$$C_i > \text{Median}(C) \wedge (Y - C_i) < PL$$

where PL denotes the national poverty line.

In addition to binary classification, a dwelling-specific escape income was derived, defined as the minimum

income required for a household to avoid LIHC classification given its energy cost.

Combined TEE & BRDE indicator

To reduce misclassification associated with single-threshold indicators, a combined TEE & BRDE indicator was applied. A dwelling was classified as energy poor if it simultaneously satisfied:

1. Energy expenditure exceeding 10% of household income (TEE),
2. Required energy cost above the median (BRDE),
3. Residual income after energy costs below the poverty threshold.

This combined formulation integrates affordability stress, relative energy burden, and income vulnerability within a single classification framework.

Low income combined with energy expenditure indicators (LICEEIs)

LICEEIs were implemented to capture households experiencing energy poverty due to the interaction of low income and energy-related constraints, including hidden energy poverty. The indicator combines low residual income status with either:

- high required energy costs, or
- unusually low energy consumption relative to dwelling characteristics (used as a proxy for under-heating).

This formulation enables identification of households whose energy poverty may not be fully captured by expenditure-based thresholds alone.

CEI (composite expenditure indicator)

CEI integrates multiple expenditure and income dimensions into a single composite score. Required energy costs and income measures were normalised and combined to produce a continuous vulnerability index, allowing households to be ranked by degree of energy poverty severity rather than classified using a binary threshold.

BREDEM-type model-based indicator

A BREDEM-type indicator was applied using EPC-derived delivered energy and building characteristics as proxies for required energy needs. By focusing on modelled energy demand rather than observed consumption, this indicator captures structurally driven energy needs and enables identification of hidden energy poverty associated with constrained energy use.

Step 3: results generation and comparative analysis

Following the application of the selected energy poverty indicators, results were generated and analysed at dwelling (household proxy) level for the residential building stock of Dublin. This step focuses on three complementary result layers: (i) initial household-level insights, (ii) indicator-specific outcomes, and (iii) cross-indicator comparison.

Initial household-level results for Dublin

The first stage of analysis examines the distribution of key energy poverty-related variables across the full sample of dwellings. This includes:

- distribution of required annual household energy costs,
- identification of high-cost dwellings,
- distribution of residual income under assumed income scenarios,
- derivation of dwelling-specific escape income thresholds.

These results provide an initial overview of structural energy burden and affordability stress within the Dublin housing stock. By analysing required energy costs prior to applying any indicator-specific thresholds, this stage isolates the role of building energy performance in shaping household vulnerability.

Descriptive statistics and distributions are used to highlight heterogeneity across dwellings and to identify segments of the housing stock exposed to disproportionately high energy costs, independent of income assumptions.

Indicator-specific results

In the second stage, results are analysed separately for each energy poverty indicator. For each indicator, the following outputs are produced:

- the number and proportion of dwellings classified as energy poor,
- sensitivity of classification to assumed household income levels,
- relationship between classification outcomes and dwelling characteristics (e.g. typology, construction period, energy rating).

For expenditure-based indicators (LIHC, TEE, TEE & BRDE), particular attention is given to the income levels at which households transition into or out of energy poverty. Dwelling-specific escape income thresholds are used to quantify how much income is required for households to avoid energy poverty conditional on building energy performance.

For composite and model-based indicators (LICEEIs, CEI, BREDEM-type), results are interpreted in terms of vulnerability intensity and structural energy need, enabling identification of households experiencing hidden or borderline energy poverty.

This indicator-specific analysis allows differences in sensitivity, strictness, and diagnostic capacity across indicators to be systematically assessed.

Cross-indicator comparison

The final stage of analysis compares results across all implemented indicators. This includes:

- comparison of the proportion of households identified as energy poor by each indicator,

- assessment of overlap and divergence in household classification,
- identification of households consistently classified as energy poor across multiple indicators,
- evaluation of how indicator choice influences conclusions regarding the scale and nature of energy poverty.

By applying all indicators to a common technical and income-scenario baseline, the analysis enables direct comparison of indicator behaviour and robustness. Differences in classification outcomes are interpreted in relation to each indicator's underlying conceptual focus, distinguishing between income-driven, expenditure-driven, and structure-driven vulnerability.

This comparative analysis forms the basis for identifying strengths and limitations of existing indicators and provides empirical grounding for the future development of a refined multidimensional energy poverty indicator tailored to the Irish context.

Result

Initial household-level outputs

The initial stage of the results focuses on household-level outputs derived directly from the cleaned and validated EPC dataset for Dublin. This stage aims to characterise the distribution of required energy costs, identify structurally high-cost dwellings, and assess affordability pressures prior to the application of income-based energy poverty indicators.

Distribution of required annual energy costs

Figure 2 illustrates the distribution of required annual household energy costs derived from the cleaned EPC dataset for Dublin. The distribution is markedly right-skewed, indicating substantial heterogeneity in energy cost requirements across the housing stock. While the majority of dwellings cluster at relatively low to moderate cost levels, a pronounced upper tail is observed, reflecting a subset of dwellings with exceptionally high required energy costs.

The dashed vertical line denotes the median energy cost threshold (€2,129), which serves as the structural high-cost benchmark within the LIHC framework. A considerable proportion of dwellings lie to the right of this threshold, demonstrating that high required energy costs are a widespread structural feature of the housing stock rather than a marginal phenomenon. This pattern indicates that energy affordability pressures in Dublin are not confined to a small number of extreme cases, but instead affect a substantial segment of dwellings prior to the application of income-based criteria.

Overall, Figure 3.1a provides direct empirical evidence that required energy costs are unevenly distributed and structurally driven, justifying the subsequent identification of high-cost dwellings and the application of income-sensitive energy poverty indicators in the following analysis.

To better visualise the upper tail of the cost distribution, the same data are shown on a logarithmic scale in Figure 3. This representation reveals a long and continuous upper tail, confirming that extremely high energy cost values are structurally embedded within the dataset rather than being isolated outliers. These high-cost dwellings are likely associated with unfavourable building characteristics, inefficient heating systems, or large floor areas, underscoring the importance of building-related factors in energy poverty analysis.

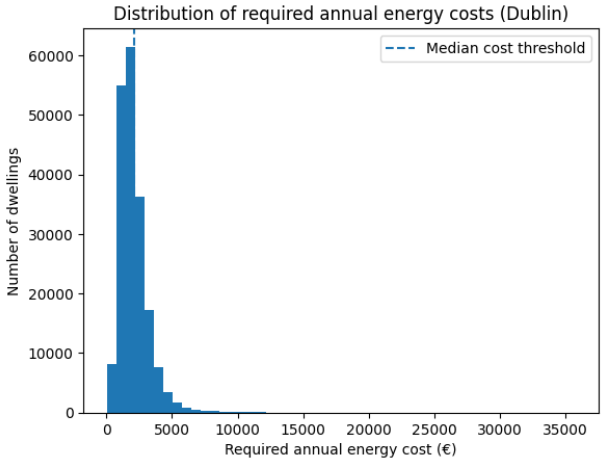

Figure 2: Distribution of required annual household energy costs (Dublin)

This pattern confirms that a subset of dwellings faces structurally elevated energy requirements spanning several orders of magnitude, reinforcing the role of building-related characteristics in shaping energy affordability pressures. The persistence of high-cost values beyond the median threshold further supports the identification of structurally high-cost dwellings prior to the application of income-based energy poverty indicators.

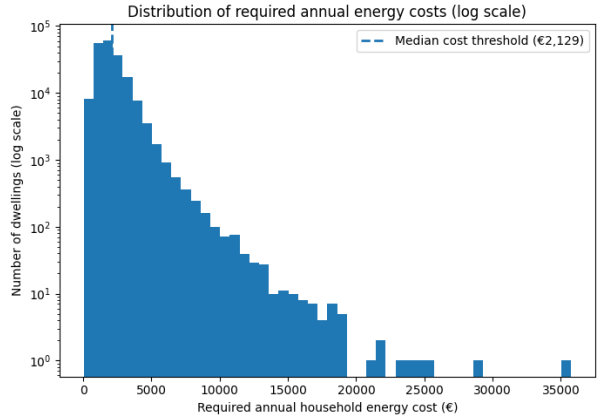

Figure 3: Distribution of required annual household energy costs (Dublin – log scale)

Identification of structurally high-cost dwellings

Using the median required annual energy cost (€2,129) as a structural threshold, dwellings were classified into high-cost and non–high-cost groups. Approximately 37% of dwellings in Dublin were identified as structurally high-cost, indicating that a substantial share of the housing stock faces elevated energy requirements independent of

household income. This classification provides the basis for subsequent residual income and escape income analyses within the LIHC framework.

Escape income distribution for structurally high-cost dwellings

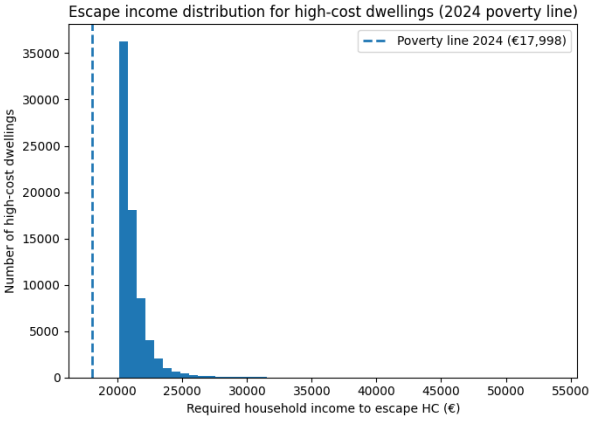

Figure 4. Distribution of escape income for high-cost dwellings

Indicator-specific results

The results reveal pronounced differences in both prevalence levels and income sensitivity across indicators. At very low assumed income levels (€10,000–€17,998), income-driven indicators such as LIHC, TEE & BRDE, and CEI identify approximately 37% of dwellings as energy poor, corresponding closely to the share of structurally high-cost dwellings. In contrast, indicators incorporating energy need and under-consumption dimensions exhibit substantially higher prevalence. LICEEI identifies approximately 52% of dwellings as energy poor, while the BREDEM-based proxy classifies up to 88% of dwellings as energy poor at the lowest income scenario. This divergence highlights the extent to which needs-based indicators capture vulnerability beyond income inadequacy alone.

As assumed household income increases, marked differences emerge in indicator sensitivity. For LIHC, TEE & BRDE, and CEI, energy poverty prevalence remains constant up to the poverty-line threshold (€17,998) and then declines sharply beyond €20,000, falling below 1% at €25,000. This stepwise reduction reflects the threshold-based nature of these indicators and their strong dependence on income adequacy.

