Abstract

Digitalisation expanded access to design, operational and environmental data, yet whole carbon-life assessment and climate risk prediction still evolve in separate, non-interoperable workflows. This fragmentation limits climate-responsive design, especially for urban flooding and heat. The paper develops a conceptual framework for digital climate indicators that link carbon performance with predictive flood and urban heat analytics. Using a structured review of recent work on BIM-integrated life cycle assessment, digital twins, machine-learning-based hazard modelling and resilience assessment, it derives key information requirements and illustrates their application. The contribution is a set of indicator families and research directions for robust, portable climate-resilience metrics.

Introduction

Climate-responsive design in the built environment is increasingly expected to achieve two intertwined objectives: reducing greenhouse-gas emissions and maintaining acceptable performance under changing climate hazards. The IPCC AR6 Synthesis Report confirms that anthropogenic climate change is already driving widespread impacts and escalating risks for cities and infrastructures (IPCC, 2023). At the same time, buildings and infrastructure are undergoing rapid digitalisation through Building Information Modelling (BIM), Geographic Information Systems (GIS), remote sensing, Internet of Things (IoT) sensing and, more recently, digital twins (DTs) that promise continuous monitoring and predictive analytics (Zhang et al., 2025; Petri et al., 2025).

Despite this convergence, analytical workflows for mitigation and adaptation remain largely fragmented. Whole-Life Carbon (WLC) is typically assessed through life cycle assessment (LCA) and Environmental Product Declarations (EPDs), increasingly connected to BIM for automated quantity take-off (Zhang et al., 2025; Parece et al., 2025; Berges-Álvarez et al., 2024). Climate risk, by contrast, is usually analysed through hydrodynamic models, microclimate simulations, remote sensing and machine learning (ML) for hazard or susceptibility mapping (Islam et al., 2025; Ahmed et al., 2025). These workflows differ in assumptions, spatial and temporal resolution, data models and outputs, and they tend to meet, if at all, late in the process, via narrative reports rather than integrated indicators.

This separation has practical consequences. Design options optimised for WLC can inadvertently increase exposure to future flooding or overheating; conversely, adaptation measures that improve robustness may carry substantial embodied-carbon burdens that are not systematically quantified. Recent work on sustainability and resilience assessment explicitly calls for methods that link hazard, damage, recovery and environmental impacts into coherent frameworks (Sesana et al., 2024; Tanguay et al., 2024). However, there is still no shared concept of digital climate indicators that consistently connect carbon, risk and resilience analytics in digital workflows.

In this paper, a digital climate indicator is defined as a computable metric derived from integrated digital artefacts (e.g., BIM/IFC, GIS, hazard layers, scenarios) to support climate-responsive and resilient decisions.

Within the wide spectrum of climate hazards, this paper uses urban flooding and urban heat as reference, since they are high-impact in cities and supported by mature geospatial and ML ecosystems for indicator computation (Islam et al., 2025; Ahmed et al., 2025).

The aim of this paper is therefore to explore under what informational and methodological conditions indicators derived from digital artefacts, BIM/IFC models, GIS layers, sensor streams and climate-scenario data, can support climate-responsive and resilient design, with urban flooding and heat as reference hazards. The contribution is conceptual and methodological: we propose a framework for digital climate indicators, identify key information requirements, and outline research questions and directions for developing robust, interoperable metrics.

The remainder of the paper is structured as follows. Section 2 reviews recent work on BIM-integrated carbon assessment, DT-enabled dynamic LCA, ML-based flood and heat analytics, and resilience assessment methods. Section 3 introduces the indicator framework and associated information requirements. Section 4 formulates research questions and methodological directions, including a minimal operational example for flood and heat. Section 5 discusses implications and typical failure modes, and Section 6 concludes with a research agenda for digital climate indicators in the built environment.

Preliminary literature review

Digital carbon tools and BIM-integrated LCA

LCA has become the reference framework for quantifying environmental impacts of buildings and infrastructures over their life cycle and is increasingly used to support low-carbon design (Zhang et al., 2025). Recent reviews show that integrating LCA with BIM has advanced substantially in terms of automating inventory compilation. A systematic review of BIM-based LCA applications reports that BIM can automate a large fraction of life cycle inventory data extraction, reducing manual work and enabling early-stage comparisons (Parece et al., 2025). However, the same review shows that life cycle impact assessment still often requires manual mapping between BIM elements and LCA or EPD datasets, and that only a minority of studies embed results into optimisation or multi-criteria decision-support processes (Parece et al., 2025).

A complementary body of work extends the focus from environmental impacts to life cycle sustainability assessment, integrating economic and social dimensions (Berges-Álvarez et al., 2024). These studies repeatedly highlight issues of inconsistent semantics, missing metadata and limited interoperability between BIM models, classification systems and LCA datasets (Zhang et al., 2025; Berges-Álvarez et al., 2024). Even when computational pipelines are sophisticated, these informational gaps can undermine the reliability and comparability of carbon indicators. In practice, this can lead to a subtle failure mode: numerical precision without semantic robustness, where whole-life carbon values appear accurate but are conditioned on incomplete or project-specific assumptions about materials and systems. Overall, the literature suggests that digital carbon tools are moving from bespoke analyses toward more standardised workflows, but that their outputs remain sensitive to information quality and scope. For digital climate indicators, this implies that indicator design must explicitly consider semantic completeness and provenance, rather than assuming that any BIM-based LCA result is a stable quantity.

DTs and dynamic environmental indicators

DTs in the built environment are generally described as digital representations of assets or systems that are continuously updated with data from sensors, simulations and operational processes (Petri et al., 2025; Luo et al., 2024). In the last few years, DTs have been proposed as platforms for moving from static sustainability metrics to dynamic, data-driven indicators. The Building Life-cycle Digital Twin (BLDT) framework, for example, combines IoT measurements, ML models and interoperable data structures to generate time-dependent LCA outputs, enabling near real-time assessment of environmental performance and supporting predictive interventions (Petri et al., 2025). More conceptual work on DT-enabled dynamic LCA underlines the importance of embedding LCA models into broader systems of objectives, data flows and stakeholder needs, arguing that a DT can host multiple assessment lenses over time rather than producing one-off results (Luo et al., 2024).

These developments highlight an important opportunity for digital climate indicators: moving from single-snapshot values to time-series indicators that reflect changing operating conditions, retrofits and climate scenarios. At the same time, they expose new challenges. If dynamic indicators are generated without clear documentation of data provenance, model calibration, drift detection and uncertainty, DTs can become "black boxes" that amplify opacity rather than reducing it. For indicators that may be used in regulatory or financial contexts, this raises concerns about auditability and trust. Thus, any proposal for dynamic climate indicators should be accompanied by explicit information requirements and governance mechanisms.

Predictive flood analytics and risk metrics

Flood risk is a prominent climate hazard for urban areas, and data-driven approaches have proliferated alongside more traditional hydrodynamic modelling. A systematic review on urban flood susceptibility mapping synthesises remote sensing datasets, topographic and land-use variables, and ML methods, reporting that models such as random forests, gradient boosting and deep neural networks can achieve high predictive performance when sufficiently rich conditioning factors are available (Islam et al., 2025). The review also notes considerable heterogeneity in how outputs are defined (susceptibility indices, probabilities, hazard classes) and in how performance is evaluated, which complicates cross-study comparison (Islam et al., 2025).

Case studies using deep learning and hybrid schemes confirm that ML can identify dominant drivers of flood susceptibility and refine spatial resolution, but also show sensitivity to data quality, feature selection and transferability across regions (Islam et al., 2025). From the standpoint of digital climate indicators, the key point is that sophisticated hazard models do not automatically generate design-relevant risk metrics. Their outputs need to be linked to assets, functions and decision thresholds, and these links are often treated informally or in a project-specific way. Moreover, if flood susceptibility layers are not aligned with design models in terms of coordinate systems, resolution and temporal reference, there is a risk that indicators derived from them may look precise but be geometrically or temporally misaligned.

Predictive heat analytics and urban heat indicators

Urban heat and the urban heat island (UHI) effect have similarly attracted ML-based methods. A recent review of predictive approaches for UHI reports a shift from purely statistical or physics-based models towards ML, deep learning and hybrid approaches, using satellite imagery, in situ measurements and urban morphological data as inputs (Ahmed et al., 2025). Studies show that deep models can capture complex, non-linear relationships between land cover, building density, vegetation and surface temperature, yielding improved predictive accuracy compared to conventional methods (Ahmed et

Table 1: Literature-gap matrix

al., 2025). However, the same review emphasises limitations in generalisability, given that models trained on one urban context may perform poorly when applied elsewhere without retraining or adaptation (Ahmed et al., 2025).

For digital climate indicators, heat prediction is directly relevant to cooling loads, indoor overheating risk and outdoor comfort. Yet, as with flood models, heat predictions are typically published as thermal maps or statistics, not as indicators tied to specific buildings, spaces or design decisions. Without clear information on spatial correspondence, scenario assumptions and temporal resolution, integrating such outputs into carbon and resilience indicators becomes difficult.

Resilience assessment methods and metrics

Resilience assessment in the built environment has evolved from qualitative descriptions to more structured frameworks and tools. A critical review of resilience assessment tools for the built environment notes a proliferation of methods but also fragmentation, inconsistent definitions and limited empirical validation (Cerè et al., 2017). The authors argue that many tools remain diagnostic rather than operational, and that the relationship between resilience and sustainability is often under-specified (Cerè et al., 2017).

More recent work proposes quantitative key performance indicators (KPIs) for risk and resilience assessment of assets exposed to climatic and non-climatic hazards, combining concepts such as robustness, redundancy, exposure and recovery (Ricciardi et al., 2025). A systematic review of sustainability and resilience assessment methods in the construction sector further documents the uneven development of approaches and calls for integrated frameworks that explicitly link hazard scenarios, damage, recovery trajectories and environmental impacts (Sesana et al., 2024). In a related contribution, the sustainability of resilient built environments is examined by combining performance-based damage assessment under hazards with LCA of repair and retrofit interventions, illustrating both synergies and trade-offs between resilience and environmental performance (Tanguay et al., 2024).

Taken together, this literature indicates that resilience is conceptually rich and quantitatively expressible, but that indicators remain heterogeneous and only partially integrated into digital design and management tools. For digital climate indicators, this reinforces the need to anchor resilience metrics in clear functional definitions and information requirements.

While the reviewed literature demonstrates significant progress within individual analytical domains, it also reveals a persistent fragmentation across carbon assessment, climate risk modelling and resilience analysis. BIM-integrated life cycle assessment workflows primarily address mitigation objectives, but rarely engage with hazard exposure or recovery dynamics. Conversely, flood and urban heat modelling studies provide increasingly accurate hazard predictions, yet typically remain detached from asset-level carbon implications and resilience metrics. Resilience assessment frameworks offer conceptual and quantitative tools to describe system response and recovery but are often weakly connected to digital design and hazard analytics.

Cross-cutting gaps and integration challenges

Across the reviewed literature, a recurring limitation is the lack of integration between analytical domains that are increasingly interdependent under climate change. Carbon assessment studies typically operate at building scale and rely on static or weakly scenario-dependent assumptions, while flood and urban heat modelling often adopt district or city scales driven by climate scenarios that are not aligned with those used in mitigation analyses. This mismatch in spatial and temporal scales complicates the joint interpretation of results and limits their decision relevance.

A further cross-cutting gap concerns uncertainty communication. While uncertainty is acknowledged in both life cycle assessment and climate risk modelling, it is rarely propagated or interpreted consistently when outputs from different domains are combined. As a result, decision-makers may be exposed to indicators that appear precise but embed heterogeneous and implicit assumptions.

Finally, the mapping between hazards, asset performance and functional consequences remains weakly formalised in much of the literature. Flood and heat indicators often describe exposure or intensity, while resilience metrics attempt to capture response and recovery, yet explicit links between hazard levels, asset degradation and downtime are rarely integrated into digital workflows.

Table 2: Indicator families, information requirements, and typical gaps for flood- and heat-related applications

	Key Information elements	Alignment needs	Typical gaps
Carbon performance (WLC)	• BIM-based quantities • Material specifications • Environmental Product Declarations (EPDs) • Operational profiles • Decarbonisation scenarios	• Semantic alignment between BIM elements and LCA datasets • Temporal alignment with energy and grid scenarios	• Missing or inconsistent material metadata • Partial system boundaries • Limited transparency on scenario assumptions
Climate risk (flood & heat)	• Flood susceptibility or hazard maps • Urban heat metrics (e.g. land surface temperature, heat indices) • Exposure data • Basic vulnerability attributes	• Spatial alignment between hazard layers and asset geometries • Consistent resolution and coordinate systems • Scenario coherence	• Resolution mismatch • Limited transferability of ML models • Weak linkage between hazard scores and asset-level consequences
Resilience performance	• Functional definitions • Performance thresholds • Recovery time assumptions • Interdependency between systems	• Temporal alignment between hazard events and recovery models • Explicit performance metrics	• Qualitative or poorly validated recovery assumptions • Lack of standardised resilience metrics

These gaps motivate the need for a structured framework that explicitly connects carbon performance, climate risk and resilience through shared information requirements and transparent alignment processes

Table 2 synthesises these patterns by positioning the main literature streams against the three indicator families considered in this paper, highlighting both areas of maturity and structural gaps, and it motivates the need for an integrative indicator framework capable of bridging these domains.

Proposed framework

Concept of digital climate indicators

The aim of the present work consists in defining a digital climate indicator as a metric derived from digital representations of the built environment (e.g.. BIM and IFC models, GIS layers, sensor data and climate-scenario datasets) to support climate-responsive and resilient decision-making. Unlike generic performance metrics, digital climate indicators are explicitly conditioned on the quality, completeness and alignment of the underlying information from which they are computed.

The need for such indicators emerges from the growing availability of digital data and analytical tools, coupled with the persistent separation between mitigation-oriented assessments (e.g. whole-life carbon, WLC) and adaptation-oriented analyses (e.g. climate risk mapping). Recent literature shows that while BIM-integrated life cycle assessment (LCA) workflows and DTs enable increasingly automated and dynamic carbon assessment (Parece et al., 2025; Petri et al., 2025), climate risk analytics, particularly for flooding and heat, are often developed independently using geospatial data and machine learning (ML) models (Islam et al., 2025; Ahmed et al., 2025). As a result, outputs are difficult to combine in a coherent and decision-relevant manner. Digital climate indicators are therefore not conceived as new standalone metrics, but as integrative constructs that explicitly link carbon performance, climate risk and resilience performance under clearly defined information requirements. Their value lies not only in numerical results, but in their ability to make assumptions, dependencies and uncertainties explicit across heterogeneous digital workflows.

Indicator families and hazard focus

The development of the indicator is structured along three indicator families: carbon performance, climate risk, and resilience performance. These families correspond to distinct but interdependent decision questions: how much an asset contributes to climate change, how exposed it is to climate hazards, and how it performs and recovers when those hazards occur. Within the broad spectrum of climate-related hazards, this framework focuses explicitly on urban flooding and urban heat. This choice is motivated by three considerations. First, flooding and heat are consistently identified as dominant climate threats for urban areas, with significant impacts on infrastructure functionality, public health and economic activity (IPCC, 2023). Second, both hazards are supported by relatively mature digital ecosystems, including remote sensing, urban morphology datasets and ML-based susceptibility or prediction models, making them suitable for indicator computation at building and district scales (Islam et al., 2025; Ahmed et al., 2025). Third, flood and heat hazards exhibit strong interactions with both operational and embodied carbon, as well as with resilience metrics such as downtime and recovery, making them particularly relevant for illustrating cross-domain trade-offs. By concentrating on flooding and heat, the framework achieves methodological clarity while remaining representative of broader multi-hazard challenges faced by climate-resilient design.

Information requirements and alignment conditions

A recurring finding across the reviewed literature is that the main barriers to integrated climate assessment are not

purely computational, but informational. The computation of digital climate indicators depends on the availability, alignment and interpretability of heterogeneous data sources. Table 2 synthesises the key information requirements associated with each indicator family, with explicit reference to flood and heat-related applications. For carbon performance indicators, such as WLC, required information includes BIM-based quantities, material specifications, Environmental Product Declarations (EPDs), operational profiles and decarbonisation scenarios (Zhang et al., 2025; Berges-Álvarez et al., 2024). Semantic alignment between BIM elements and LCA datasets is critical, missing or inconsistent metadata can lead to systematic underestimation or exclusion of relevant components. For climate risk indicators, flood susceptibility maps and urban heat metrics must be spatially linked to asset geometries through consistent coordinate systems and resolution. ML-based models can provide high-resolution hazard predictions, but their outputs must be interpreted within explicit scenario and validation boundaries to avoid false precision (Islam et al., 2025; Ahmed et al., 2025).

For resilience performance indicators, information requirements extend beyond hazards to include functional definitions, performance thresholds and recovery assumptions. Literature on resilience assessment highlights that these aspects are often weakly formalised or treated qualitatively, limiting indicator comparability and robustness (Cerè et al., 2017; Sesana et al., 2024).

Across all families, spatial alignment, temporal and scenario transparency, and uncertainty representation emerge as cross-cutting requirements. Table 2 identifies the minimum information elements required for each indicator family. Figure 1 translates these requirements into an operational alignment sequence and it conceptually illustrates the proposed workflow for computing digital climate indicators by explicitly articulating how heterogeneous digital data sources are transformed into decision-relevant metrics. The workflow is structured around three main stages: data sourcing, alignment and processing, and indicator computation. Rather than assuming seamless interoperability, the figure makes visible the intermediate alignment steps (i.e.; semantic enrichment, spatial matching between assets and hazard layers, temporal and scenario harmonisation, and uncertainty characterisation) that condition the correctness and robustness of the resulting indicators. By positioning these steps explicitly between data ingestion and indicator outputs, the workflow highlights where information gaps, misalignments or implicit assumptions may propagate into carbon, flood and heat risk, and resilience metrics. This articulation provides the basis for a critical discussion of typical failure modes and limitations, which are addressed in the following section.

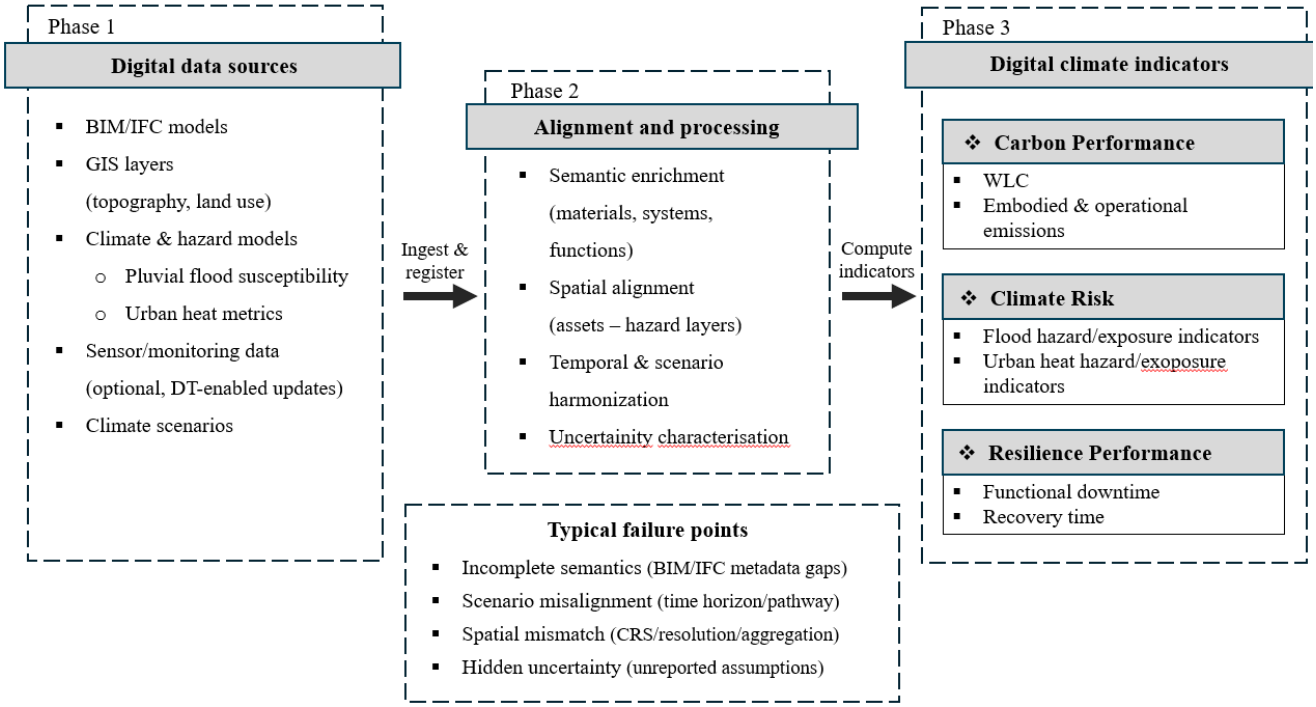

Figure 1: Conceptual workflow for digital indicators' computation in three action-oriented stages, integrating WLC, flood and urban heat risk, and resilience performance

Indicator validity, scale, and decision context

A critical aspect of digital climate indicators concerns their validity across scales and decision contexts. Indicators computed at building scale may be suitable for early design choices or retrofit comparisons, whereas district-scale indicators are more relevant for planning decisions, infrastructure prioritisation and portfolio-level assessment. The proposed framework does not prescribe a single scale of application; instead, it requires that the scale of indicator computation is explicitly aligned with the intended decision context.

In this perspective, indicator validity is not primarily defined by predictive accuracy, but by internal consistency, transparency of assumptions and sensitivity

to information completeness. Whole-life carbon indicators, for example, may support robust comparison between alternative design strategies even when absolute emission values are uncertain, provided that system boundaries, material mappings and scenarios are consistently defined.

Similarly, flood and urban heat indicators are often more informative when used to position options relative to one another rather than to predict exact hazard impacts. By making scale and decision context explicit, the framework helps prevent the misuse of indicators outside their domain of validity and supports more appropriate interpretation of results. This shift from optimisation to comparative reasoning is particularly relevant for climate-responsive design, where decisions must be made under deep uncertainty and evolving boundary conditions.

Research questions and methodological directions

The proposed framework motivates a set of research questions aimed at advancing the development and use of digital climate indicators for flood- and heat-related applications. Such questions are derived from the literature review and framework synthesis and are presented as a research agenda rather than being fully answered within the present contribution.

RQ1 - Indicator correctness

Under what information conditions can integrated carbon, flood/heat risk and resilience indicators be considered correct representations of climate performance? This question concerns the relationship between indicator definitions and the completeness and consistency of the underlying digital information.

RQ2 - Portability and interoperability

To what extent can indicators computed for flood and heat hazards be reproduced across projects, tools and local contexts? Given the documented variability in BIM semantics, LCA datasets and ML-based hazard models, this question addresses the limits of indicator transferability (Parece et al., 2025; Islam et al., 2025).

RQ3 - Uncertainty and robustness

How should uncertainty from climate scenarios, hazard models and recovery assumptions be propagated and communicated through digital climate indicators? Prior work on sustainability and resilience assessment suggests that robustness-oriented representations may be more decision-relevant than single deterministic values (Sesana et al., 2024; Tanguay et al., 2024).

RQ4 - Dynamic updating through DTs

When indicators are computed and updated within DT-based environments, how can provenance, versioning and validation be managed to avoid drift and loss of comparability over time (Petri et al., 2025; Luo et al., 2024)?

Mini operational example: flood- and heat-responsive indicators

Aiming at illustrating the applicability without introducing a full case study, a minimal operational example is presented below, applying the workflow introduced in Figure 1 to the case of urban flooding and urban heat, illustrating how the same sequence of data ingestion, alignment and indicator computation can be instantiated for concrete climate hazards. The example is intentionally procedural (computability-focused) and does not claim empirical validation of indicator values.

In this example, the digital artefacts required at each step correspond directly to the information requirements outlined in Table 2. Concretely, the BIM/IFC inputs must be enriched with the minimum attributes required for WLC mapping (e.g., construction assemblies, key system descriptors, and stable identifiers to link to EPD datasets), as well as basic functional zoning information to support resilience metrics. The flood and heat layers must then be aligned to asset geometries through explicit georeferencing and scale handling (e.g., aggregation rules when raster resolution is coarser than building/zone geometry, and consistent assumptions on reference elevation for flood susceptibility interpretation). Finally, temporal and scenario harmonisation is required to avoid false precision, ensuring that carbon and hazard indicators refer to compatible horizons and scenario choices (e.g., heat-related operational impacts under specified climate pathways).

Carbon performance indicators are derived from a BIM-based WLC assessment, including embodied emissions associated with building fabric and adaptation measures, as well as operational emissions influenced by increased cooling demand under projected heat conditions. These computations assume the availability of semantically enriched BIM models and scenario-based energy profiles, but do not require real-time monitoring or full operational calibration.

Climate risk indicators are computed by spatially linking asset geometries to pluvial flood susceptibility maps and urban heat metrics derived from remote sensing and machine-learning-based models. At this stage, the workflow relies on consistent spatial resolution and explicit scenario selection rather than on hazard model optimisation.

Resilience performance is expressed through simplified metrics such as functional downtime and recovery time following representative flood and heat events. These metrics are not intended as predictive estimates, but as comparative indicators that allow alternative design or adaptation options to be positioned relative to one another.

By following the workflow in Figure 1, the example demonstrates how carbon, flood and heat risk, and resilience indicators can be jointly computed under clearly stated assumptions. The resulting indicators support comparative reasoning across options, rather than optimisation, and make explicit where trade-offs and uncertainties enter the decision process.

Discussion

The proposed framework aims to respond to recurrent limitations observed in current digital climate assessment practices through the research questions introduced

previously. Rather than providing definitive solutions, the framework clarifies how integrated digital climate indicators can be constructed and interpreted under explicit conditions, and where their limitations remain.