In contrast, LICEEI and BREDEM exhibit a more gradual decline with rising income. Notably, at an assumed income of €20,000, LICEEI continues to classify 38% of dwellings as energy poor, while BREDEM identifies over 42%, indicating persistent vulnerability driven by high structural energy needs rather than low income alone. However, at higher income levels (€25,000 and above), convergence across indicators is observed, with prevalence dropping to negligible levels for all measures.

Overall, these results demonstrate that indicator choice substantially influences both the scale and interpretation of energy poverty. Income-driven indicators primarily identify affordability-driven vulnerability, while needs-based indicators reveal a broader set of households exposed to structurally driven energy hardship. This finding provides strong empirical justification for cross-indicator comparison and for the development of multidimensional approaches to energy poverty assessment.

Cross-indicator comparison

Figure 5 compares the sensitivity of energy poverty classification to assumed household income across all examined indicators. Clear and systematic differences are observed in both the level and persistence of energy poverty identified by each indicator, highlighting the strong influence of methodological choice on assessment outcomes.

At low assumed income levels (€10,000–€17,998), income-driven indicators (LIHC, TEE & BRDE, and CEI) converge at approximately 37%, closely matching the income-independent share of structurally high-cost dwellings. This indicates that, at low incomes, affordability constraints dominate classification outcomes, and energy poverty identification is primarily driven by the high-cost condition embedded within these indicators.

In contrast, indicators incorporating building energy needs and consumption constraints exhibit substantially higher prevalence. LICEEI identifies around 52% of dwellings as energy poor across low-income scenarios, while the BREDEM-based proxy reaches values as high as 88% at the lowest assumed income. This divergence demonstrates that needs-based indicators capture a broader set of vulnerable dwellings, including those facing high structural energy requirements that are not fully reflected in income-based measures.

As assumed income increases, sharp discontinuities emerge for income-sensitive indicators. For LIHC, TEE & BRDE, and CEI, energy poverty prevalence collapses rapidly beyond €20,000, approaching zero at €25,000 and above. This stepwise behaviour reflects the threshold-based structure of these indicators and underscores their strong dependence on income adequacy rather than persistent dwelling-level energy demand.

By contrast, LICEEI and BREDEM display a more gradual decline with increasing income. Notably, both indicators continue to identify a substantial share of households as energy poor at €20,000, indicating that elevated energy needs remain a significant source of vulnerability even when income approaches moderate levels. However, convergence across all indicators is observed at higher incomes, where prevalence becomes negligible, suggesting that income sufficiency eventually offsets structural energy cost pressures.

Overall, the cross-indicator comparison confirms that energy poverty is inherently multidimensional. Income-based indicators primarily identify affordability-driven vulnerability, while needs-based indicators reveal structurally driven energy hardship linked to building performance. These findings demonstrate that reliance on a single indicator risks mischaracterising both the scale and nature of energy poverty, providing strong empirical

support for comparative and multidimensional assessment approaches.

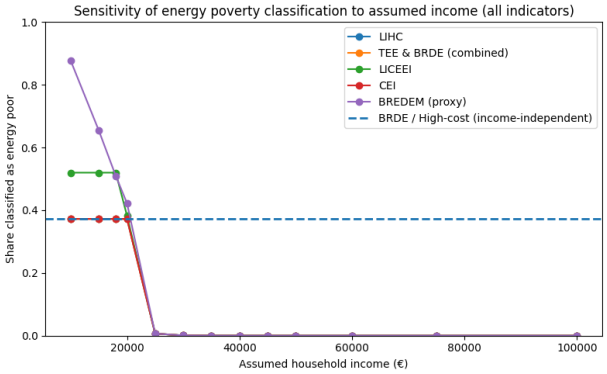

Figure 5: Sensitivity of EP share to income (all indicators)

Discussion and future directions

The results demonstrate that energy poverty in Dublin is strongly shaped by both household income and structurally driven energy costs associated with building performance. The initial household-level analysis shows a highly uneven distribution of required energy costs, with a substantial share of dwellings facing structurally high energy requirements. This structural heterogeneity directly translates into elevated escape income thresholds for many households, indicating that energy poverty cannot be explained by low income alone.

The indicator-specific and cross-indicator analyses further reveal that energy poverty prevalence and classification are highly sensitive to the choice of indicator. Income-based measures such as LIHC and TEE & BRDE primarily identify affordability-driven vulnerability and exhibit sharp threshold effects as income increases. In contrast, needs-based indicators, including LICEEI and the BREDEM-based proxy, capture a broader and more persistent form of vulnerability linked to building inefficiency and elevated energy demand. These findings confirm that reliance on a single indicator risks mischaracterising both the scale and nature of energy poverty.

From a policy perspective, the results highlight the need for integrated assessment frameworks in the Irish context. While income support measures may alleviate energy poverty for some households, the persistence of vulnerability among structurally high-cost dwellings underscores the importance of targeted building retrofit interventions. Future work in Ireland could benefit from the development of multidimensional energy poverty indicators that combine economic affordability, building energy performance, and aspects of household comfort and well-being, such as thermal adequacy and the ability to maintain healthy indoor conditions.

Several limitations should be acknowledged. The analysis relies on EPC-derived estimates of required energy costs rather than measured consumption, which may not fully capture behavioural effects such as under-heating or rebound. Household income was represented through assumed income scenarios, rather than observed microdata, which limits the ability to reflect actual income distributions. In addition, comfort-related dimensions were not explicitly quantified in the current framework.

Future research should therefore focus on integrating EPC data with household survey datasets and measured energy consumption where available, enabling more robust validation of energy poverty indicators. Expanding the framework to incorporate multidimensional well-being and comfort metrics would further enhance its relevance for policy design and evaluation, supporting more effective and equitable energy poverty interventions in Ireland.

QUANTIFYING THE ROLE OF ASSET MAINTENANCE FOR RESILIENT INFRASTRUCTURE

Shyamratna Yadav, Chirag Kothari, and Anushka Singh Rathore
Department of Civil Engineering, Indian Institute of Technology Kanpur, Kanpur, India

Abstract

Asset maintenance and infrastructure resilience are directly related. However, most resilience assessments overlook pre-disaster asset condition. This study develops a probabilistic lifecycle framework integrating stochastic condition-index (CI) evolution, performance degradation, recovery modeling, and explicit maintenance strategies within a multi-hazard simulation environment. The framework quantifies how pre-event maintenance shapes resilience trajectories. Application to a representative bridge portfolio demonstrates that preventive maintenance consistently improves lifecycle performance and the Composite Resilience Performance Index (CRPI), while rehabilitation provides substantial but time-dependent recovery gains. The proposed framework offers a quantitative decision-support tool linking maintenance actions to resilience outcomes, supporting resilience-informed infrastructure planning and management.

Introduction

Critical infrastructure and lifelines such as bridges are fundamental to economic activity, emergency response, and community well-being (Bruneau et al. 2003, Francis and Bekera 2014). The capacity of these assets to resist, absorb and recover from disruptive events determines not only direct repair needs but also continuity of services, the integrity of value chains, and public safety (Bruneau et al. 2003, Cimellaro 2016). Modern resilience thinking therefore extends conventional engineering objectives into life-cycle goals that prioritise robustness, rapidity, redundancy and resourcefulness. Despite this conceptual progress, routine asset management rarely incorporates explicit traceable resilience objectives in maintenance decision processes (Pant et al. 2019).

During normal operating conditions (pre-event or pre-disaster), the infrastructure components often degrade through multiple mechanisms such as chloride ingress, corrosion, fatigue accumulation, scour and freeze–thaw cycles that often produce nonlinear transitions to accelerated capacity loss and discrete damage states (Li 2003, Ghodoosi et al. 2018). Thus, the performance of an asset also decreases during pre-event/pre-disaster phase. Resilience and fragility assessments that assume "as-new" properties therefore risk overestimating robustness and understating recovery needs (Yang and Frangopol 2019). The pre-event condition of an asset is not a peripheral descriptor but a primary determinant of resilience trajectories within the performance–time framework (Poulin and Kane 2021).

As far as pre-event condition is concerned, Practitioners commonly summarise structural health using composite condition indices (CIs) that aggregate inspection observations, monitoring signals and surrogate indicators into a single, interpretable metric (Li 2003, Li and Gao 2022). Treating CI as an explicit, time-evolving state variable creates a direct modelling bridge between maintenance actions, state-dependent vulnerability, and post-event recovery dynamics. Empirical and modelling studies indicate that poorer pre-event condition is associated with larger immediate performance losses and slower recovery for comparable hazard intensities, implying that maintenance which improves CI yields resilience benefits beyond mere reductions in repair effort (Salem et al. 2020, Poulin and Kane 2021). Accordingly, CI provides a practical means to connect inspection data and maintenance choices to probabilistic performance outcomes.

Further, how CI changes over time due to wear and tear dictates maintenance strategies. Maintenance strategies vary in timing, triggering mechanism, cost structure and mobilization lag. Broadly, strategies can be classified as corrective (reactive), preventive (periodic), predictive (condition-based) and rehabilitative (capacity-restoring or upgrading) (Durán and Vergara 2022, Applegate and Tien 2019). These approaches interact with resilience in different ways: preventive and predictive actions tend to preserve pre-event resilience by slowing deterioration, whereas corrective and rehabilitative interventions accelerate recovery and can modify fragility characteristics (Li and Gao 2022, Salem et al. 2020). Because mobilization lag and implementation constraints differ across strategies, resilience-aware decision support must weigh time-dependent benefits (for example, avoided downtime and reduced recovery time) alongside operational feasibility and budgetary limits.

Thus, under normal operation conditions, the maintenance decisions are driven by asset deterioration, maintenance strategies, and budget availability. Additionally, assets' health is impacted by extreme weather events. Fragility curves are used to represent this information.(Otárola et al. 2022) Fragility curves translate hazard intensity into damage probability. Classical fragility

formulations commonly assume fixed vulnerability parameters, but recent advances emphasise state-dependent fragility in which median and dispersion parameters vary with CI, cumulative damage or material degradation (Izadi et al. 2020, Otárola et al. 2022). Physically, section loss or foundation scour lowers the intensity required to reach a given damage state; conversely, CI improvements through maintenance shift fragility curves toward lower damage probabilities for the same hazard level. Including CI explicitly in fragility models thus provides a mechanistic pathway to quantify how maintenance investments alter risk exposure and expected performance under stochastic hazards (Liu et al. 2020). State-aware fragility operationalises the causal linkage between maintenance and risk.

Multi-hazard and cascading risk chains introduce further complexity. Infrastructure commonly experiences sequences of hazards—earthquakes followed by floods or landslides, storms that induce scour and amplify hydraulic vulnerability—where coupled hazards produce non-additive impacts (Ganin et al. 2017, Dong and Frangopol 2016). Prior events can increase susceptibility to subsequent hazards (for example, seismic damage that exacerbates scour), which may reprioritise maintenance when single-hazard assumptions are used Dong and Frangopol (2016). Robust resilience planning therefore requires propagation of uncertainty across multi-hazard sequences and explicit accounting for how maintenance alters residual capacity available to withstand future events. Consequently, life-cycle analyses that simulate hazard sequences and maintenance interactions are essential for realistic prioritisation.