Indicator correctness (RQ1) emerges primarily as an information-driven challenge. As illustrated by the workflow in Figure 1, the framework makes explicit that indicator validity depends on semantic completeness, spatial alignment and scenario consistency across heterogeneous digital inputs. This represents a clear advance over approaches in which carbon, flood or heat indicators are computed independently, often masking underlying assumptions. At the same time, the framework does not eliminate epistemic uncertainty: if information is incomplete or misaligned, indicators may still be internally consistent yet only partially representative. The contribution therefore lies in making such limitations visible rather than implicit.

Portability and interoperability (RQ2) are addressed by structuring indicators around shared information requirements rather than tool-specific implementations. Table 2 highlights how carbon, climate risk and resilience indicators rely on different datasets and modelling choices, many of which are context dependent. While this limits full transferability, the framework supports partial portability by enabling indicators to be recomputed consistently across projects, if information requirements are met. A remaining challenge concerns machine-learning-based flood and heat models, whose sensitivity to local training data constrains cross-context comparability and requires careful documentation.

Uncertainty and robustness (RQ3) are treated implicitly through the framework's emphasis on comparative rather than absolute indicator interpretation. As suggested by the operational example, integrated indicators are more effective in positioning design or adaptation options relative to one another than in providing precise predictive values. This shift aligns with recent work advocating robustness-oriented assessment in climate-resilient design but also raises challenges in communicating uncertainty without undermining decision confidence. The framework offers a structure for this communication, but methodological advances are still needed to operationalise uncertainty propagation across indicator families.

Dynamic updating through digital twins (RQ4) represents both an opportunity and a risk. DT-based environments enable indicators to be recalculated as new data become available, supporting adaptive decision-making over time. However, without explicit governance mechanisms, such as versioning, provenance tracking and validation rules, dynamic updating may compromise indicator comparability and trust. The framework highlights these risks by positioning updating as a conditional capability rather than an inherent benefit, underscoring the need for controlled integration rather than continuous recalculation.

The framework does not aim to provide empirical validation of indicator values, nor to define new standards, thresholds or regulatory metrics. Its purpose is to clarify the informational and alignment conditions under which integrated digital climate indicators can be computed and meaningfully interpreted.

Despite its potential, the framework has deliberate limitations: it does not harmonise underlying carbon, flood/heat, or resilience models, and comparability remains dependent on the transparency and context-dependence of adopted datasets and assumptions. Addressing these limitations requires empirical multi-context testing and governance mechanisms (e.g., provenance, versioning and validation rules), which are beyond the scope of this contribution.

Overall, the proposed framework enables a more transparent and structured engagement with carbon, flood and heat risk, and resilience indicators, while also exposing the practical and methodological challenges that remain. Its value lies less in resolving these challenges than in providing a coherent basis for addressing them in future empirical and methodological work.

Conclusion

This paper has addressed the challenge of linking mitigation and adaptation-oriented analyses in the built environment by proposing a framework for digital climate indicators that integrate whole-life carbon performance, flood and urban heat risk, and resilience metrics. While digitalisation has enabled unprecedented access to data and analytical tools, current workflows remain fragmented, limiting their ability to support climate-responsive and resilient design decisions.

Building on a structured review of recent literature, it is shown that the technical components required for integration, BIM-based carbon assessment, DT-enabled dynamic analysis, ML-based hazard modelling and resilience metrics, are already available, but rarely combined under explicit information requirements. By organising indicators into three families and articulating the alignment steps needed to compute them, the proposed framework clarifies where and why integration succeeds or fails. The workflow illustrated in Figure 1 and the information mapping in Table 2 provide a conceptual scaffold for moving from isolated analyses to coherent, decision-relevant indicators. The focus on urban flooding and urban heat has allowed the framework to be grounded in high-impact, data-rich hazards that are representative of broader climate challenges. The mini operational example demonstrates how integrated indicators can reveal cross-domain interactions and trade-offs that would remain hidden in siloed assessments, even without a full case study.

The lasting contribution of this work lies not in defining new metrics, but in reframing indicator development as an information-driven and methodologically explicit process. Taken together, the framework allows a first set of methodological answers to the proposed research questions to be stated. Regarding indicator correctness (RQ1), the paper clarifies that "correctness" is conditional on explicit information requirements and alignment steps: integrated indicators become fragile when BIM/IFC semantics are incomplete for WLC mapping, when hazard

layers are not spatially matched to assets, or when temporal/scenario assumptions are inconsistent. Regarding portability (RQ2), the framework supports recomputation across projects by making the required inputs and mappings explicit, but comparability remains constrained by context-dependence of datasets and by the transferability limits of flood and heat models. Regarding uncertainty (RQ3), the paper supports a robustness-oriented interpretation: the most defensible use of integrated indicators at early stages is comparative reasoning across options under stated scenarios, rather than absolute prediction. Finally, for dynamic updating (RQ4), the framework highlights that DT-enabled recalculation is useful only under governance mechanisms (provenance, versioning and validation rules) that preserve traceability and comparability over time. In this perspective, digital climate indicators should be treated as information-driven constructs whose validity depends on explicit assumptions, alignment conditions and decision context. By reframing indicator development around information requirements and integration workflows, this paper contributes a structured basis for linking carbon performance, flood and urban heat risk, and resilience within digital design and assessment processes. Future work will focus on applying the proposed framework to real urban case studies exposed to flood and heat stress, to test indicator computability, sensitivity to information completeness, and usefulness for comparing design and adaptation options. Such applications will be essential to further consolidate the framework and to support the responsible use of integrated indicators in climate-responsive and resilient design.

From a practical standpoint, these conclusions suggest that deployment-oriented work should treat information requirements and alignment procedures as first-class deliverables, alongside algorithmic components. For research evaluation, this implies reporting integration effort (e.g., BIM/IFC enrichment steps, spatial matching rules, scenario harmonisation choices, and governance overhead) as part of methodological transparency, rather than focusing solely on model accuracy.

Ultimately, advancing digital climate indicators requires not only better models, but clearer assumptions, shared information requirements and critical reflection on how indicators are used in practice.

Abstract

Weather disruptions endanger transport network operations and accessibility, hindering people's possibilities to reach opportunities and services. While most research focuses on infrastructure impacts, few studies have examined how different socioeconomic groups experience such disruptions. This paper introduces a comprehensive method for assessing transport resilience to extreme weather and includes a case study highlighting social disparities in access to healthcare services. The case study reveals that access to essential city services varies by socioeconomic strata and that extreme weather events can exacerbate inequalities.

Introduction

Maintaining physical connection between distant places has been fundamental to the functioning of societies and economies throughout history. Transport networks enable the movement of people and goods, serving as the backbone of economic activity and societal development (Zhang and Cheng, 2023). In recent decades, these infrastructure systems have faced significant challenges due to the increasing intensity and frequency of extreme weather events (Kurth et al, 2020). The disruptions caused by these events have had several implications, including economic losses, casualties, and physical and psychological health issues among affected populations (European Environment Agency, 2024).

Research on transport infrastructure resilience to extreme weather constantly operationalises resilience as a time-dependent property of service that combines (i) the ability to withstand or absorb a disruption, (ii) the capacity to adapt to new settings, and (iii) the ability to recover within acceptable time and cost envelopes (Bruneau et al., 2003; Li et al., 2020; Wassmer et al., 2024). Hence, resilience metrics are described in operational terms (e.g., speed, delays), network-topology terms (e.g., efficiency under link removal), accessibility terms (e.g., reachable opportunities), or monetised socioeconomic impacts (e.g., wage loss) (Afrin and Yodo, 2020; Faturechi and Miller-Hooks, 2014; Hadjidemetriou et al., 2022). As a consequence of this approach, the role of social disparities among affected communities is often overlooked.

For example, the operational approach to resilience treats performance metrics, such as time delays, as both the primary measure of impact and diagnostic tool for inferring management priorities. From operational approaches, a resilient transport network is resistant to disturbances and can recover rapidly in case of occurrence, ensuring traffic flow and reducing congestion (Ganin et al., 2017; Zhang et al., 2017). In this line, Rebally et al. (2026) assess the impact on traffic of the 2013 flood in Calgary (Canada) using HEC-RAS for flood modelling and SUMO for micro-scale traffic simulation, and demonstrate the extent to which the flooding event causes longer travel times and distances, and how the disruption leads to cascading impacts. Likewise, Liu et al. (2026) integrate the effects of flooding, reduced visibility, and traffic signal failures during extreme rainfall to evaluate network performance by estimating the average delay per time slice and a delay-based resilience index in a case study of Greater London. In these and similar studies, transport resilience is measured by observing or simulating operational degradation and recovery in traffic or service variables under specified meteorological conditions. This stance treats disruption impact as a departure from the original “steady-state”, and resilience as the shape of the performance-time profile, frequently summarised into a scalar “resilience index” for comparison across different scenarios (Achillopoulou et al., 2020; Zhang et al., 2024).

Scholars across fields and perspectives do not deny the importance of societies' ability to withstand shocks, but call for awareness of how that goal is pursued (Cutter, 2016). Uncritically applied, resilience may imply short-term stability at the cost of long-term vulnerability. However, if conceived critically, resilience can be aligned with transformative adaptation and social justice, thereby making communities safer and more equitable. In this line, a significant share of research in transport resilience has shifted from “traffic loss” to “activity loss”.

A major stream of research treats resilience and vulnerability to extreme weather events as changes in access (to opportunities, locations, services, etc.) rather than as changes in traffic speed, flow or time delays. In this approach, the impact of weather-related disruption is translated into the extent to which it elongates or interrupts effective connections between people and destinations, and resilience is evaluated by how rapidly and unevenly accessibility is restored or substituted (Martín et al., 2021). Accessibility metrics are frequently

integrated with link-removal experiments and hazard overlays. For example, Martín et al. (2021) compare how territorial accessibility is reduced under the cumulative exclusion of transport links through random removal, removal by criticality, and targeted removal in high-flood-risk areas. Other studies, like Farahmand et al. (2024) focus on metrics such as agency costs, user costs, and environmental costs to enable targeted investment through benefit-cost analysis. Overall, the methodological importance lies in integrating climate change factors and effectively coupling network criticality with hazard-informed failure mechanisms (Martín et al., 2021).

Further critical perspectives serve a crucial function in prompting the question: 'Resilience for whom and to what end?' (Cretney, 2014; Cutter, 2016). For example, little is said about prioritising emergency vehicles when recovering the level of service (Wassmer et al., 2024; Wu and Chen, 2023), or trips by road users trying to reach healthcare facilities.

A critical gap exists in leveraging existing methodologies to account for social disparities in access to essential services through the existing infrastructure, particularly in the context of weather-related disruptions. For this reason, this paper leverages transport modelling principles to investigate the effect of weather-related disruptions on trips to healthcare facilities across users from households with different socioeconomic strata. To achieve this, the proposed workflow, the required data and preprocessing procedures, model specifications, and the disruption experiment design are presented in the Methodology chapter. Then, a case study of a real midsize city in Colombia is presented, highlighting pre-existing disparities among households categorised as low-, mid-, and high-socioeconomic stratum households in access to healthcare services and how a flooding disruption can deepen these disparities.

Methodology

This paper leverages transport planning tools and data from Origin-Destination (OD) surveys to develop a reproducible workflow for estimating the impact of extreme-weather-related disruptions on groups of people with different income levels and trip purposes. The main steps in the workflow are (i) the construction of the model in Geographical Information Systems (GIS) of the city's road network, (ii) the simulation of the OD demand matrix distribution over the network under static traffic assignment, and (iii) the quantification of network performance and travel times for groups of interest for a baseline "as-is" scenario and a disrupted scenario.

Data and tools

The proposed workflow requires: (i) geographical network and zoning data; (ii) the demand OD matrices for the established zoning; and (iii) the disruption layer (i.e., flooding risk map). The network can be assembled from GIS vector layers representing nodes (i.e., intersections and connections between origins and destinations), links (i.e., roads), and zones (i.e., Transport Analysis Zones). This study employs AequilibraE for modelling and aligns data requirements with this tool (Camargo, 2015). However, other software can be used to build the model. Overall, network data can be accessed using OpenStreetMap (OSM), obtained from local transport authorities, or built from a basic geometric representation of the network. Table 1 summarises the network attributes that must be specified.

Table 1: Network attributes specification

Data	Format	Source(s)
Nodes (N)	Geometry	OSM
N_ID	ID number of node	
N_IsCentroid	1: is a centroid 0: is not a centroid	Computed
Links (L)	Geometry	OSM
L_NodeA	ID number of node A	
L_NodeB	ID number of node B	
L_Direction	1: from A to B 0: both ways -1: from B to A	
L_Distance	Length [m]	
L_Lanes (AB & BA)	Number of lanes	
L_Speed (AB & BA)	Speed [km/h]	Observed/ Estimated
L_Type	'Default' or 'Connector'	Computed
L_TravelTime (AB & BA)	Travel time [s]	Computed
L_Capacity (AB & BA)	Total capacity [PCU/h]	Computed
Zones (Z)	Geometry	OD survey – Transport Analysis Zones (TAZs)
Z_ID	ID number of zone	

OD demand matrices must be provided, including the origin zone (i), destination zone (j), and number of trips (from i to j). For this study, the static traffic assignment approach assumes a single network for Passenger Car Unit (PCU) assignment, so trips are computed by assigning 1.0 PCU to car trips and 0.4 PCU to motorcycle trips. Table 2 lists the fields required for the OD matrices.