Methodologically, several research streams are mature enough to be integrated into a unified life-cycle framework: stochastic degradation and ageing models (Liu et al. 2020); Bayesian updating of fragility from damage observations (Li and Gao 2022); Monte Carlo simulation of multi-hazard portfolios (Liu et al. 2020); and translation of probabilistic service availability into prioritisation metrics (Poulin and Kane 2021). Nevertheless, three gaps constrain uptake in practice: (1) multi-hazard, state-aware fragility models that directly ingest CI observations are not standard in maintenance portfolios; (2) non-additive coupling of sequential hazard damage within life-cycle analyses remains underexplored; and (3) end-to-end frameworks that convert CI-driven resilience metrics into quantitative decision criteria for maintenance prioritisation under uncertainty are still nascent (Ouyang 2014, Pant et al. 2019).Addressing these gaps would make resilience metrics actionable for asset managers operating under resource constraints.

This paper addresses these gaps by developing a probabilistic lifecycle framework that can be used to estimate the role of asset maintenance in improving resilience of an infrastructure system. The developed framework integrates probabilistic life-cycle methodology linking stochastic CI dynamics with CI-congruent fragility, defines decision policies for preventive, corrective and rehabilitative maintenance strategies , simulates multi-hazard and cascade scenarios via Monte Carlo sampling, and translates probabilistic performance trajectories into resilience-oriented metrics for strategy ranking and portfolio prioritisation. We demonstrate the framework on a synthetic span-bridge portfolio to illustrate how CI-aware fragility modelling combined with hazard sequencing can materially influence resilience outcomes and inform maintenance prioritisation in resource-constrained settings. The proposed approach aims to provide infrastructure operators with a practicable decision-support tool that integrates inspection and maintenance information into investment choices guided by resilience objectives and contemporary asset-management standards (International Organization for Standardization 2014, United Nations Office for Disaster Risk Reduction (UNDRR) 2022, World Bank 2021).

Methodology

This section summarises the probabilistic simulation engine used to compare corrective, preventive and rehabilitation maintenance strategies. The model couples (i) a physics-informed, condition-dependent deterioration law, (ii) log-normal fragility models conditioned on asset condition, (iii) deterministic damage-state (DS) selection via a shared event shock, (iv) loss mapping to condition index (CI), and (v) recovery dynamics. Outputs are life-cycle and event-level resilience metrics (CRPI, Robustness, Recoverability, Rapidity). The approach follows established resilience and fragility practices Bruneau et al. (2003), Cimellaro et al. (2010), Porter (2015), Committee et al. (2013).

Simulation workflow

A Monte-Carlo ensemble of N trials is executed. For each trial: The framework will be implemented using a Monte Carlo loop, where the entire simulation process will be repeated several times in order to capture the variability of hazard occurrence.

1. Pre-sample multi-hazard events (AEPs and intensities) and a uniform shock variable $u \in [0, 1)$ per event; the same u is replayed across all strategies to ensure comparability. All simulations are performed over a fixed lifecycle horizon with identical time discretization, ensuring that all Monte Carlo trials are equal in duration and directly comparable across maintenance strategies.
2. Propagate monthly deterioration (strategy-neutral physics).
3. Schedule/apply maintenance according to the tested strategy (Preventive: periodic jump; Corrective: post-event patch with delay; Rehabilitation: triggered explicit target).
4. If an event occurs at time t, evaluate fragility (CI-conditioned), determine DS via u, map DS to loss fraction, and update CI.
5. Apply recovery dynamics and record time series /

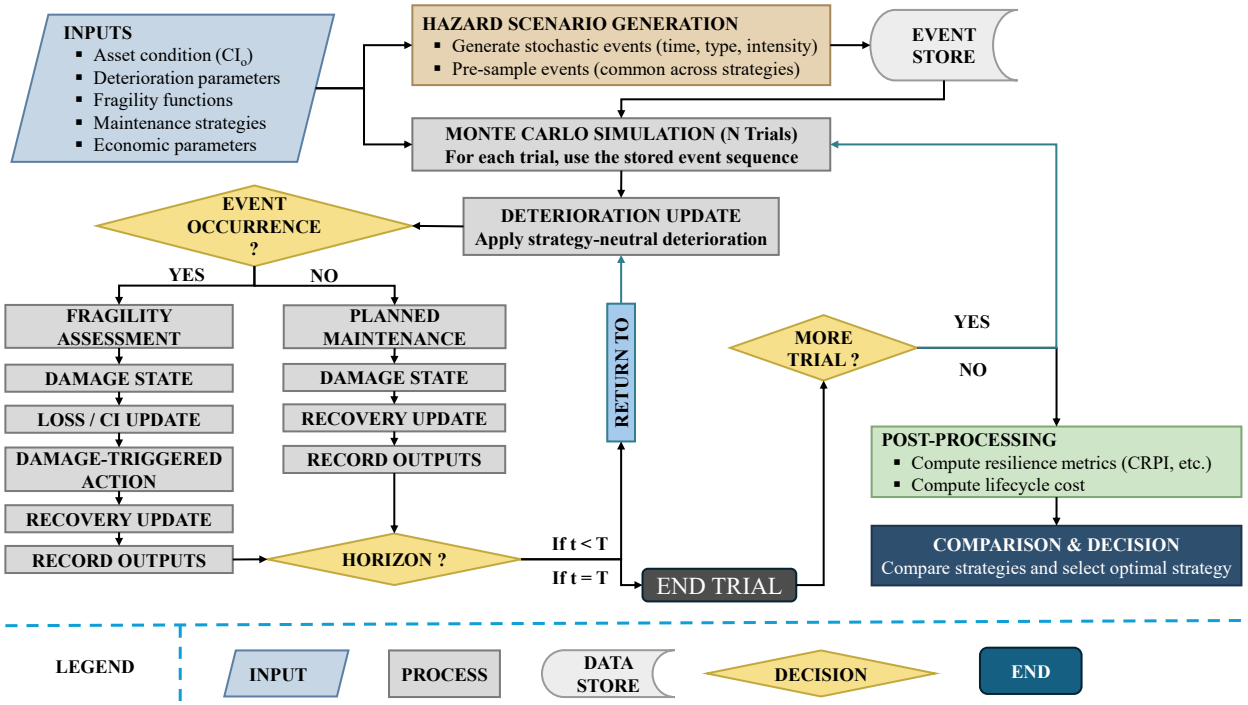

Figure 1: Methodology framework for lifecycle resilience assessment and maintenance strategy comparison, highlighting the integrated simulation process for hazard generation, condition deterioration, damage evaluation, recovery, and maintenance within a fixed time horizon, allowing for fair comparison of maintenance strategies for decision-making purposes.

event outcomes.

Deterioration model

Monthly evolution of asset condition is represented using an age- and condition-dependent deterioration process, with the Condition Index (CI) treated as a bounded state variable in the range $[0, 100]$. The formulation captures stage-wise ageing behaviour, age-related acceleration, and condition-sensitive degradation, while remaining computationally efficient for life-cycle Monte-Carlo simulation.

A smooth transition between early-life and late-life deterioration regimes is modelled using a logistic stage-weight function,

$$w(a) = \frac{1}{1 + \exp\left(-\frac{a - a_0}{s}\right)}, \tag{1}$$

where a denotes asset age (years), a_0 is the transition age, and s controls the smoothness of the transition.

The effective baseline annual deterioration rate is defined as

$$\bar{r}_{\text{base}} = r_{\text{base}}\big[(1 - w(a)) + w(a) \cdot \text{PM}\big], \tag{2}$$

where r_{base} is the nominal baseline rate and PM scales late-stage deterioration intensity. Age- and condition-dependent acceleration is incorporated through

$$r_{\text{ann}}(a, \text{CI}) = \bar{r}_{\text{base}}\,(1 + \gamma a)\big(1 + \eta(1 - \text{CI}/100)\big), \tag{3}$$

with γ governing age-related acceleration and η controlling sensitivity to declining condition.

For numerical implementation, the annual rate is converted to a monthly rate,

$$r_{\text{m}} = \frac{r_{\text{ann}}}{12}. \tag{4}$$

CI evolution over a time step Δ_t is computed using an exponential decay update,

$$\text{CI}_{t+\Delta} = \text{CI}_t \exp(-r_{\text{m}}\Delta_t), \tag{5}$$

which preserves positivity and ensures numerical stability over long simulation horizons.

This expression describes transitions from early to late ageing, rapid degradation at low CI, and continuous degradation dynamics as described in established deterioration modelling practice (McKibbins et al. 2019). The deterioration process is modelled as strategy-neutral, with maintenance activities affecting CI by discrete gains or recovery dynamics, but not affecting the deterioration physics.

Fragility and damage-state selection

For each hazard intensity I and DS threshold index j the exceedance (upper tail) probability is modeled by a log-normal CDF:

$$P(\text{DS} \geq j \mid I, \text{CI}) = \Phi\left(\frac{\ln I - \ln \mu_j^*(\text{CI})}{\beta_j}\right), \tag{6}$$

where $\Phi(\cdot)$ is the standard normal CDF, β_j is dispersion and $\mu_j^*(\text{CI})$ is the CI-adjusted median:

$$\mu_j^*(\text{CI}) = \mu_j \cdot \left[1 + \phi\frac{\text{CI} - 50}{50}\right] \tag{7}$$

Incremental probabilities for No Damage, DS1, DS2, ... are obtained from successive differences of (6) as customary Porter (2015), Committee et al. (2013). A deterministic DS label is selected by comparing the incremental CDF to the pre-sampled u (same u used across strategies for that event) — this enforces paired comparison across strategies.

Loss mapping and immediate post-event CI

Event-induced damage states (DS) are translated into fractional condition losses L_{DS} using mean loss values (or bounded ranges where uncertainty is characterised). The immediate post-event condition is computed as

$$\mathrm{CI}_{\mathrm{post}} = \mathrm{CI}_{\mathrm{pre}}\big(1 - L_{\mathrm{DS}}\big). \tag{8}$$

By ensuring that the logic of intervention actions determines the differences in condition states after events for various strategies, this deterministic transformation eliminates the impact of maintenance and recovery actions.