Table 2: Fields required for OD matrices

Field	Format	Source(s)
Origin	ID number of zone	OD survey (individuals)
Destination	ID number of zone	
Trips	PCU/h	
Mode	'car' or 'motorcycle'	OD survey (households)
Others (e.g., income level, trip purpose, etc.)	-	OD survey

The preprocessing procedure includes verifying network connectivity (i.e., every link has a start and an end node; no nodes or links are isolated from the network; each zone has a centroid node; and each centroid node is associated with a connector link to the network). Also, some network attributes are either observed or computed from the available OSM data. Speed (free-flow) on links can be observed or estimated from the link road class (e.g., highway, local, collector, etc.), the topology of the network, and the traffic management systems (e.g., heavy signalling cities with many intersections and pedestrian crosswalks require a lower speed than metropolitan areas connected by major roads or highways). Travel time is computed based on link speed and distance, and capacity is assumed to be the standard value per lane (1800 PCU/h/lane).

The simulation requires that the OD matrices be balanced with the Production-Attraction (P-A) vectors (i.e., the total number of trips produced equals the total number of trips attracted). Trips from OD surveys are converted to PCUs using assigned mode-specific values and aggregated across fields of interest based on the available data (e.g., trip purpose, income level, etc.).

Model specification

The model follows the principles of a 4-step transport model for an urban setting (Ortuzar and Willumsen, 2024). However, the first three steps (i) trip generation, (ii) distribution, and (iii) mode choice are intentionally fixed to isolate the effects of the weather-related disruption on (iv) the assignment step. The network is represented as a graph for the car mode (or PCU), where the supply representation and cost function are given via the congested travel time on the links, which is computed post-assignment using the Bureau of Public Roads (BPR) as Volume-Delay Function (VDF) (Bureau of Public Roads, 1964):

$$t = t_0\left(1 + \alpha\left(\frac{v}{c}\right)^{\beta}\right) \quad (1)$$

Where for each link, t0 is the initial travel time defined using estimated/observed free-flow speed, v is the assigned flow, c is the capacity, and α and β are parameters of the BPR function that define how early and sharply congestion starts.

The model employs two different assignment steps. The initial assignment is made using the methodology All-or-Nothing (AoN) (Bureau of Public Roads, 1964) to ensure network connectivity. This is done by loading the entire demand onto a single least-cost path computed using the initial travel time (i.e., there is no feedback from congestion, as the paths are defined by the static cost). Once the model implements the AoN assignment, the model moves to the User Equilibrium (UE) assignment (Patriksson, 1994), which operationalises Wardrop's principle: no traveller can reduce their travel time by unilaterally changing routes, given the congestion created by everyone else. The UE assignment is an iterative procedure in which each iteration takes the current estimate of travel times on the network's links, finds the shortest path, assigns flows, updates travel times using the previously defined VDF function, and then repeats until the convergence criterion is met.

Modelling outputs

Once the OD matrix trips are assigned to the network, traffic flow (PCU/h) and travel times are obtained for each used link. Then, instead of determining resilience in terms of operational variables that average the experience across all the road users in the network, the travel time for every group defined by the previously chosen fields of interest (e.g., income level, trip purpose) can be computed using the initial OD trips matrix and the OD congested times matrix, as:

$$\bar{T}^{(g)} = \frac{\Sigma_i \Sigma_j D_{ij}^{(g)} T_{ij}}{\Sigma_i \Sigma_j D_{ij}^{(g)}} \quad (2)$$

Where g is the index for the groups made of chosen fields (e.g., higher income level travelling for work), Dij(g) is the demand for group g from the origin i to the destination j, and Tij is the congested time from i to j. Obtaining travel times for different user types is not only useful for acknowledging disparities between groups but also for understanding whether these disparities are exacerbated under disruption scenarios.

Disruption experiment design (flood scenario)

The disruption input is a polygon layer delineating high-risk areas for disruption (e.g., flooding). The disruption mechanism reduces link capacities in proportion to the length share of each link intersecting the risk areas, scaled by a scenario severity parameter. Flood share in links is computed as the percentage of the link's length that overlaps the flooding area. The capacity reduction rule induced, and the corresponding parameters are as follows:

$$cap_{flood} = cap_0(1 - severity \cdot flood_{share}) \quad (3)$$

Where cap_{flood} is the new capacity of the link to be used for the trip assignment, cap0 is the initial capacity considered for the baseline scenario, and the severity is a parameter that determines how the link's capacity is affected by the portion affected by the flood. However, a capacity floor is required to prevent convergence issues caused by ODs that are 4disconnected and cannot be assigned.

Case study

To test the proposed workflow, the case study compares a baseline assignment with a flooding scenario for Villavicencio, a mid-sized city of approximately 600.000 inhabitants and an urban centre spanning up to 70 km2, located in the eastern plains of Colombia. Using data from the Origin-Destination Survey conducted in the city in

2022, travel times for people from households in lower-, middle-, and higher socioeconomic strata whose purpose of travel is "health" are obtained. The results of the baseline scenario show the extent to which times differ across socioeconomic strata and how they change during a flooding-induced disruption across the network.

Figures 1 and 2 display the network (links only) and zoning (TAZs) of Villavicencio, highlighting flood-prone areas along the city's rivers, as well as the density of "health" trips production (Figure 1) and attraction (Figure 2).

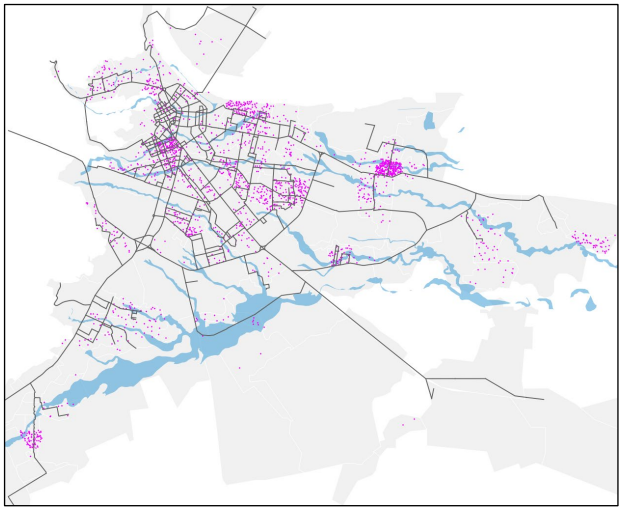

Figure 1: Villavicencio's network, flood-prone areas and "healthcare" trips production

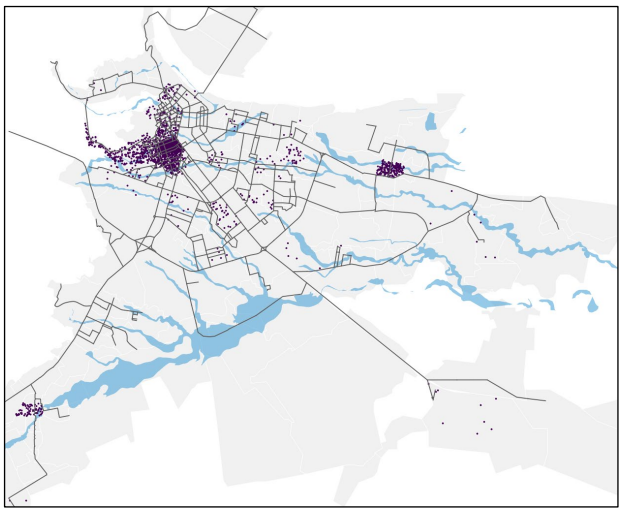

Figure 2: Villavicencio's network, flood-prone areas and "healthcare" trips attraction

The OD survey gathers information on approximately 11.500 trips that, after applying expansion factors, account for approximately 880,000 trips, of which 300,000 are by car or motorcycle (as driver or taxi user). Of the total number of trips, around 23.000 are made to access healthcare. However, despite the provision of health centres at each of the three corners of the triangular urban area, access remains unequally distributed across the population. In Colombia, households are classified in six socioeconomic strata based on their location, surrounding infrastructure, and access to public services (e.g., water and energy supply) (DANE, 2021). Table 3 shows the number of "health" trips by stratum (of the household) and mode during a day.

Table 3: Number of "health" trips by mode and level of income

Socioeconomic strata	Trips by car	Trips by motorcycle	Other modes
Low (1 & 2)	2786	1601	10244
Middle (3 & 4)	4125	1036	2870
High (4 & 6)	248	29	129

Since the methodology is based on static traffic assignment, using only trips observed during the highest-demand hour would produce a sparse OD matrix and exclude a substantial number of "health" trips. Therefore, the OD pattern was determined from a 3-hour period with the highest demand, which provides better spatial coverage of trips.

To ensure consistency with the static assignment framework, in which network capacities are represented on an hourly basis, the 3-hour OD matrix is converted into an equivalent peak-hour matrix using the expression:

$$T_{ij} = \frac{T_{1h,max}}{T_{3h,max}} \cdot T_{ij,3h} \quad (4)$$

The resultant OD matrix is converted to PCU by assigning 1.0 PCU to cars and 0.4 PCU to motorcycles. Along with the network properties, topology and scenario settings, traffic assignment is conducted to obtain congested travel times for every OD pair. The UE assignment is conducted using $\alpha = 0.3$ and $\beta = 2.0$. This procedure is carried out for the baseline and disruption scenarios, in which the link segments that intersect the flood-prone area (highlighted in Figure 3) are used to reduce capacity accordingly.

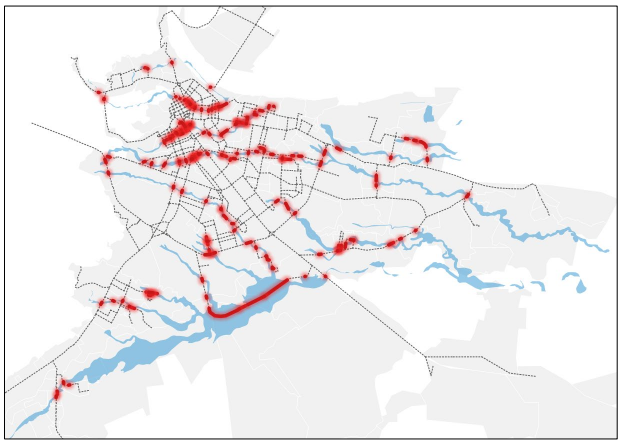

Figure 3: Network links intersecting flood-prone areas

Table 4 presents the number of health trips considered in the modelling period, and the estimated travel time across

the three socioeconomic strata groups and simulated scenarios.

Table 4: Travel time by scenario, socioeconomic stratum for "health" trips on the 3-hour peak period

Scenario	Socio-economic stratum	Health trips	Health trips avg travel time, min
Baseline	Low	1049	29.9
	Middle	950	17.9
	High	67	13.4
Disruption	Low	1049	31.8
	Middle	950	18.6
	High	67	13.9

The results of the baseline scenario show that access to health services in the city is not equally distributed among people across different socioeconomic strata. Even in the absence of disruption, the network topology and urban setting make it more difficult for most of the people in the city, who live in lower socioeconomic stratum households, to access health services in the city. People in this stratum experience travel times up to 67% longer than those in middle-stratum households and 123% longer than those in higher-stratum households.

In the flooding scenario, travel times are generally longer for all trips because congestion from reduced capacity on affected links impacts everyone. Nevertheless, the results show that the flooding does not have the same effect on everyone in the city. Travel time for trips by people in lower stratum households to access health services increases by 6.5%, by 3.9% for middle stratum households, and by 3.8% for high stratum households. Thus, the urban setting and transport network not only provide reduced access to healthcare services for people in less favourable conditions but also allow for this gap to be stretched during flooding-related disruptions.

Conclusions

This paper presents a methodology that leverages transport demand modelling tools and OD survey data to assess the impact of weather-related disruptions beyond traffic metrics. Although transport modelling is a valuable tool for understanding the observable effects of disruptions on transport operations, it is crucial to continue developing methodologies that translate traffic performance assessments into a more comprehensive resilience assessment of transport networks.

The main contribution of this paper is to advance this line by proposing a workflow that accounts for social disparities in the context of transport network disruptions. Further research can improve the methodology by incorporating tools that enable dynamic analysis of the disruption over time (e.g., agent-based modelling), while still examining the impact of these events on people rather than on assets or operations. Other disruptions can also be considered, as the methodology allows for the implementation of additional event types that ultimately affect the network's capacity.

The findings of the case study are inherently shaped by the specific socioeconomic conditions, land-use configuration, and transport network topology of Villavicencio. Accordingly, they should not be interpreted as evidence that weather-related disruptions intensify social disparities in the same way across all cities. Nevertheless, the proposed methodology is broadly transferable, as it can be implemented in many urban contexts where the input data typically used in demand estimation studies are available. Furthermore, rather than seeking to predict real-world conditions, the case study is intended to illustrate the potential of the proposed methodology to bring social disparities in accessibility to the forefront. In doing so, the methodology supports a more nuanced understanding of how inequalities influence access to vital urban services in normal conditions and how they may be amplified during disruptions such as flooding.