Recovery and maintenance models

Recovery toward a target CI is modelled by an exponential approach:

$$\mathrm{CI}(t) = \mathrm{CI}_{\mathrm{post}} + \big(\mathrm{CI}_{\mathrm{target}} - \mathrm{CI}_{\mathrm{post}}\big)\big(1 - e^{-kt}\big), \tag{9}$$

where k is a recovery rate parameter calibrated by resourcefulness and strategy ($k = k_0 \cdot \alpha_{\mathrm{strat}} \cdot \alpha_{\mathrm{res}}$). In the implementation:

- **Preventive**: scheduled periodic jumps (no change to physics): $\mathrm{CI} \leftarrow \min(100, \mathrm{CI} + G)$ at interval.
- **Corrective**: post-event patch scheduled after a resource dependent delay; gain is fraction of event loss subject to a patch cap.
- **Rehabilitation**: triggered when CI falls below a threshold; scheduled to reach an explicit $\mathrm{CI}_{\mathrm{target}}$.

Resilience metrics (CRPI and event metrics)

Normalized performance is $p(t) = \mathrm{CI}(t)/100$. Life-cycle CRPI ($\mathrm{CRPI}_{\mathrm{life}}$) is the time-average normalized area under the performance curve:

$$\mathrm{CRPI}_{\mathrm{life}} = \frac{1}{T}\int_0^T p(t)\,dt. \tag{10}$$

Event-window metrics are computed on the recovery curve following an event Poulin and Kane (2021):

- **Robustness** = $p_{\mathrm{post}}/p_{\mathrm{pre}}$.
- **Recoverability** = $p_\infty/p_{\mathrm{pre}}$ (final steady value relative to pre-event).
- **Rapidity** = $1/\tau_{95}$, where τ_{95} is the time to reach 95% of pre-event performance.
- **$\mathrm{CRPI}_{\mathrm{event}}$** = normalized AUC of the recovery curve over the event window.

Monte-Carlo design and reproducibility

The Monte-Carlo simulations are performed using either fixed or random seeds. For each simulation run, the hazard events are pre-sampled, and a uniform random variable $u \in [0, 1)$ is generated for each event. The same realization of the hazard process and the corresponding sequence of u values are used for all maintenance strategies, such that the differences between all pairs of outcomes are only due to the maintenance strategies.

The cascading effects are modeled in two ways: (i) ordered scheduling of follow-on hazards within a specified vulnerability window, and (ii) probabilistic hazard intensity amplification if the asset is still in the vulnerable post-event state. The simulation outputs for each simulation run include time series of CI, event sequences, maintenance schedules, cost data, and aggregated resilience values, which are exported in structured CSV format.

Implementation details

The simulation engine is implemented with a monthly time step, deterministic damage state (DS) choice, and explicit scheduling of maintenance events. Repair and rehabilitation events are applied when the month of their scheduled execution is reached, allowing for mobilization delays and event timing to be handled consistently across simulations.

Results from the simulation engine include pre- and post-event fragility plots (S-curves with DS indicators), resilience phase plots, resilience dividend summaries, and event-level CSV files summarizing CI trajectories, event histories, maintenance events, and costs. These results enable traceability, diagnostic analysis, and post-simulation processing of lifecycle and event-level metrics.

The simulation methodology is consistent with existing frameworks for resilience quantification and fragility modeling as reported in the literature (Bruneau et al. 2003, Cimellaro et al. 2010, Porter 2015, Committee et al. 2013). Degradation modeling is based on principles recommended in industry guidelines (Owen 2023), and Monte-Carlo simulation and metric estimation follow standard stochastic simulation procedures(Otárola et al. 2022). To ensure transparency and reproducibility, the complete implementation of the simulation framework is provided in a publicly accessible repository (Yadav 2026).

Assumptions and limitations

- Damage-state (DS) to loss mapping is done by using mean fractional losses to facilitate deterministic and repeatable paired comparisons of maintenance strategies. The variability of loss estimates is not sampled in the baseline simulations.
- The degradation process is considered strategy agnostic, where the baseline degradation physics are the same for all strategies, and the impact of maintenance is only felt after repair and recovery activities.
- The analysis is done based on resilience performance metrics or other related metrics. However, other economic valuation metrics such as resilience dividend, net present value, or life cycle cost are not included in the analysis for the current study. The consideration of these metrics, along with other consequence-based

factors such as traffic demand or network importance, is an important area for future research directions.

Results and discussion

This section presents numerical results obtained from the Monte-Carlo simulation framework and discusses their implications for maintenance-strategy selection. The number of simulations (5000 for each strategy) was chosen to ensure that there was convergence of the resilience metrics, as no significant changes were found in the results for a larger number of simulations.

Ensemble summary statistics

Table 1 summarizes ensemble lifecycle resilience metrics obtained from 5000 Monte–Carlo realizations per strategy, including mean and standard deviation of $\mathrm{CRPI}_{\mathrm{life}}$ along with robustness, recoverability, and rapidity. Figure 2 shows the corresponding $\mathrm{CRPI}_{\mathrm{life}}$ distributions. Preventive maintenance exhibits the highest median and the narrowest interquartile range, indicating both superior and stable lifecycle performance. The no-maintenance strategy shows the lowest median and a pronounced lower tail, reflecting frequent excursions into low-performance states. Corrective and rehabilitation strategies provide intermediate performance with larger dispersion than preventive maintenance. These ensemble results demonstrate that scheduled preventive actions improve average resilience while reducing variability across hazard realizations.

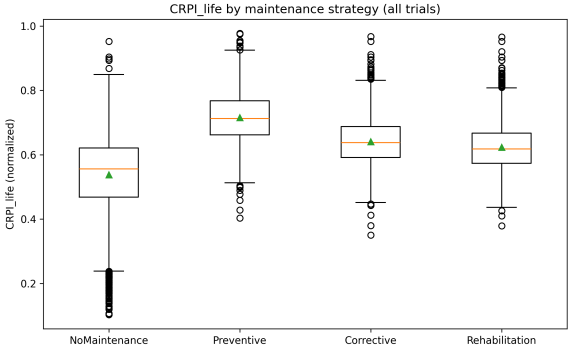

Figure 2: Distribution of lifecycle Composite Resilience Performance Index (CRPI_{life}) across 5000 Monte–Carlo trials for each maintenance strategy. Boxes indicate interquartile ranges, whiskers denote 1.5×IQR, and markers represent ensemble means.

Table 1: Ensemble lifecycle resilience metrics for maintenance strategies (5000 Monte–Carlo trials per strategy).

Strategy	Mean $\mathrm{CRPI}_{\mathrm{life}}$	Robustness	Recoverability	Rapidity
No Maintenance	0.5376	0.9474	0.9974	0.5499
Preventive	0.7158	0.9483	0.9974	0.4755
Corrective	0.6405	0.9474	0.9974	0.5499
Rehabilitation	0.6235	0.9474	0.9974	0.5417

To better understand how infrastructure behaves under each maintenance strategy, a representative trial is examined in detail. This trial run helps explain the ensemble results by showing condition changes, damage response, and recovery at the event level.

Event-level behaviour and fragility mapping

Fig. 3 shows prior vs post S-curves for a representative event. Key points:

- Pre-event condition (CI) shifts fragility medians, increasing probability of severe DS when CI is low.
- A deterministic per-event shock u is reused across strategies to isolate strategy effects.
- Post-event CI uses the mean-loss mapping $\mathrm{CI}_{\mathrm{post}} = \mathrm{CI}_{\mathrm{pre}}(1 - L_{\mathrm{DS}})$.

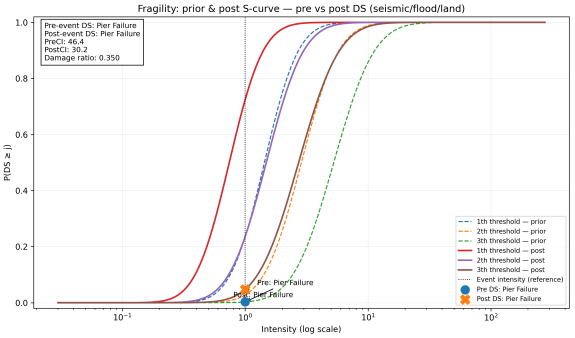

Figure 3: Condition-dependent fragility S-curves (prior and post) with realized damage states for a representative hazard, showing the effect of asset condition on damage exceedance probability.

Resilience phase diagrams (illustrative trial)

Figures (4–7) depict sample single-trial realizations to demonstrate the behavior of each maintenance strategy, whereas statistical results are based on all Monte Carlo simulation runs. Representative resilience phase diagrams illustrate the joint evolution of asset condition and performance for the illustrative trial. Monthly Condition Index (CI) trajectories are shown in the left subpanels, while the corresponding normalized performance used to compute $\mathrm{CRPI}_{\mathrm{life}}$ is shown in the right subpanels. Preventive maintenance produces frequent moderate CI restorations that stabilize baseline condition and sustain performance. Corrective maintenance results in event-triggered recovery with implementation delays and partial restoration, whereas rehabilitation generates large but infrequent CI resets governed by trigger thresholds. These trial-level dynamics provide mechanistic insight into the ensemble $\mathrm{CRPI}_{\mathrm{life}}$ trends reported in Table 1 and Figure 2.

Lifecycle dynamics and recovery mechanisms

Representative resilience phase diagrams (Figures 4–5) illustrate how ensemble trends arise from trial-level condition and performance trajectories. Under no maintenance, continuous deterioration exposes progressively weakened assets to successive hazards, leading to sustained performance decline. Preventive maintenance introduces frequent moderate CI restorations that stabilize baseline condition, thereby limiting damage severity and shortening recovery periods. Corrective maintenance relies on post-damage interventions with implementation delays, result-

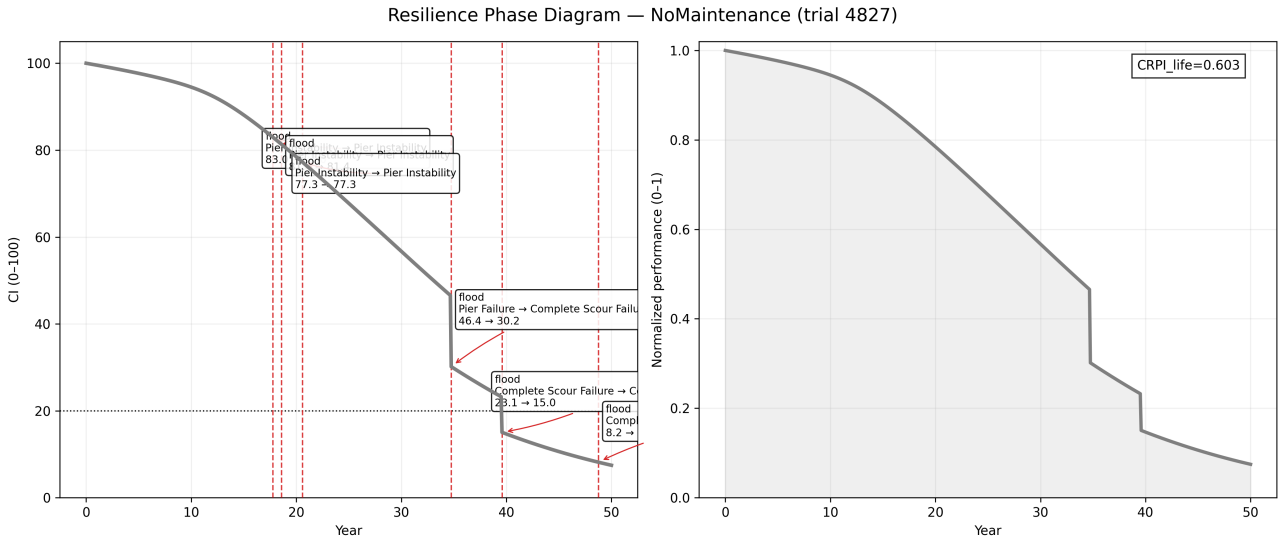

Figure 4: Representative Resilience Phase Diagram for No Maintenance Strategy, with monthly degradation of Condition Index shown in the left panel, and corresponding performance trajectory shown in the right panel.