Finally, the policy implications for Villavicencio point to the need for further investigation into how residents from lower socioeconomic strata access healthcare facilities using modes other than private vehicles, particularly public transport, as these groups appear to depend more heavily on such modes for this type of trip. In this context, a prudent priority would be to strengthen transport connectivity under baseline conditions, since access to healthcare already appears more difficult for populations in less favourable circumstances, even in the absence of disruption. This suggests the value of complementing the city's efforts to expand the spatial provision of healthcare facilities across the urban area with a closer assessment of the transport connections serving those locations, as well as of healthcare-related services that remain concentrated in the city centre.

AUTOMATIC ROOF TYPE CLASSIFICATION FROM CITYJSON FOR RULE-BASED ROOF STRUCTURE'S MATERIAL QUANTITY ASSESSMENT

Dušan Isailović[1], Aleksandra Parezanović[1], Zorana Petojević[1,2], Nenad Brodić[1]
[1]University of Belgrade, Faculty of Civil Engineering, Serbia;

Abstract

Current city-scale material stock assessment relies on archetype-based estimation with limited geometric grounding or on city-to-BIM conversion workflows that are costly and sensitive to representation detail. Both hinder auditable roof typology and quantity derivation from open 3D city models. This paper proposes an interpretable CityJSON pipeline that merges roof meshes into planar patches, extracts roof metrics (area, projection, slopes, span), performs rule-based roof classification (flat/shed/gable/hip/complex), and computes rule-based roof-layer and timber quantities. On 88 labelled buildings, LoD2 achieves 0.716 accuracy (macro-F1 0.543); BIM comparison on six buildings supports feasibility. The contribution is a reproducible, explainable roof-to-quantities method with quantified LoD sensitivity.

Introduction

Cities are increasingly adopting open 3D city models to support planning, permitting, resilience, and environmental assessment. At the same time, circular construction and urban mining require reliable, scalable estimates of material stocks and flows in the existing building stock—especially for elements that dominate mass and replacement cycles. Roofs are a particularly relevant target: they strongly influence building performance and refurbishment needs, they exhibit recurring typologies that relate to structural systems, and they are well represented in city models through explicitly modeled roof surfaces. Yet turning city-model roof geometry into material quantities remains challenging because the data are typically triangulated, vary across levels of detail (LoD), and rarely contain construction semantics beyond coarse surface types.

Most existing city-scale quantity and stock assessment approaches rely on one of two strategies. The first is archetype-based estimation, where building age, use, and generic typologies are used to assign typical assemblies and materials. These methods can scale well, but their accuracy depends heavily on assumptions and weak geometric coupling. The second strategy is a geometry-driven pipeline that extracts measurements from 3D models, then maps them to construction rules. While promising, such pipelines must address practical issues: roof geometry is often fragmented into many small facets, different LoDs represent the same roof differently, and black-box methods (e.g., deep learning) can be difficult to audit when outputs directly drive normative structural selection and material take-offs.

This paper argues that, for city-scale roof material quantification, interpretability and robustness to representational variability are as important as raw classification accuracy. Instead of relying on end-to-end learning, we propose a deterministic workflow that explicitly links roof geometry to roof type labels and quantity-relevant metrics, enabling traceable propagation from input model to material quantities. The workflow uses CityJSON as an open and lightweight representation and focuses on (i) merging triangulated roof faces into planar roof patches, (ii) extracting roof metrics needed by rule-based quantity models, and (iii) classifying roof types using explainable geometric rules. Because LoD can substantially alter planar fragmentation and rule triggers, we explicitly evaluate the same classifier on both LoD2 and LoD3 representations of the same area to quantify typology stability and to support guidance on which LoD is more appropriate for operational quantity pipelines.

The method is demonstrated on a Belgrade test area with 88 manually labelled buildings. In addition, a subset of six buildings is reconstructed in BIM to provide baseline take-offs for validating rule-based roof-layer and timber quantities. Beyond reporting classification performance, we analyze how roof typology errors affect downstream material estimates—showing that some materials (e.g., timber) are relatively robust to subtype ambiguity, while others (notably concrete in flat-roof archetypes) are highly sensitive to flat/non-flat misclassification due to archetype switching.

Related work

3D city models as a basis for urban-scale assessment

Open 3D city models (CityGML/CityJSON) are increasingly used as a geometric backbone for city-scale analyses because they provide consistent building envelopes and semantic surface classes (e.g., RoofSurface) that can be processed automatically. CityJSON in particular has been positioned as a lightweight, developer-friendly encoding of CityGML concepts for practical processing workflows (Ledoux, et al., 2019). The Levels of Detail (LoD2, LoD3) used in such models follow the conceptual definitions of CityGML 3.0, where LoD2 represents generalized roof structures and LoD3 introduces detailed architectural

features such as dormers and roof superstructures (Open Geospatial Consortium, 2026).

Large-scale LoD2/LoD3 building models are commonly generated from airborne LiDAR and photogrammetric data using automated reconstruction pipelines that detect planar roof segments and infer roof topology (Haala & Brenner, 1999). These workflows often assign roof types explicitly as dataset attributes (e.g., *roofType* in CityGML), reflecting the inferred geometric archetype of the roof.

However, such attributes are not consistently available across datasets, are derived using dataset-specific assumptions, and are typically not designed for construction-oriented interpretation or material quantity estimation. As a result, relying directly on dataset-provided roof types may limit reproducibility and applicability across heterogeneous data sources.

Roof type inference from city models and remote sensing

Roof typology inference has been studied from multiple perspectives. A line of work targets roof shape classification for energy and solar potential assessment using machine learning on roof features, showing that roof-type prediction is feasible but sensitive to the quality and representativeness of training data and features (Mohajeri, et al., 2018). Other research infers roof type from sparse or derived building attributes, demonstrating that the "flat vs non-flat" decision can often be made robustly and that a small set of geometric attributes can be highly informative (Biljecki & Dehbi, 2019). Recent datasets and studies also highlight how roof typologies can be learned from CityJSON-labelled corpora, reporting roof classification performance in the 70–75% range across multiple European cities—comparable to the performance envelope observed in practical city-scale pipelines (Sitong, Chengzhi, Chi, & Qiuxian, 2023).

In parallel, deep learning approaches—often driven by aerial imagery—have been used to classify roof types (flat, gable, hip, etc.), benefiting from large training sets but typically offering limited traceability between the decision and the 3D geometry that will later drive construction quantities (Buyukdemircioglu, Can, & Kocaman, 2021). For applications such as material quantity estimation, where classification outcomes directly affect structural assumptions, interpretability becomes a critical requirement.

BIM–GIS integration and material stock/quantity assessment

A growing body of work addresses BIM–GIS integration for circular construction and city-scale material stock assessment. Recent studies combine remote sensing, 3D GIS and BIM to improve material estimation at building and element levels (Parezanović, Nadaždi, Isailović, Višnjevac, & Petojević, 2025). In the EC3 community specifically, approaches have also been proposed for converting 3D city models to BIM to support automated quantity take-offs (Dušan Isailović, Ana Nadaždi, Aleksandra Parezanović, Zorana Petojević, & Nenad Višnjevac, 2025). Complementary review work highlights interoperability challenges and the importance of consistent semantics in CityGML-based environments (Janisio-Pawłowska & Pawłowski, 2024).

At the urban scale, material stock datasets and frameworks commonly rely on city model geometry (footprints, heights, LoDs) combined with building attributes (age, typology, structural system) to compute material quantities (Pei, Biljecki, & Stouffs, 2022). While these approaches scale efficiently, they often rely on weak geometric coupling or require costly BIM conversion workflows.

Positioning of this paper

Across the literature, roof type inference is often treated as an intermediate step within 3D reconstruction pipelines or as a standalone classification task for applications such as solar potential assessment. In many operational datasets, roof types are already inferred during LiDAR- or photogrammetry-based reconstruction and may be available as attributes. However, these attributes are not consistently available, are dataset-specific, and are not designed for construction-oriented interpretation or material quantity estimation.

The novelty of this work lies not in roof classification alone, but in integrating roof plane extraction, geometric metric derivation, typology inference, and rule-based material quantity estimation into a single interpretable and auditable workflow. In this context, roof typology serves as a bridge between geometric representation and construction semantics, enabling traceable propagation from city-model geometry to material quantities.

Furthermore, this work explicitly investigates the sensitivity of roof typology inference to different Levels of Detail (LoD2 vs LoD3), highlighting how geometric representation affects both classification stability and downstream quantity estimation. This connection between representation, semantics, and quantities remains underexplored in existing literature.

Method

The proposed workflow is an interpretable, city-scale pipeline that derives roof typology and quantity-relevant metrics from an open 3D city model. For each building, we:

1. Extract roof surfaces from CityJSON,
2. Merge triangulated roof faces into planar roof patches ("roof planes"),
3. Derive a roof-plane adjacency representation from shared edges,
4. Compute roof metrics required for material quantity rules,
5. Classify roof type using explicit geometric rules,
6. Map the classified roof type and span proxy to a normative structural archetype and compute timber quantities, and
7. Compute additional roof-layer quantities from roof area/projection using rule tables.

The workflow is executed primarily on LoD2; LoD3 is used to discuss representation-induced fragmentation effects and the resulting differences in typology stability.

The workflow uses:

- Cityjson lod2 (primary) and lod3 (comparative) building models for the Belgrade test area;
- Rule-based roof classifier implementation developed from the original roof_classifier.py into the lod2-selected version;
- Manual roof-type labels for evaluation; and
- Normative tables and rules for timber roof structure selection and quantity factors, plus roof-layer material rules.

The workflow produces:

- Roof type label (roof_type_automatic) and QA indicators;
- Roof metrics (roof area, horizontal projection area, slope statistics, plane count, span proxy);
- Normative structural type;
- Timber volume estimate;
- Roof-layer quantities; and
- For a BIM-modeled subset, a comparison against BIM-derived baseline take-offs.

For each building, roof faces are selected primarily using CityJSON semantics (e.g., RoofSurface), ensuring the method remains consistent with semantic organization where available. When semantics are incomplete, a geometric fallback can be applied by selecting upward-facing faces within the upper elevation band of the building envelope (reported as a limitation and used only when necessary).

Planar roof patch (roof plane) extraction

City models typically represent roofs as triangulated meshes; direct triangle-level reasoning is unstable and inflates the number of planes. Therefore, roof faces are merged into larger planar patches ("roof planes") using a deterministic clustering procedure:

1. Per-face geometry: for each face, compute a unit normal vector, face area, and a representative point (e.g., centroid).
2. Plane merging: faces are clustered into planes using (a) normal similarity (angle between normals below a tolerance) and (b) coplanarity (distance from the face representative point to the candidate plane below a tolerance). This normal + coplanarity merging prevents parallel-but-offset patches from being merged, which is important for detailed models where small roof features can create offset but parallel surfaces.
3. Plane attributes: for each roof plane, compute total area (sum of merged face areas), area-weighted mean normal, and slope angle relative to horizontal.

Roof-plane adjacency representation and ridge/valley proxies

To capture roof topology beyond plane counts and slopes, plane adjacency is derived from shared edges between faces. An edge map is created over roof faces; each undirected edge is stored using a canonical orientation (e.g., smaller vertex index first) to make adjacency deterministic. Two planes are adjacent if any face from plane A shares an edge with any face from plane B. Shared-edge lengths are accumulated per plane pair and aggregated per roof.

For each shared edge between two planes, a dihedral sign proxy is computed using plane normals and a consistently oriented edge vector. Edges classified as convex act as ridge proxies and concave edges act as valley proxies. These proxies support explainable complexity assessment and can be used for detailing-related quantity rules (e.g., ridge/valley flashing length), even if the present paper focuses primarily on area-driven roof layers and structural timber.

Roof metrics extraction

For each building roof, we compute a set of metrics used both for classification and for quantity estimation:

- Roof surface area: sum of roof plane areas.
- Horizontal projection area: projection of roof surfaces onto the horizontal plane; implemented to support polygon holes (outer ring minus inner rings) where applicable.
- Slope metrics: maximum slope of the steepest plane (and optional area-weighted summaries).
- Plane count: number of roof planes after merging.
- Span proxy: derived from the building footprint, obtained by selecting the largest near-base horizontal ring and computing a conservative span proxy (typically the shorter side of the footprint bounding rectangle).

Quality indicators (QA) are computed to support interpretation (especially for LoD3): non-manifold edge counts and tiny-plane statistics (number and area ratio of very small planes). These indicators do not change the LoD2 operational method, but help explain LoD3 fragmentation effects.

Rule-based roof type classification

Roofs are classified into a construction-oriented typology set: gable, shed, complex, flat, and hip (Figure 1). The classifier is intentionally rule-based to remain interpretable and auditable at city scale and to support downstream normative mapping and material computations.

Figure 1: Roof types for automatic classification.

The concept used for the decision logic is as follows:

1. Detect flat roofs based on near-horizontal slope conditions (including robust handling of small steep facets);
2. Detect shed roofs by a single dominant pitch/orientation;
3. Detect mansard roofs by the coexistence of shallow and steep planes above area thresholds;
4. Separate gable and hip using plane orientation dominance and adjacency structure; and
5. Assign complex as a conservative fallback when rules are inconclusive or roofs are irregular/fragmented.

LoD2 is used as the primary input because its roof geometry is typically less fragmented and more stable for plane merging and rule triggers. LoD3 introduces additional small facets (dormers, chimneys, parapets), inflating plane counts and disturbing dominance logic, therefore LoD3 is treated as comparative evidence.

Mapping roof types to normative structural classes

To estimate timber quantities, each roof is mapped to a normative structural class based on roof type and the span proxy L. The mapping follows normative span intervals and a deterministic tie-breaking strategy: where multiple classes cover the same span, the class with minimum timber consumption is selected; gaps are resolved by selecting the next stronger admissible class; spans above the maximum use the strongest available class as an upper approximation.

For hip roofs, timber consumption is approximated using gable-roof normative rules at this level of abstraction. Complex roofs are treated as gable-equivalent for baseline normative selection by span, with an additional correction factor representing geometric complexity (derived from concave-edge intensity proxies).

Roof structure's material quantity estimation

Timber volume is computed as:

$$V_{timber} = A_{proj} \times r_{norm} \times k \quad (1)$$

where A_{proj} is the horizontal projection of the roof's area, r_{norm} is the normative timber consumption rate (m³ per m² of horizontal projection) for the selected class, and k is a correction factor (k = 1 by default; k > 1 for complex roofs based on complexity bins).

This formulation couples geometry-derived area and span to normative structural selection and complexity-aware adjustments.

Concrete quantity in flat roof structures is computed much more straightforward, as:

$$V_{concrete} = A_{roof} \times d_{slab} \quad (2)$$

where A_{roof} is the roof's area, and d_{slab} is the concrete slab thickness.

Pseudocode below provides the step-by-step operational detail.

FOR each Building in CityJSON:

1) Extract roof faces

- *Prefer semantic RoofSurface faces*
- *Else fallback: upward-facing faces near top elevation*

2) Compute per-face geometry

- *normal, area, centroid, horizontal projection area (holes supported)*

3) Merge faces into roof planes

- *cluster by (normal angle tolerance) AND (coplanarity distance tolerance)*
- *compute plane area + plane slope*

4) Build plane adjacency + ridge/valley proxies

- *construct deterministic shared-edge map (canonical edge key)*
- *for each shared edge between different planes:*
  - *accumulate shared-edge length*
  - *classify as convex (ridge proxy) or concave (valley proxy)*

5) Compute roof metrics + QA

- *roof area, projected area, max slope, plane count*
- *footprint span proxy from largest near-base horizontal ring*
- *QA: non-manifold edges, tiny-plane statistics*

6) Classify roof type (rule-based)

- *decide flat vs non-flat from slope*
- *detect shed / gable / hip using plane counts, dominant plane areas,*
- *slope distribution, concave ratio, and footprint aspect ratio*
- *else fallback: complex*

7) Export per-building results (roof_type + metrics)

Implementation notes and reproducibility

All processing is deterministic with explicit parameter thresholds (e.g., plane normal tolerance, coplanarity tolerance, minimum shared-edge length, and slope cutoffs). Intermediate outputs (roof planes, QA indicators, roof metrics) are exported alongside final labels and quantities to support diagnosis and sensitivity analyses, enabling reproducibility and auditability.

Data and case study

Study area and datasets

The case study is conducted on a dense, mixed building block in Belgrade (Serbia), selected as a representative urban fabric with a wide variety of roof geometries (flat roofs, mono-pitch roofs, and multi-patch roofs with local superstructures). The study area is used to demonstrate an end-to-end workflow for:

- Automatic roof type inference from an open 3D city model,
- Roof metrics extraction, and
- Rule-based material quantity assessment for roof layers and the timber roof structure.

Two CityJSON datasets are used for the same spatial extent: a LoD2 model, where roof geometry is represented with a cleaner set of roof facets, and a LoD3 model, which additionally encodes façade openings and finer roof

superstructures (Figure 2). While the classifier can be executed on both datasets, LoD2 is treated as the primary operational input, and LoD3 is used to illustrate how increased geometric detail can affect planar fragmentation and typology stability.

The evaluation dataset contains 88 buildings with manually assigned roof type labels. A subset of six buildings was further modelled in BIM to obtain baseline take-offs for validating roof structure quantities and timber volumes (Figure 3).

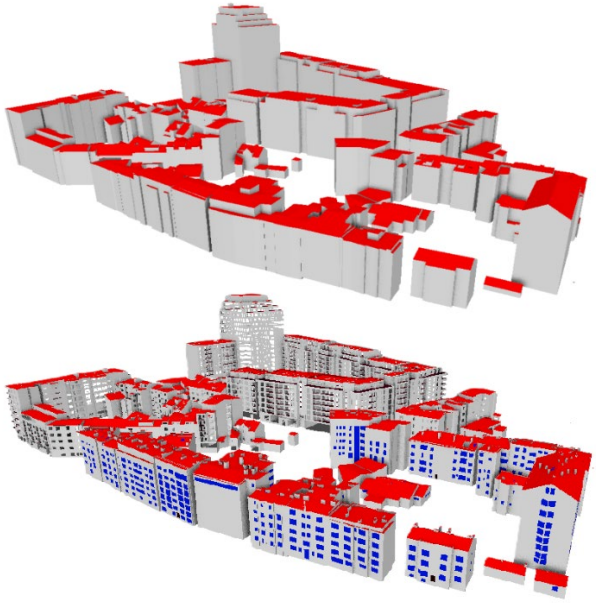

Figure 2: 3D City models of the case area at various level of detail: CityJSON models at LoD2 (top), and LoD3 (bottom).

3D city models (CityJSON LoD2 and LoD3)

Both city models follow the CityJSON data model and represent buildings as boundary representations with triangulated surfaces. Roof faces are semantically identifiable (RoofSurface) and are used as the primary input for plane merging, metric extraction, and roof type classification. The two levels of detail differ mainly in the degree of geometric fragmentation: LoD2 tends to express roofs as a smaller number of planar patches, whereas LoD3 introduces additional small facets (e.g., dormers, chimneys, parapets), which increases the number of planes after merging and may perturb dominance-based rules. This LoD effect is reported in the Results section through LoD2–LoD3 prediction agreement–

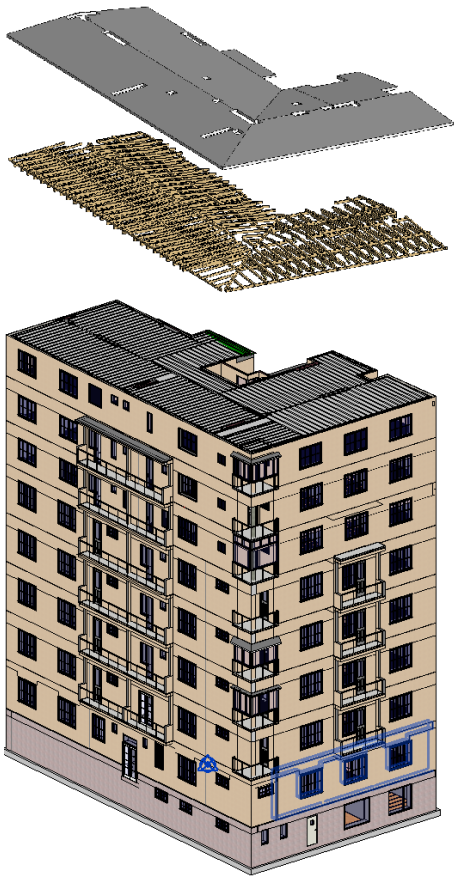

Figure 3: BIM model of a residential building from the case area needed for validation of a roof structure's material quantity computation.

Results

Roof type classification

The evaluation uses 88 labelled buildings from the Belgrade test area. Using CityJSON LoD2 as input, the classifier achieves an overall accuracy of 0.716 and a macro-averaged F1-score of 0.543. Running the same code on the LoD3 model yields an accuracy of 0.557 and macro-F1 of 0.403. Agreement between LoD2 and LoD3-based predictions is 0.534 (Cohen's $\kappa = 0.375$), indicating that the choice of LoD representation affects typology stability even when the algorithm is unchanged.

Table 1 (LoD2) and Table 2 (LoD3) report per-class precision/recall/F1 against manual labels, while Table 3 and Table 4 provide the corresponding confusion matrices. Across both LoDs, errors concentrate on (i) flat vs non-flat ambiguity and (ii) gable vs complex ambiguity.

Extracted roof metrics and their role in the pipeline

For each building, the workflow reports plane count, maximum roof slope, roof area, horizontal projection area, and a footprint span proxy. These metrics provide the inputs to the material quantity rules and enable explainable links between geometry, typology, and quantities.

Table 1: Roof type classification performance using CityJSON LoD2 as input (automatic predictions vs manual labels). Support denotes the number of labelled buildings per class; macro-averages are computed across classes.

Roof type	Support (n)	Precision	Recall	F1
flat	16	1.000	0.562	0.720
shed	24	1.000	0.833	0.909
gable	12	0.400	0.333	0.364
hip	1	0.000	0.000	0.000
complex	35	0.625	0.857	0.723
Macro avg	88	0.605	0.517	0.543
Overall accuracy	88			0.716

Table 2: Table 2. Roof type classification performance using CityJSON LoD3 as input (same code and rules; automatic predictions vs manual labels). Differences relative to Table 1 quantify sensitivity to LoD representation.

Roof type	Support (n)	Precision	Recall	F1
flat	16	0.643	0.562	0.600
shed	24	0.647	0.917	0.759
gable	12	0.000	0.000	0.000
hip	1	0.000	0.000	0.000
complex	35	0.737	0.400	0.519
Macro avg	88	0.405	0.376	0.403
Overall accuracy	88			0.557

Table 3: Confusion matrix for LoD2-based classification (rows: manual labels; columns: automatic predictions).

Pred flat	Pred shed	Pred gable	Pred hip	Pred complex
9	0	0	0	7
0	20	2	0	2
0	0	4	0	8
0	0	0	0	1
0	0	4	1	30

Table 4: Confusion matrix for LoD3-based classification (rows: manual labels; columns: automatic predictions).

Pred flat	Pred shed	Pred gable	Pred hip	Pred complex
9	5	0	0	2
0	22	0	0	2
0	9	0	0	3
0	1	0	0	0
5	6	0	0	24

Implications for material quantities

Using identical quantity rules, the mean absolute difference between automatic and manual estimates is 4.32 m³ for timber (mean relative error 0.033) and 7.80 m³ for concrete (mean relative error 0.385, computed where manual concrete > 0). Table 6 summarizes this sensitivity.

Concrete quantities are particularly sensitive to the flat/non-flat decision: 5 of 14 manually labelled flat roofs are classified as non-flat in the LoD2-based predictions and 8 of 14 in the LoD3-based predictions (Table 5). Because concrete quantities are only computed for flat-roof structural archetypes, these misclassifications force the concrete estimate to zero and therefore dominate concrete errors.

For the BIM validation subset (n=6), Table 7 compares automatic and manual rule-based quantities against BIM-derived baselines. Across buildings where a BIM baseline is available, the mean relative error of the automatic estimate is 0.647 for timber and 0.600 for concrete (where BIM baseline > 0). Remaining discrepancies are expected to reflect both typology errors and differences in modelling scope between rule-based archetypes and BIM take-offs.

Table 5: Agreement between LoD2- and LoD3-based automatic roof type predictions, including flat-roof sensitivity. Cohen's κ complements exact agreement by adjusting for chance agreement.

Metric	Value
Exact agreement (LoD2 vs LoD3 predictions)	0.511
Cohen's κ (LoD2 vs LoD3 predictions)	0.335
Flat roofs misclassified (LoD2 predictions)	1/10
Flat roofs misclassified (LoD3 predictions)	3/10

Table 6: Sensitivity of rule-based material quantities to roof type classification (automatic vs manual labels, same quantity rules). Concrete quantities are evaluated only for roofs mapped to flat-roof structural archetypes.

Material / group	MAE (m³)	Mean rel. error	Interpretation
Timber (all buildings)	3.22	0.023	Stable for pitched roofs; differences mainly driven by typology/normative-type mapping
Concrete (flat-roof archetypes only)	15.48	0.400	Highly sensitive to flat/non-flat decision; misclassification forces concrete estimate to 0

Table 7: BIM validation subset (n=6): automatic and manual rule-based quantities compared against BIM-derived baseline take-offs. Remaining differences may reflect both typology errors and modelling-scope differences (e.g., inclusion of secondary timber members).