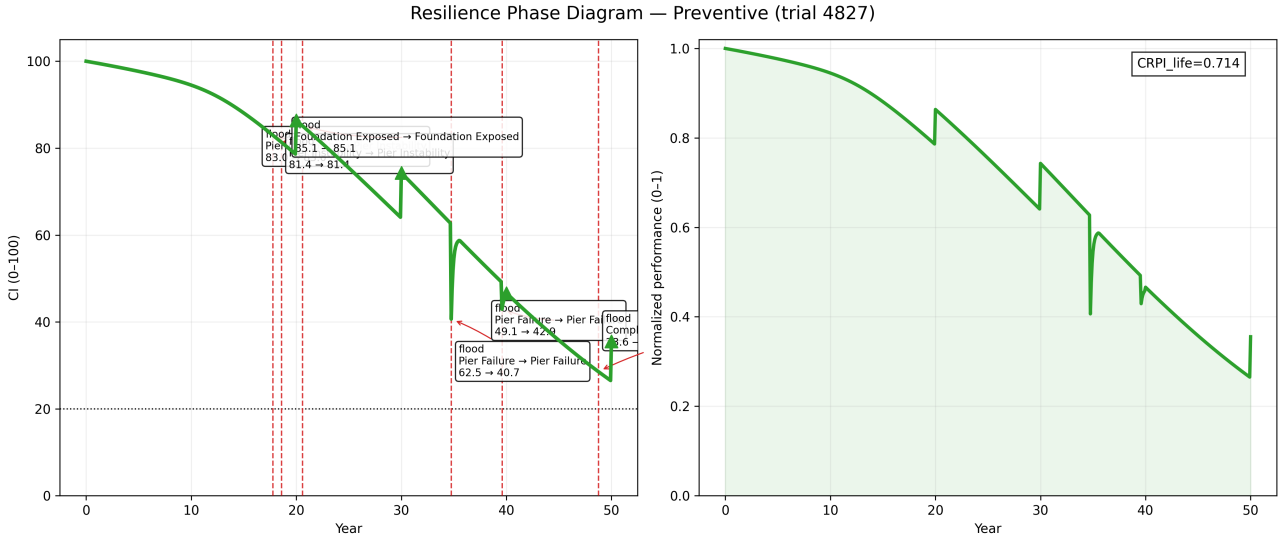

Figure 5: Representative resilience phase diagram for the preventive maintenance strategy (single trial), with the Condition Index on the left and the corresponding normalized performance used in the calculation of the CRPI on the right.

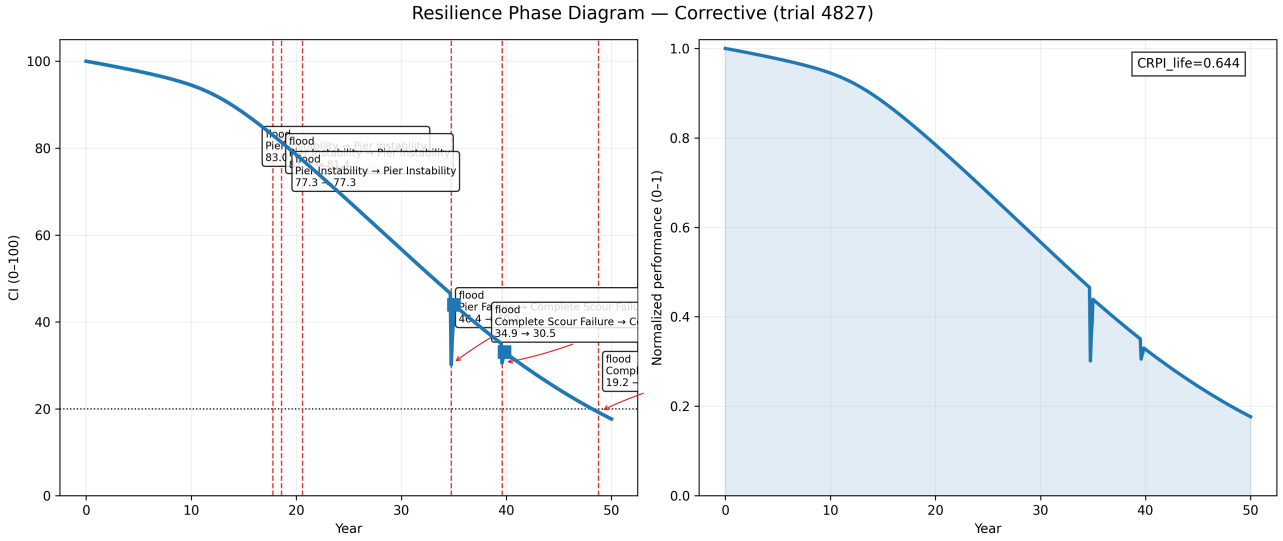

Figure 6: Representative resilience phase diagram for the corrective maintenance strategy (single trial): Condition Index (left) and normalized performance (right) used for the computation of the CRPI.

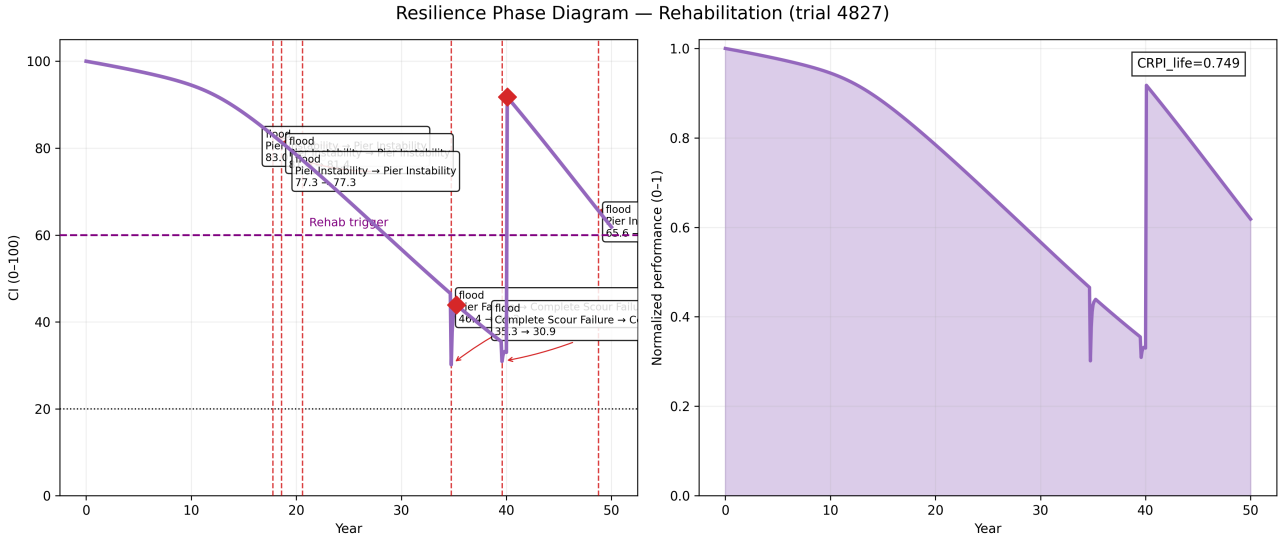

Figure 7: Representative Resilience Phase Diagram for Rehabilitation Strategy (single trial): Condition Index (left), and corresponding normalized performance for CRPI computation (right), highlighting threshold triggering and lifecycle restoration.

ing in partial and delayed recovery, while rehabilitation produces large but infrequent CI resets governed by trigger thresholds, allowing substantial degradation between interventions.

These contrasting recovery behaviors explain the ensemble outcomes summarized in Table 1 and visualized in Figure 2. Preventive maintenance achieves the highest mean $\mathrm{CRPI}_{\mathrm{life}}$ (0.716) with the lowest dispersion, whereas no maintenance exhibits both the lowest mean value (0.538) and the largest variability. Corrective and rehabilitation strategies yield intermediate life-cycle performance.

Implications for resilience-informed maintenance

Combining Table 1, Figure 2, Figure 3 and the phase diagrams shows that life-cycle resilience in this study is driven primarily by pre-event asset condition. Preventive maintenance preserves higher CI prior to hazard exposure, shifts fragility toward lower damage probabilities, reduces immediate losses and time in low-performance states, and therefore yields higher mean $\mathrm{CRPI}_{\mathrm{life}}$ and lower ensemble variability. Corrective and rehabilitation strategies provide post-event recovery but are limited by delay and infrequency, producing lower mean CRPI and greater uncertainty. Although the framework provides quantification of the impact of maintenance strategies on resilience performance, the decision-making process is also dependent on the consequences of failure. Therefore, assets with higher traffic demand or network importance may need higher prioritization even when the resilience performance is similar. The resilience indicator CRPI is a component of the decision-making process and should be used in conjunction with consequence-based measures.

Conclusions

This study shows that asset maintenance during normal operating conditions is critical to improving infrastructure resilience. Resilience thinking must extend to the pre-event stage of the lifecycle: proactive condition preservation strengthens robustness, limits damage at hazard exposure, and accelerates recovery. By embedding maintenance within a probabilistic Monte–Carlo lifecycle framework that couples condition-index (CI) evolution with CI-conditioned fragility, the analysis places pre-event condition at the center of resilience outcomes.

Across strategies, preventive (scheduled) maintenance consistently delivers the highest lifecycle resilience by reducing time spent in high-vulnerability CI ranges. Corrective maintenance provides moderate benefits but is strongly controlled by repair delay and effectiveness, while rehabilitation yields large one-time CI recovery yet is highly sensitive to cost, timing and trigger rules. A key mechanism is the condition-dependent shift in fragility: lower pre-event CI substantially increases the probability of severe damage states and collapse, amplifying the value of proactive, condition-preserving interventions.