Building ID	Manual roof type	Auto roof type (LoD2 pipeline)	# planes	Max slope (°)	Timber Auto (m³)	Timber Manual (m³)	Timber BIM (m³)	Concrete Auto (m³)	Concrete Manual (m³)	Concrete BIM (m³)
Cv_90	complex	complex	5.0	6.54	22.87	22.87	19.28	0.0	0.0	0.0
Dl_55	gable	complex	6.0	32.85	15.64	17.37	16.48	0.0	0.0	0.0
StGl_34	gable	complex	5.0	29.83	13.17	10.98	4.07	0.0	0.0	0.0
StGl_36	complex	complex	9.0	45.91	16.47	16.47	18.57	0.0	0.0	0.0
Dl_28	flat	complex	6.0	18.16	36.23	0.0	0.0	0.0	68.11	67.14
Dl_57	flat	flat	2.0	2.54	0.0	0.0	0.0	8.42	8.42	10.52

Discussion

Interpreting classification performance and error structure

The results suggest that an interpretable, rule-based classifier can support operational roof typology inference at city scale when applied to a semantically structured LoD2 CityJSON model. On the 88-building dataset, LoD2 classification achieves 0.716 overall accuracy with a macro-averaged F1 of 0.543, indicating that several roof types exhibit distinctive planar signatures, while performance remains uneven across classes.

Two ambiguity families dominate. Flat vs non-flat errors arise when small steep facets on otherwise flat roofs (e.g., parapets or technical housings) affect slope-based triggers even after robustness filtering. Gable vs complex errors occur for multi-part roofs (annexes, terraces, multiple ridges), where "complex" acts as a conservative fallback suggesting that a single roof archetype may be insufficient without segmentation.

Why LoD2 is operationally preferable, and what LoD3 adds

LoD2 is operationally preferable because it preserves the primary roof shape with less fragmentation, while LoD3 adds superstructures and small facets that perturb dominance-based rules. This representational sensitivity is visible in the LoD2–LoD3 agreement statistics (0.511 exact agreement, $\kappa = 0.335$), indicating only moderate stability when the algorithm is unchanged but the geometric representation differs. LoD3 is therefore best treated as diagnostic evidence motivating generalization/feature suppression or a "structural roof surface" abstraction.

Effects of typology errors on material quantities

Typology errors propagate asymmetrically into quantities. Timber estimates are comparatively stable because most non-flat types map to pitched-roof families and are driven primarily by projection area and span-based normative selection; this is reflected in a timber MAE of 3.22 m³ (mean relative error 0.023) between automatic- and manual-driven estimates under identical quantity rules.

Concrete is highly sensitive because it is computed only for flat-roof archetypes; misclassifying a flat roof as non-flat forces the concrete estimate to zero and creates step-change errors. Accordingly, concrete shows a larger MAE of 15.48 m³ (mean relative error 0.400, computed where manual concrete > 0). For city-scale accounting, improving the flat/non-flat decision (e.g., area-weighted flatness indicators rather than max-slope triggers) is likely to yield larger downstream gains than refining pitched-roof subtypes.

Interpretable rules vs. end-to-end deep learning

The rule-based approach is appropriate here because it provides traceability from geometry → typology → archetype → quantities, is data-efficient when labelled city-scale roof datasets are limited, and aligns naturally with normative quantity rules. Deep learning remains a useful complement, e.g., as a lightweight model applied only to ambiguous cases (near flat thresholds or "complex" candidates) or as a calibration layer for threshold tuning.

Limitations and targeted improvements

Three limitations follow from the error modes: (1) single label per building roof, which motivates roof-instance segmentation; (2) fragmentation sensitivity, suggesting area-weighted flatness indicators rather than max-slope triggers; and (3) validation scope, since the BIM subset (n=6) supports feasibility but should be expanded for stronger generalisation claims.

Conclusions

This paper presented an interpretable CityJSON-based workflow for automated roof type classification and roof metrics extraction, enabling rule-based estimation of roof material quantities at city scale. Using a Belgrade test area, the approach demonstrated that a rule-driven classifier can provide reliable roof typology inference when applied to a semantically structured LoD2 city model, while simultaneously producing the geometry-derived parameters required for downstream quantity

rules (roof areas, projected areas, slope statistics, plane counts, and a footprint-based span proxy).

The results show that classification errors are structured rather than random. Misclassifications concentrate on flat versus non-flat ambiguity caused by small steep facets on otherwise flat roofs and gable versus complex ambiguity for irregular or multi-part roofs. Importantly, the study quantified how such typology errors propagate to quantity estimation: timber volume estimates remain comparatively stable across non-flat typologies, whereas concrete quantities are highly sensitive to flat roof recall because flat/non-flat decisions control whether the flat-roof archetype branch is applied at all.

A key methodological takeaway is that LoD selection matters. While the same classifier can be executed on LoD3, LoD2 provides a more stable basis for city-scale roof typology inference due to reduced geometric fragmentation. LoD3 is therefore best interpreted as a complementary dataset for diagnosing representation-induced instability and motivating generalization and segmentation strategies.

Future work

Future work will prioritize:

1. Roof instance segmentation to handle buildings with multiple roof components (main roof vs annex), reducing “complex” fallbacks and improving quantity mapping;
2. Lod3 generalization to suppress/aggregate superstructure facets into a stable “structural roof surface” prior to classification; and
3. Improved flat-roof robustness using area-weighted flatness indicators to reduce flat/non-flat errors that dominate concrete quantities.
4. In addition, we will expand validation beyond six BIM baselines and report uncertainty via sensitivity analysis over key thresholds and normative mappings.

EXPLORING FLOOD VULNERABILITY PATTERNS AND RESIDENTIAL FLOOD IMPACTS IN URBAN ENVIRONMENT

Hyun Jeong Koo[1] and Vassiliki Demetracopoulou[2]
[1]Wayne State University, United States of America
[2]Rutgers University

Abstract

This study analyzes FEMA flood insurance claims and Zillow housing data in Detroit, United States, using ZIP-code-level metrics and damage-based quartiles to identify neighborhood-scale spatial patterns. Results show statistically significant differences in housing price and claim frequency across damage quartiles, with higher-damage ZIP codes characterized by lower housing values and more frequent flood claims. Housing characteristics showed moderate correlations with flood damage but were insufficient preditors in regression models. By jointly examining flood damage and housing characteristics at the neighborhood scale, this study advances understanding of residential flood vulnerability and provides evidence to support more informed planning and mitigation efforts.

Introduction

Urban flooding has increased in frequency and severity in recent decades, driven by climate change, urbanization, and aging infrastructure, with wide-ranging impacts on transportation systems, utilities, and housing. In the United States, older urban centers are particularly vulnerable due to legacy stormwater systems, high impervious surface coverage, and development patterns that predate modern flood management standards (US EPA, 2021; ASCE, 2025). These conditions contribute to recurrent flood damage, including roadway inundation, service disruptions, and residential property losses.

Vulnerable and low-income communities are often disproportionately affected by urban flooding, as housing characteristics such as older structures, basement units, and limited floodproofing intersect with a reduced capacity to afford repairs or mitigation measures (Cutter et al., 2003; Wing et al., 2022). As a result, urban flooding represents not only an infrastructure resilience challenge but also a mechanism through which existing social and economic inequities are intensified.

Despite increasing attention to urban flooding and social vulnerability, empirical research remains limited on how flooding impacts intersect with housing and residential characteristics at the neighborhood scale. This study addresses this gap by examining relationships between flooding indicators and housing characteristics in Detroit, Michigan, using FEMA flood insurance claims and Zillow housing data. Detroit provides a critical case for analyzing urban flooding dynamics due to the combined effects of aging infrastructure, extensive impervious surfaces, climate-driven precipitation extremes, and persistent socioeconomic vulnerability. By jointly analyzing flooding indicators, such as total flood damage derived from FEMA claims, and housing characteristics, such as average housing price and built year obtained from Zillow, this research advances neighborhood-scale understanding of urban flood vulnerability and supports more equitable flood mitigation and housing resilience strategies.

Literature review

Urban flooding is primarily driven by short-term or continuous rainfall that exceeds the capacity of the drainage system (Liu et al., 2020; Qi et al., 2020). Unlike traditional flood hazards, urban flooding is strongly shaped by land-use patterns, impervious surface coverage, drainage system design, and infrastructure condition. Climate change has further intensified urban flooding by increasing the frequency and magnitude of short-duration, high-intensity precipitation events (IPCC, 2021). Numerous studies have documented rising flood-related damages in U.S. cities, including transportation disruptions, property losses, and repeated service outages (Wing et al., 2022).

A substantial body of literature has demonstrated that flood impacts are unevenly distributed across populations. Social vulnerability theory emphasizes that socioeconomic characteristics, such as income, race, age, and housing tenure influence exposure, sensitivity, and recovery capacity during hazard events (Cutter et al., 2003; Cutter et al., 2008). In the context of flooding, lower-income and marginalized communities often face higher exposure to flood hazards and experience greater difficulty recovering from flood-related losses.

Recent large-scale studies have strong evidence of systematic inequities in flood risk and damage across the United States. Wing et al. (2022) showed that socially vulnerable populations are disproportionately exposed to flood risk, even after accounting for physical flood hazard condition. Kousky (2018) further noted that limited access to insurance, savings, and credit constrains post-flood recovery, leading to cumulative and compounding

losses over time. These inequities are particularly pronounced in cities such as Detroit, where historical disinvestment and infrastructure decline intersect with contemporary climate risks.

Housing characteristics play a critical role in shaping flood vulnerability, yet they remain underexplored relative to broader socioeconomic indicators. Prior research has shown that older housing stock is often more susceptible to flood damage due to aging materials, basement configurations, and limited incorporation of flood-resilient design features (Elliott & Clement, 2017; Tate et al., 2021). Older homes are also more likely to be served by combined sewer systems, increasing exposure to sewer backups and surface flooding during heavy rainfall events.

Housing value has been identified as an important indicator for both structural condition and adaptive capacity. Lower-value housing is often associated with deferred maintenance, limited floodproofing, and reduced access to resources for mitigation or repair (FEMA, 2023; Kousky, 2018). Several studies have documented higher relative flood losses in lower-income or lower-value housing areas, even when controlling for hazard intensity (Wing et al., 2022; Shokry et al., 2022). However, much of this work relies on modeled flood exposure or survey-based vulnerability indices rather than observed damage data.

Despite growing recognition of the role of housing in flood vulnerability, relatively few studies have empirically linked observed flood damage with neighborhood-scale housing characteristics using claims-based data. Existing research often focuses on floodplain exposure, hydrologic modeling, or county-level socioeconomic indicators, which may obscure localized patterns of residential vulnerability within cities (Tate et al., 2021). Moreover, while FEMA's National Flood Insurance Program (NFIP) data have been used extensively to study flood losses, they are less frequently combined with independent housing datasets to examine structural and economic housing attributes at spatial scales.

This study addresses this gap by examining how observed flood losses relate to housing characteristics in a legacy urban context, using FEMA flood insurance claims and housing data in the City of Detroit.

Research methodology

To achieve the goal of this study, two primary datasets were used: (1) FEMA National Flood Insurance Program (NFIP) residential claims for the City of Detroit, which provide information on total building and contents losses for flood-affected properties, and (2) publicly available housing data from Zillow that include parcel-level characteristics such as built year, estimated housing value, and selected structural attributes. These datasets were selected because they offer complementary perspectives. NFIP claims capture observed flood damage and loss outcomes, while Zillow housing data provides descriptive indicators of neighborhood housing stock, including housing prices and the year of construction. The Zillow housing data were obtained in 2024.

Both datasets underwent systematic preprocessing before analysis. NFIP records were screened to remove entries with incomplete flood damage information. Housing data were similarly cleaned by excluding parcels with missing year built, estimated value, or location attributes. Duplicate records, unmatched parcels, and entries lacking ZIP code identifiers were removed to ensure consistency and data quality across datasets.

After preprocessing, the two datasets were spatially joined using ZIP code identifiers, enabling aggregation of parcel-level housing attributes with ZIP-level flood damage data (Table 1). This process produced a unified dataset suitable for neighborhood-scale analysis while retaining comparability of housing characteristics (e.g., year built and housing value) across geographic areas. ZIP codes were then grouped into quartiles based on total flood damage, representing increasing levels of flood impact. This quartile-based stratification enabled systematic comparisons across damage-intensity groups and supported subsequent statistical analyses.

Table 1: Zip-code-level variables dataset

Variables	Definition	Source
Total Flood Damage	Sum of building and contents losses for claims in each ZIP Code	FEMA
Number of Losses	Count of residential claims per ZIP code	FEMA
Water Level	Average reported flood water depth associated with residential claims	FEMA
Average Housing Price	Mean Zillow housing value estimate per Zip code	Zillow
Average Built Year	Mean built year of residential parcels per ZIP code	Zillow
Average Frontage Length	Mean frontage length for parcels in each Zip code	Zillow

The study employed a multi-step analytical framework to examine relationships between neighborhood housing characteristics and flood losses. First, correlation analysis quantified linear associations between flood damage and key variables, including water level, housing price, and year built. Second, one-way analysis of variance (ANOVA) tests assessed whether housing characteristics differed significantly across four damage-based quartile groups. Third, regression models were estimated to evaluate the explanatory power of housing attributes in predicting total flood damage. Finally, an unsupervised machine learning approach (i.e., clustering analysis) was applied to identify data-driven neighborhood groupings based on flood damage and housing characteristics.