The quantitative results should be interpreted in light of the modelling assumptions used here (simplified loss/cost representation, deterministic event impacts, strategy-independent deterioration physics and a single-asset formulation). Extensions such as stochastic loss dispersion, Bayesian fragility updating from observed damage, resource-constrained optimization with discounting, and multi-asset modelling would increase decision relevance.

Overall, the results support prioritising preventive, pre-event maintenance as a core asset-management strategy to enhance resilience under increasing hazard uncertainty.

AUTOMATED BUILDING CLASSIFICATION FOR SCALABLE URBAN MATERIAL STOCK ASSESSMENT

Elisa Iliste, Ingrid Viskus, Ergo Pikas and Targo Kalamees
Tallinn University of Technology, Tallinn, Estonia

Abstract

Soviet-era apartment blocks in Eastern Europe are being demolished, generating mixed waste and limiting circular reuse. Existing assessments rely on generic archetypes and lack element-level material detail. This study develops an automated algorithm to detect standardised Soviet building series for scalable material stock analysis. A distance-based classification using apartment layouts, floor area, height, and staircases was validated on 337 buildings and applied to Estonia's building stock. The model achieved 70% series-level accuracy, with dominant series represent 61% of the stock. This element-level quantification enables targeted deconstruction and higher material recovery for circular economy planning.

Introduction

Across Eastern Europe, a substantial share of the housing stock consists of Soviet-era buildings constructed during periods of mass housing development. Built under conditions prioritising speed and quantity over long-term durability (Meuser and Zadorin, 2015), now exhibiting declining living conditions, deteriorating structural integrity, and architectural obsolescence.

The Soviet-era housing stock in Estonia is characterised by residential districts dominated by standardised pre-fabricated concrete apartment buildings. These structures, ranging primarily from 3- 5 to 9 and 16-storey tower blocks, were assembled using a limited number of industrial mass-produced series (e.g 1-317, 1-464, 111-121, etc.). Visually, these districts present a repetitive landscape of rectangular blocks grouped around semi-open courtyards or distributed freely to ensure better daylight conditions (Glendinning, 2019).

Figure 1: Example of a typical 5-storey 111-121 series building

Many of the soviet era buildings are facing abandonment; they no longer function as viable housing, both socially and economically, leading to deterioration and inevitable demolition (Eurofound, 2023). Traditional demolition practices generate large quantities of mixed construction and demolition waste, much of which is directed to landfilling or low-value processing, reinforcing a linear "produce-use-discard" economic model (Ilomets *et al.*, 2022). However, research highlights that demolition waste contains substantial amounts of materials—such as concrete, masonry, and timber—that have high reuse or recycling potential if handled appropriately (Sakthibala *et al.*, 2025). Selective deconstruction, as opposed to conventional demolition, enables materials to be separated at source, significantly improving their quality and recyclability while retaining economic value (Ilomets *et al.*, 2022). Timeliness is critical: early intervention allows material recovery before deterioration, maximising both environmental and economic benefits.

Despite this circular economic opportunity, current approaches to assessing urban material stocks face significant limitations. Research on material potential in existing buildings is constrained by data availability (Romero Perez de Tudela *et al.*, 2020; Tirado *et al.*, 2021). Urban analytics typically rely on building archetypes based on usage type and construction year only, without differentiating material composition, many rely only of building volume or area (Ali *et al.*, 2021; Oliveira *et al.*, 2024). In Urban Energy Modelling, for example, LOD1 or LOD2 models are used to calculate building volumes (Xu *et al.*, 2023), making them appropriate for envelope material quantities but failing to represent building interiors. From machine-learning applications (Markopoulou *et al.*, 2024) used image-based segmentation with cadastral data, and (Ghione *et al.*, 2022) used CNN-based building classification for Oslo's building stock. The main limitation of these image-based solutions is the computational efficiency.

Soviet-era architecture offers a unique opportunity: its centralised design templates and documented material specifications make it an ideal candidate for systematic detection and material quantification. Many of these buildings are remotely located, built for factory workers, and thus disproportionately affected by population decline (Glendinning, 2019). While collections of original design drawings exist (Meuser and Zadorin, 2015). Much of the documentation is largely available only in Russian,

limiting accessibility. Recent advances in AI-powered translation and computer vision now make these previously unviable data sources accessible for large-scale analysis.

If building series—can be reliably detected from readily available building data, it becomes possible to estimate material stocks at urban and national scales without costly individual building surveys. This is essential for circular economy planning, enabling municipalities to identify buildings with high reuse potential, prioritise selective deconstruction over conventional demolition, and plan material recovery operations before building deterioration advances.

This research addresses this opportunity by developing an automated detection algorithm for building series using open building registry data. The design science research methodology is employed to develop and evaluate the detection algorithm and demonstrate its application for material stock quantification. The algorithm is designed to operate with minimal input parameters, while maintaining sufficient accuracy for practical decision-making. To operationalise the main aim, the following research questions are posed:

RQ1: Can building series be automatically detected from open building registry data, and what classification accuracy can be achieved at the building stock level?

RQ2: Does this building series classification provide sufficient granularity to support circular economy planning and material stock quantification at element level?

This research makes three key contributions. First, it presents a novel distance-based classification approach for detecting building series using only four parameters (apartment configuration, floor areas, building height, and number of staircases). Second, it validates the method on Estonia's complete apartment building stock (13,200+ buildings), demonstrating up to 80% accuracy. Third, it demonstrates element-level material quantification for the 111-121 building series, revealing approximately 4.86 million m³ of concrete and 0.23 million tons of steel.

Methods

The design research methodology was employed to develop the building series and type detection algorithm. The development process comprised the following steps:

- Development criteria were defined
- Input parameters were selected based on data availability, relevance, and the objective of minimizing the number of required variables to ensure scalability and the possibility of manual data entry.
- Algorithm logic and calculation procedures were developed, including classification rules and parameter threshold definitions.
- The algorithm was implemented, tested and applied to the full Estonian apartment building dataset
- Validation was conducted using a smaller reference dataset to assess classification accuracy.
- Material quantities were calculated for one representative building series to demonstrate the applicability of the developed approach.

Data sets

A dataset of 437 buildings with expert-assigned series and types was utilised as ground truth. Out of those buildings, 65% had information about both the series and the extension. The other 35% of buildings were untypical, meaning they didn't have a series assigned to them. This set was divided into two. First, a set of 337 apartment buildings was used to validate the workflow itself. Another 100 buildings were used for additional validation for the national-level mapping.

Additionally, a dataset containing all Estonian apartment buildings was utilised for the nation-level mapping. Before applying the workflow, the dataset was pre-processed. Wooden apartment buildings (approximately 5,700) were excluded because the template library does not include wooden buildings. Buildings constructed before 1945 (approximately 1,300 buildings) were also excluded, as the template set is limited to post-war standardized designs, corresponding to the established classification of Estonian apartment building archetypes. After this filtering 13,200 buildings remained.

Data Sources

The Estonian Building Register (EBR) is a public database that contains information on all Estonian buildings. It includes various types of data, such as the year of first use, purpose of use, dimensions (footprint area, heated area, and building height), apartment-specific data (apartment number, floor of entry, area, number of rooms) and building technical data that provide information on building envelope materials. It has an open data policy and web services for data acquisition.

A collection containing general information on more than 100 Soviet-era building designs was used to develop a database of templates serving as benchmarks for the distance-based classification. The level of detail and machine-readable data varied across the designs. Only those designs containing the parameters required for the detection algorithm were included in the final template database.

Evaluation Methods

Recall was used to measure the proportion of correctly identified buildings for each series and is defined as:

$$\text{Recall}_s = \frac{TP_s}{TP_s + FN_s} \quad (1)$$

where TP_s is the number of true positives for series s, and FN_s is the number of false negatives (i.e. buildings belonging to series s that were assigned to a different series). High recall indicates that the method is effective at detecting buildings of a given series when they are present.

The overall classification error rate is defined as the proportion of incorrectly classified buildings:

$$\text{Error rate} = \frac{N_{\text{incorrect}}}{N_{\text{total}}} \quad (2)$$

where $N_{\text{incorrect}}$ is the number of buildings whose predicted series does not match the validated series, and N_{total} is the total number of evaluated buildings. In addition, a filtered error rate was computed by excluding buildings that do

not correspond to any known template ("untypical" buildings), providing an estimate of performance for standardised building types only.

The false-positive rate for a given series measures the extent to which buildings from other series are incorrectly assigned to it:

$$\text{FP rate}_s = \frac{FP_s}{TP_s + FP_s} \quad (3)$$

where FP_s is the number of buildings incorrectly assigned to series s. High false-positive rates indicate that a series acts as an attractor for structurally similar but distinct building series.

Building Series and Type Representation

General data from 75 designs across 11 series were compiled into design templates to serve as benchmarks for distance calculations. Templates were implemented as Python objects using a set of data classes. Each template encodes one building design and is described by six main attributes, sampled in Table 1.

First, the series and series extension (type) identify the building family and the specific design variant (e.g., 1-464-1KE). Together, they form a unique series identifier.

Second, the series type indicates whether the template represents a whole building (WHOLE) or a modular staircase or block (MODULE). The whole series corresponds to complete buildings with multiple staircases, whereas the modular series describes a single repeatable building staircase.

Third, the spatial pattern describes the apartment configuration on a typical floor. This is represented as a nested list. For whole buildings, each inner list corresponds to one staircase and contains the number of apartments in each segment of that staircase. For modular buildings, the pattern consists of a single list representing one module.

Fourth, the area pattern stores the floor area associated with each staircase. Instead of storing the area of individual apartments, the total area per staircase is used.

Fifth, the number of floors is represented as a list. For buildings with a fixed height, this list contains a single value. For building series occurring at multiple heights, the list includes all typical numbers of floors.

Finally, all templates are stored in a central template library that serves as a registry and allows filtering by series type or other attributes.

This representation provides a machine-readable encoding of architectural typologies, while preserving the hierarchical structure of real buildings.

Table 1: Template instance examples, Value A represents a modular type, Value B represents the whole building type

Attribute	Value A	Value B
Series	'111-121'	'1-464'
Extension	'03E'	'17'
Type	Module	Whole
Pattern	[[4, 4, 2, 3]]	[[2,1,3], [2,2,2], [2,2,2], [3,1,2]]
Area Pattern	[255.0]	[136, 136, 136, 136]
Floor nr	[9]	[4]

Developed Workflow

The developed building series detection workflow consists of three main phases: (1) Data Augmentation and Preprocessing; (2) Distance calculation; (3) Classification and Scoring. The workflow is illustrated on Figure 2.

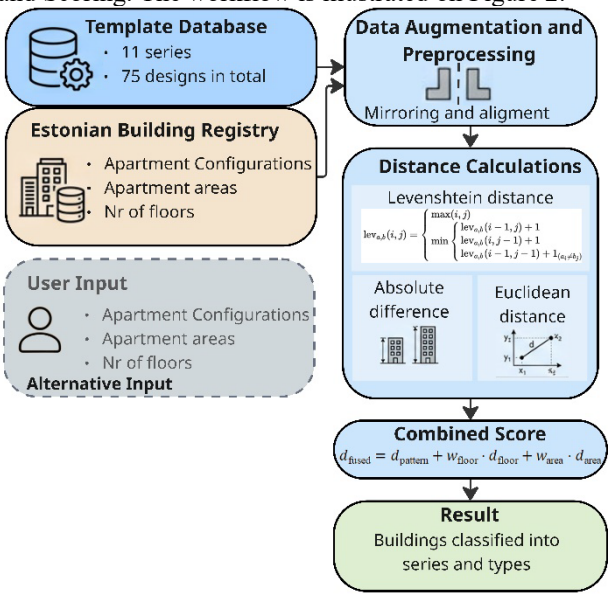

Figure 2: Series detection workflow

Three principal design criteria guided the development of the framework:

- Machine-readable and scalable representation of the building series, the data must be easily expandable with new information
- Robustness to structural variation and data inconsistencies:

Data Augmentation and Pre-Processing

To account for symmetric building layouts and staircase ordering inconsistencies, the matching procedure evaluates both the original and mirrored configurations of each building. Mirroring is implemented by reversing the order of staircases in the building representation. This accounts for cases where the same building design may be recorded with opposite orientations in the source data. For each building, two configurations are therefore considered: the original staircase sequence and its mirrored counterpart. For each configuration, the full matching workflow is executed independently.

Modular building series have to be treated differently from whole-building series. While whole-building templates represent complete buildings with a fixed configuration, modular templates represent configurable staircase units that may appear multiple times within a building and be mixed.

For modular series, templates are first grouped by their base series code. Each staircase of the subject building is then independently matched against all modular templates within the corresponding series. The best matching module for each staircase is selected using the minimum Levenshtein distance, considering both the original and mirrored module patterns.

The total distance for a modular series is computed as the sum of the per-staircase distances:

$$d_{\text{module}} = \sum_{i=1}^{n} \min\left(dL(s_i, m_j)\right) \quad (4)$$

where $s_i$is the apartment pattern of a staircase $i$in the building, and $m_j$are the available module patterns for the series. For each modular series, only the configuration with the smallest distance is selected for further calculations to minimise computational cost.

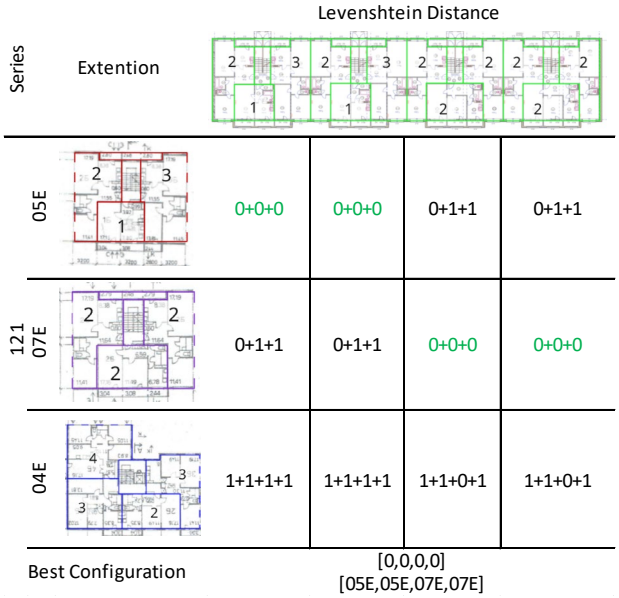

Figure 3: Example of finding the best modular configuration over a series using the Levenshtein distance

Distance Calculations

Apartment Pattern distance

Pattern similarity is computed using the Levenshtein (edit) distance between the subject building's staircase sequences and the template sequences. This metric was chosen because the objective is to identify the most similar structural configuration rather than to measure numerical proximity. The staircase sequences represent categorical configurations rather than continuous numerical variables; therefore, computing absolute or Euclidean differences would not meaningfully capture the similarity. The Levenshtein distance is calculated as shown in Equation 5.

$$\text{lev}_{a,b}(i,j) = \begin{cases} \max(i,j) & \text{if } \min(i,j) = 0, \\ \min\begin{cases} \text{lev}_{a,b}(i-1,j) + 1 \\ \text{lev}_{a,b}(i,j-1) + 1 \\ \text{lev}_{a,b}(i-1,j-1) + 1_{(a_i \neq b_j)} \end{cases} & \text{otherwise.} \end{cases} \quad (5)$$

The algorithm considers both original and mirrored building configurations.

Floor distance

The floor distance quantifies the difference between building floor count and the template specifications:

$$d_{\text{floor}} = \min_{f \in F} \; | \, n_{\text{floors}} - f \, | \quad (6)$$

where $f$is the set of allowed floor counts from the template and $\boldsymbol{n}_{\text{floors}}$is the actual building floor count.

Area Distance

Area similarity is calculated using the Euclidean distance, with each staircase acting as a dimension. For building staircase areas $\mathbf{A}_B = [a_1, a_2, \ldots, a_n]$and template areas $\mathbf{A}_T = [t_1, t_2, \ldots, t_n]$:

$$d_{\text{area}} = \sqrt{\sum_{i=1}^{n} \delta_i^2} \quad (7)$$

where the percentage difference for each valid staircase pair is:

$$\delta_i = \begin{cases} \min\left(\frac{| \, a_i - t_i \, |}{t_i}, 1.0\right) & \text{if } a_i > 0 \text{ and } t_i > 0 \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

Fused Distance Score

All distances are combined using a weighted linear combination:

$$d_{fused} = d_{pattern} + w_{floor} \cdot d_{floor} + w_{area} \cdot d_{area} \quad (9)$$

where $w_{\text{floor}}$and w_{area} control the relative importance of floor and area constraints and allow to prioritize the pattern distance. In this paper, these were chosen as 0.5.

Validation of the workflow

337 buildings were used to assess the performance of the proposed workflow. The overall classification accuracy was 60% for series and 50% for templates. When excluding the generic unclassified category, accuracy increases to 80% for series and 70% for templates, indicating a higher performance for well-defined building types. To assess scalability, the runtime of the classification workflow was measured.

The violin plot shows that while the average distance for correct predictions is 1.2, the median distance is lower (0.4), indicating that the majority of correctly classified buildings have very small distances, with the mean being influenced by a limited number of high-distance outliers (mainly the unassigned buildings, which have an average distance of 3.5). The average and median distances for incorrectly assigned templates are 2.8 and 2.7, respectively.

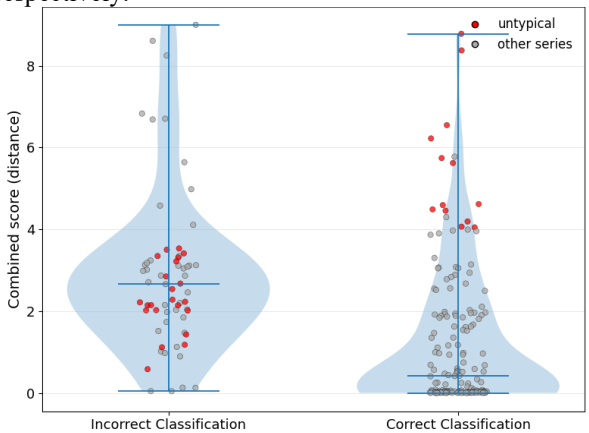

Figure 4: Distribution of the combined distance score by correctness, showing separation between correctly and incorrectly classified buildings.

To assess the performance of the proposed classification approach, we analysed the confusion matrix(Table 2) between the validated building series and the final predicted series. Columns represent the ground-truth (validated) series, while rows represent the model predictions.

The model demonstrates strong performance for several major building series. High, over 90% recall is observed for 121(100%),72057 (100%),10(93%),133(92%) and 1-464 (91%). These results suggest that the proposed features effectively capture the characteristics of the most well-defined building types.

In contrast, several series exhibit poor recall. Series 113-EKE, 66, 22 and 3F-2F all have a recall of 0. indicating that these categories are either underrepresented in the training data or insufficiently distinguishable from other series. The generic category also performs poorly, correctly classifying only 37 % of true instances.

The errors show consistent confusion between specific series. For example,

- 1Э-318 → 121 (36%), indicating that over one third of buildings from series 1Э-318 are systematically misclassified as 121.
- 113-EKE 10 → 23 (50%), suggesting strong similarity between these two series.

These results indicate families of series that are structurally similar and difficult to distinguish using a flat multi-class classification scheme.

Several series show a disproportionate number of false positives. Series 121 absorbs 36% of true 1Э-318, 11% of true Other, and 3% of true 1-317, despite having perfect recall. Similarly, the Other class accounts for 18% of true 1э-318, 10% of true 113-EKE 11, and 7% of true 133. Series 23 also generates notable false positives, including 50% of true 113-EKE 10 and 13% of true 113-EKE 11.

Nation-level mapping

The combined distance metric was computed for the 13,200 buildings. The full building stock (13,200 buildings) was processed in approximately seconds on a standard desktop machine. As a result of this classification, the most frequent series were 1-317 (14.26%), 10 (13.47%), 111-121 (13.00%), 72057 (11.29%), and 23 (9.45%). Together, these five series account for over 61% of all classified buildings.

The assigned building series was validated using a sample of 100 buildings. The overall classification error rate was 36%; excluding buildings that did not correspond to any known template reduced it to 28%. The recall remained high for 1-464 (98%); 1-317 also showed a high recall of 82%.

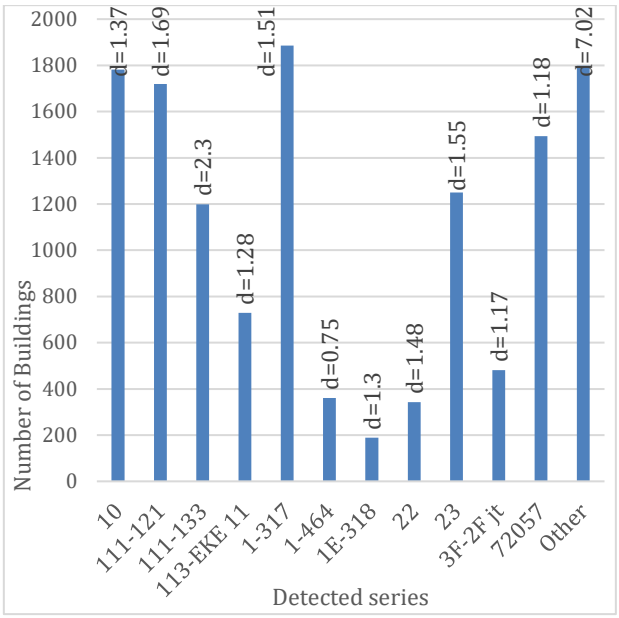

Figure 5: Building Stock Classification by Detected Series with Average Distance Score (d)

Material quantities calculation

To demonstrate the proposed workflow, a material stock calculation was performed for the 111-121 series. The series was selected for two reasons: firstly, it is one of the most prevalent building types in the national stock

Table 2: Confusion Matrix, in the column are the validated series, in the row the automatically classified series, green indicates a match and red the correct classification

Result / Validated	10	22	23	66	121	133	72057	113-EKE 10	113-EKE 11	113-EKE 12	1-317	1-464	1Э-318	Other	3F-2F

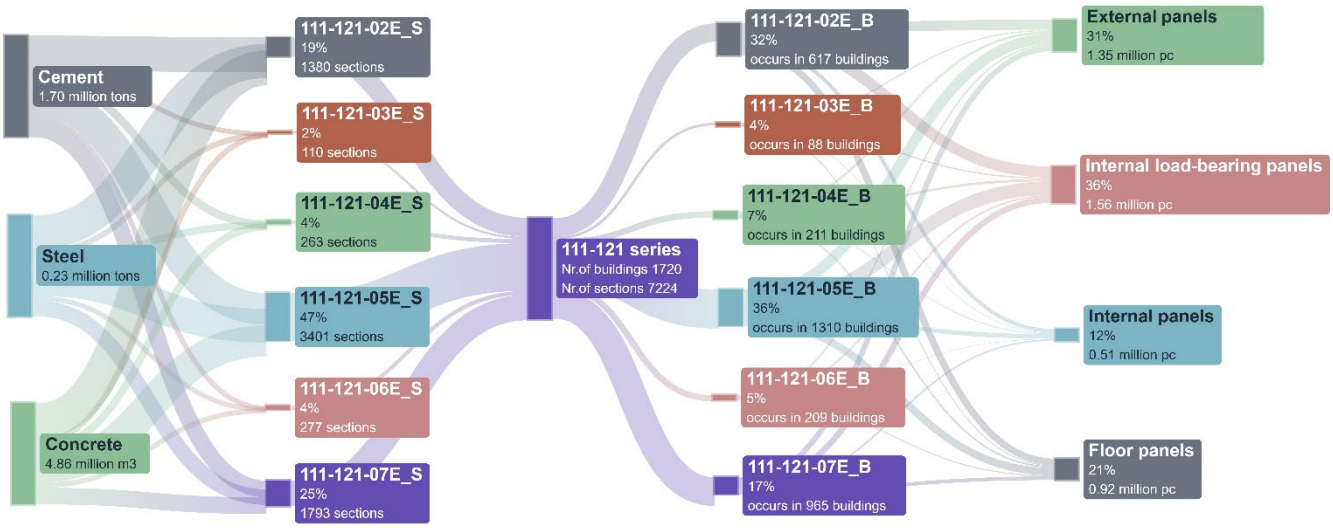

Figure 6: Material flow analysis for the 111-121 series: Central nodes represent building section templates, with flows splitting into two paths: left quantifies raw materials (concrete, steel, cement) for recycling estimates, and right classifies prefabricated components (floor and wall panels) for reuse planning.

(N=1720 detected buildings); secondly, the 111-121 series is modular, consisting of various section types assembled in different configurations. This modularity allows analysis in which material quantities are calculated for a specific section template rather than using generic building averages.

The analysis focused on the six most frequently detected types in the series, which collectively account for the vast majority of the 111-121 building stock.

Total material stock (M*total*) for the series was calculated by aggregating the specific material quantities of each identified section type:

$$M_{total} = \sum_{i=1}^{k} \left(N_i \times Q_{(i,m)} \right) \qquad (10)$$

Where:

Ni is the total count of detected sections of type *i* across the entire building stock (derived from the dataset's frequency distribution; e.g., type 111-121-05E appears 3401 times).

Qi,m is the quantity of a specific material *m* (e.g., reinforced concrete in *m*3, steel in tons) per single section of type *i*, extracted from the original design passports (reference project documentation).

k is the number of unique section templates identified (e.g., 02E, 05E, 07E, etc.)

As shown in Figure 6 The material flow analysis reveals distinct patterns. Although 5-storey building sections (Types 05E and 07E) are numerically dominant, accounting for over 70% of all sections, the 9-storey sections contribute disproportionately to the total material mass due to their larger building volume. The analysis indicates a total embodied stock for series 111-121 of approximately 4.86 million m3 of concrete, 1.70 tons of cement, and 0.23 million tons of steel for this series alone. Breaking this down by element type, the floor slabs (panels) account for the largest share at ~36%. This level of granularity is crucial for circular planning as it distinguishes between elements based on their material complexity and 'cleanness', which are the key factors in evaluating the reuse potential. Unlike the external wall panels, which in Soviet-era construction often consist of composite layers that are difficult to separate and whose insulating layers are often problematic to reuse, floor and internal load-bearing panels are typically monolithic reinforced concrete elements. That according to (Ilomets *et al.*, 2022) This structural homogeneity gives floor panels a higher potential for direct reuse, with an estimated recovery of up to 90% for floor slabs in good condition. He also confirms that internal load-bearing elements are one of the most valuable components, as they are generally well-preserved and clean.

Discussion

The results demonstrate that building series can be systematically identified from open building registry data with meaningful accuracy. For the primary validation dataset (337 buildings), the overall classification accuracy was 60% for series and 50% for templates. When excluding buildings that do not correspond to any known template (generic/unclassified category), the accuracy increases to 80% for series and 70% for templates. At the national level, validation yielded an overall accuracy of 64%, which rose to 72% when excluding unclassified buildings.

This performance is comparable to machine learning approaches reported in the literature, such as the 87% accuracy reported by Markopoulou et al. (2024). However, the distance-based approach offers distinct advantages in interpretability, minimal data requirements, and computational efficiency. Previous material stock studies have relied on statistical averages, applying material intensity coefficients (*kg*/*m*2 *or kg*/*m*3) to floor area or building volume (Oliveira *et al.*, 2024). While effective for large-scale estimates, these methods fail to capture the structural heterogeneity within building series. For example, taller sections require more reinforcement steel and concrete per m2 than lower counterparts due to structural requirements. The ability to detect these patterns enables more accurate quantification of material

properties for engineering design rather than relying on statistical averages.

Although distance-based similarity metrics perform well across several building series, the results suggest that additional descriptive dimensions are needed to improve robustness, particularly for identifying atypical buildings that do not conform to any standardised series. Such cases are inherently difficult to capture using purely rule-based or metric-based approaches.

Machine learning, therefore, constitutes a promising direction for future work. While the current number of templates is too large to support a classification model with the available data, machine learning could be employed in a hybrid framework. For instance, a predictive model could assist in ranking candidate series rather than series and extensions, resolve ambiguities when multiple templates exhibit similar distance values, and flag buildings that deviate substantially from known typologies.

The implications of the results extend beyond quantifying material stock. Building series detection enables the systematic application of any series-specific data at the urban scale. This includes thermal properties and spatial data for energy modelling, as well as structural characteristics and construction details for renovation planning.

While the proposed method is developed and demonstrated on standardised Soviet-era building typologies, the underlying framework is not unique to this context. Similar industrialised and prefabricated housing approaches were widely implemented across Europe during the post-war period. These systems share key characteristics with Soviet building series, including modular design, limited layout variation, and predefined structural and spatial configurations.

Comparable patterns can also be observed in other European contexts, such as the Swedish Million Programme (Berggren and Wall, 2019), where large volumes of residential buildings were constructed using standardised designs. Although the specific notion of “series” may not be explicitly defined in all these contexts, the underlying logic of repetition is consistent.

Several limitations remain. First, data availability and quality significantly affect applicability and scalability. While Estonia's comprehensive building registry enabled national-scale analysis, many Eastern European countries lack a comparable open data infrastructure.

Second, parameter sensitivity poses a critical challenge. Building registries often contain inconsistencies and data quality issues that directly affect large-scale assessments that rely on these sources. Errors in registry data propagate through the classification workflow, leading to potential misclassification of building series. Consequently, the classification accuracy is highly sensitive to the quality of input parameters. Small deviations in recorded apartment configurations, floor areas, or building heights can lead to incorrect template assignments. The confusion matrix revealed systematic misclassifications between specific series pairs (e.g., 1Э-318 → 121 at 36%, 113-EKE 10 → 23 at 50%), indicating that the four-parameter representation may be insufficient to distinguish closely related designs.

Third, template database coverage constrains comprehensiveness. The 75 designs represent major series but cannot capture the full diversity of Soviet-era construction. The "generic" category had only 37% recall, serving as a catch-all for buildings that did not match known templates. Expanding the database requires access to original design documentation.

Fourth, building modifications and renovations significantly impact classification accuracy. Soviet-era buildings have undergone various interventions during their 40-70-year lifespans: apartment reconfigurations that alter spatial patterns, balcony enclosures that change floor area, and roof additions that modify building height. The building registry may not consistently reflect these changes, leading to mismatches between recorded parameters and actual characteristics.

Despite these limitations, the method provides a practical foundation for circular economy planning where detailed building-level surveys are infeasible. The element-level material quantification demonstrated for the 111-121 series offers actionable information for selective deconstruction planning. Future research should expand the validation dataset, focus on hybrid classification frameworks that combine distance metrics with machine learning, conduct validation studies in other Eastern European countries, and integrate building condition assessment to account for deterioration and modifications.

Conclusions

This paper proposes an automated series of building detection for urban material stock assessment, focusing on Soviet-era standardised buildings in Estonia.

The results show that building series can be automatically detected from open building registry data with meaningful accuracy. Using four parameters: apartment configuration, floor areas, building height, and number of staircases, the distance-based algorithm achieved 60% overall accuracy for series and 50% for templates across 337 validation buildings. Excluding the generic unclassified category, accuracy increased to 80% for series and 70% for templates. National-scale classification of 13,200 buildings yielded a similar accuracy of 64% for all series, increasing to 72% when excluding non-standardised buildings.

Building series classification provides sufficient granularity for circular economy planning and element-level material stock quantification. The 111-121 series (1,720 buildings) revealed approximately 4.86 million m³ of concrete, 0.23 million tons of steel, and 1.70 million tons of cement. Floor slabs account for 36% of total material mass. This granularity is essential because it distinguishes elements by reuse potential—monolithic floor panels offer up to 90% recovery, compared with composite external wall panels with problematic insulation layers.

This work provides three key contributions: (1) Novel distance-based classification with minimal input parameters maintaining practical accuracy; (2) Validation

on Estonia's complete apartment building stock, demonstrating national-scale scalability; (3) Element-level material quantification, distinguishing components by reuse potential.