This integrated methodological approach supported both exploratory and inferential analyses, enabling a structured assessment of the relationships between neighborhood housing characteristics and flood impacts at the neighborhood scale.

Data analysis and results

Total flood damage and the number of NFIP residential claims varied substantially across Detroit ZIP codes, indicating pronounced spatial heterogeneity in flood impacts. Descriptive analyses indicated that ZIP codes with greater flood damage generally contained older, lower-value housing, suggesting that housing age and value may be associated with disproportionate flood impacts. These patterns were subsequently examined using correlation analysis, one-way ANOVA, regression modeling, and K-means clustering.

(1) Correlation analysis

Pearson correlation coefficients were calculated to assess the strength and direction of relationships between total flood damage and housing-related attributes (Table 2). The analysis revealed no strong linear relationship between average water level and total damage ($r = -0.148$), indicating that water depth alone does not explain ZIP-level differences in losses. This finding is consistent with prior research indicating that factors such as housing condition, age of the housing stock, drainage performance, and neighborhood infrastructure can substantially influence flood impacts beyond hydrologic intensity alone (Cutter et al., 2008; Kousky, 2018; Wing et al., 2020).

A moderate negative correlation between housing price and total damage ($r = -0.379$) indicates that lower-value housing areas experienced higher cumulative flood losses. This pattern suggests that neighborhoods characterized by older or lower-value housing may be more susceptible to flood damage, potentially due to differences in building condition, maintenance, or flood mitigation capacity.

In addition, a moderate positive correlation between year built and total damage ($r = 0.326$) indicates that areas with older housing stock tended to experience greater flood losses. Older buildings may be more vulnerable due to aging materials, basement configurations, and legacy infrastructure systems. Many Detroit neighborhoods contain pre-1950 housing and combined sewer systems, which have been associated with recurrent flooding and sewer backups. These findings highlight the importance of neighborhood housing characteristics in shaping flood impacts, alongside hydrologic factors.

Table 2: Correlation analysis results

Variables	1	2	3	4
1 Total Damage	1.00	-0.379*	0.326	-0.149
2 Housing Price		1.00	-0.109	0.330
3 Built Year			1.00	-0.422*
4 Water Level				1.00

*Significant at alpha level of 0.05.

(2) Comparative analysis across damage quartiles

To assess whether neighborhood housing characteristics differed systematically across damage levels, a one-way analysis of variance (ANOVA) was conducted comparing four ZIP code quartiles defined by total flood damage (Table 3). The results indicated statistically significant differences in average housing price across quartiles ($F(3, 26) = 4.89$, $p = 0.0079$). ZIP codes in the highest-damage quartile exhibited the lowest average housing values, reinforcing the correlation results and suggesting that economically vulnerable neighborhoods experience disproportionately high flood impacts.

There were also statistically significant differences in the number of losses per ZIP code ($F(3, 26) = 8.49$, $p = 0.0004$), with higher-damage quartiles experiencing more frequent claims. This suggests that repeated events have contributed to cumulative neighborhood-level damage patterns.

In contrast, several variables did not exhibit statistically significant variation across damage quartiles. Average water level ($p = 0.86$), year built ($p = 0.24$), and average frontage length ($p = 0.16$) did not differ significantly among groups. The lack of significance for year built, despite the moderate correlation observed earlier, suggests that housing age may be associated with flood damage but does not clearly differentiate neighborhoods when aggregated into damage-based quartiles. The nonsignificant differences in water level further indicate that structural and socioeconomic conditions may play a larger role than hydrologic indicators alone in shaping neighborhood-scale flood impacts. In summary, the ANOVA results highlight pronounced disparities in housing value across neighborhoods experiencing different levels of flood damage. Figures 2 and 3 visually present the flood level and damages per ZIP code across Detroit.

Table 3: One-way ANOVA results

Variables	df	F	p-value
Housing Price	3	4.89	0.0079
Built Year	3	1.49	0.2403
Water Level	3	0.25	0.8558
Average frontage length	3	1.89	0.1560
Number of Losses	3	8.49	0.0004

(3) Regression Modeling

To further examine predictors of total flood damage, a multiple linear regression model was estimated using average housing price, year built, average water level, and average frontage length as independent variables. The results (table 4) indicated that none of the predictors were statistically significant at conventional levels, and the overall model explained a relatively small proportion of the variance in total flood damage ($R^2 = 0.18$, $p = 0.279$). Although average housing price and year built exhibited coefficient signs consistent with earlier correlation patterns, their effects were weak and not statistically significant. These findings indicate that, at the ZIP code scale, housing-related attributes alone provide limited

explanatory power for modeling variation in total flood damage across Detroit neighborhoods.

Table 4: Regression results

Predictor	Coeffic -ient	Std. Error	t-value	p-value
Constant	22,243	-*	0.20	0.84
Housing Price	3.52	5.51	0.64	0.53
Built Year	-13.81	11.72	-1.18	0.25
Water Level	-28.87	63.00	-0.46	0.65
Average frontage length	-0.00	0.00	-0.44	0.66

* The standard error of the intercept is omitted because it does not provide meaningful interpretive value.

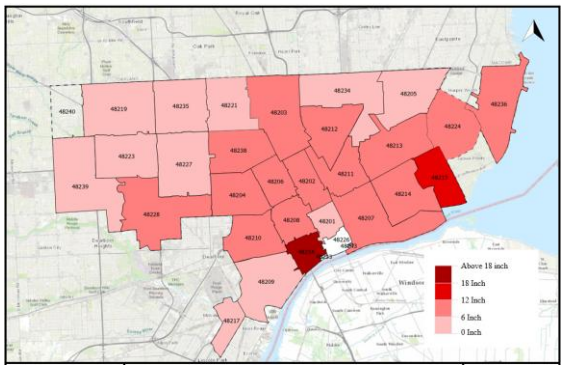

Figure 2: Detroit flood level by zip code

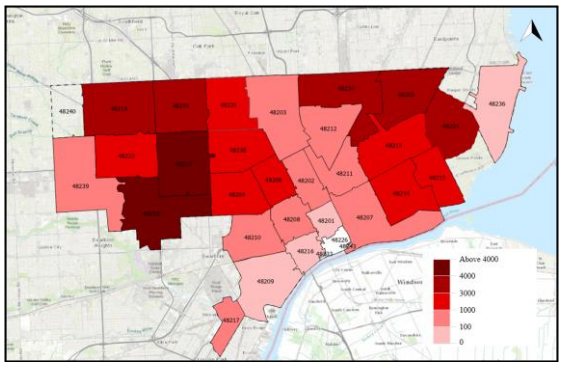

Figure 3: Detroit damage by zip code

(4) K-Means clustering analysis

To complement the quartile-based comparisons, a K-means clustering analysis (k=3) was conducted to identify data-driven neighborhood groupings based on flood damage and housing characteristics. Alternative values of *k*were explored, but k=3 yielded the most meaningful and interpretable group distinctions for the study objectives. Six variables were standardized and used in the analysis, to ensure that all variables contributed equally to the clustering process.

Table 5 presents the results of the clustering analysis, which identified three distinct flood-vulnerability profiles. Cluster 1 represents the highest-risk group, characterized by substantially higher total flood damage, lower housing values, smaller average frontage lengths, higher water levels, and the greatest number of flood loss events. The housing stock in this cluster is also older on average, indicating elevated structural vulnerability.

Clusters 0 and 2 exhibit comparatively lower flood damage and fewer loss events, along with higher housing values and larger average frontage lengths, suggesting relatively lower flood vulnerability. Although the average year built is similar across clusters, the combined economic and physical characteristics clearly differentiate the resulting risk profiles.

Notably, the highest-risk cluster closely aligns with the highest-damage quartile identified in earlier analyses, reinforcing the conclusion that older, lower-value housing areas are disproportionately affected by flooding. Overall, the clustering results demonstrate that unsupervised, data-driven classification methods can effectively identify neighborhood-level flood-vulnerability patterns and support automated flood-risk assessment and resilience planning.

Table 5. Clustering Results

Predictor	Cluster 0	Cluster 1	Cluster 2
Total Flood Damage	425	2,580	354
Housing Price	131	53	85
Built Year	1940	1942	1946
Water Level	6.0	6.5	5.5
Average frontage length	28501	1600	2600
Number of Losses	2.7	3.0	2.5

Discussion and conclusions

This study examined relationships between observed flood losses and neighborhood housing characteristics in Detroit to better understand residential flood vulnerability in a legacy urban context. The combined results of the correlation and comparative analyses indicate that neighborhood housing characteristics are associated with patterns of flood damage in Detroit, even though they do not fully explain flood losses on their own. Moderate correlations and statistically significant differences across damage quartiles show that ZIP codes with lower average housing values experienced higher cumulative flood damage and more frequent loss events. Housing age exhibited a moderate association with flood damage, but did not differ significantly across damage quartiles, suggesting that older housing stock may contribute to flood vulnerability without clearly distinguishing neighborhoods when aggregated at the ZIP-code scale. These findings indicate that economically vulnerable neighborhoods experience disproportionate flood impacts, reinforcing prior evidence that flood risk and losses are unevenly distributed. The absence of significant differences in average water levels across damage quartiles further suggests that hydrologic intensity alone

does not account for observed neighborhood-scale disparities in flood damage.

The lack of statistically significant regression results highlights the multidimensional nature of urban flood vulnerability. Flood impacts are also shaped by factors not captured in parcel-level housing datasets, including sewer system condition, drainage capacity, basement construction, neighborhood infrastructure age, and localized hydrologic pathways. In addition, aggregation at the ZIP-code scale may obscure finer-grained spatial variability in flood exposure, particularly in legacy cities where housing and infrastructure conditions vary substantially at smaller spatial scales. NFIP claims may also underrepresent total flood losses due to incomplete insurance coverage, underreporting, and socioeconomic differences in claim participation. The findings also underscore trends that warrant further exploration, such as the negative correlation between total damage and house prices in recorded flooding events. Future research should therefore explore alternative modeling approaches, including nonlinear and spatial regression models, as well as machine learning techniques that can capture complex interactions among variables. Incorporating additional covariates—such as drainage system condition, impervious surface coverage, elevation, floodplain proximity, and building-level characteristics—may also improve explanatory power. These additions clarify that the current findings are not treated as terminal, but rather as a basis for guiding more comprehensive modeling approaches in future work.

This study provides empirical evidence of neighborhood-level disparities in flood impacts using observed damage data. While the analysis is limited to the City of Detroit, similar dynamics may be present in other cities with aging housing stock, legacy infrastructure, and recurrent urban flooding. A key limitation of this study is the use of Zillow housing value estimates. Prior research has shown that automated valuation models (AVMs), including Zillow estimates, may be less reliable in areas with high housing vacancy rates, limited transaction activity, and heterogeneous property conditions (Elliott & Clement, 2017). In legacy cities, where housing markets are often fragmented and marked by significant disinvestment, estimated housing values may not fully reflect the true structural conditions or market dynamics. As a result, housing prices should be interpreted as a proxy indicator of neighborhood economic conditions rather than a precise measure of property-level value.

In addition, NFIP claims data may introduce systematic bias due to uneven participation in flood insurance programs. Enrollment in the National Flood Insurance Program is not universal and is often lower in socially vulnerable or lower-income communities due to affordability constraints, limited risk awareness, and institutional barriers (Kousky, 2018; Wing et al., 2022). Consequently, observed claims may underrepresent total flood damage in uninsured or underinsured areas, potentially biasing comparisons across neighborhoods. These limitations are particularly relevant when interpreting equity-related findings, as areas identified as lower-risk based on claims data may in fact experience substantial unreported losses. Therefore, while the results provide important insights into neighborhood-scale flood vulnerability, they should be interpreted considering the context of this work.

Future research should extend this approach to multiple cities and integrate additional variables related to infrastructure condition, drainage performance, and building-level characteristics to improve explanatory power and generalizability. In addition, future research should integrate additional data sources and finer-scale observations to more fully capture the distribution of flood impacts.

The findings presented in this study are relevant to a diverse set of stakeholders involved in urban flood risk management and housing resilience. City officials and urban planners can use the neighborhood-scale insights to prioritize flood mitigation investments, target infrastructure upgrades, and integrate housing vulnerability considerations into stormwater and resilience planning. Housing agencies and community development organizations may apply the results to identify neighborhoods where older, lower-value housing stock faces elevated flood impacts and where rehabilitation, retrofit, or assistance programs could yield the greatest equity benefits. Homeowners and residents can benefit from improved awareness of localized flood vulnerability, supporting more informed decisions regarding property-level mitigation and insurance coverage. In addition, insurers and risk analysts may use the findings to enhance neighborhood-level risk assessment and better understand the limitations of housing characteristics alone in predicting flood losses. Collectively, these results support more targeted, data-informed, and equitable approaches to urban flood mitigation and housing resilience in legacy cities.

AN ONTOLOGY-DRIVEN FRAMEWORK FOR INTELLIGENT EMBODIED CARBON DECISION-SUPPORT IN METRO STATION DESIGN

Linghui Xie, and Xueqing Zhang
Hong Kong University of Science and Technology, Hong Kong, China

Abstract

Conventional element-centric BIM-LCA integration omits temporary works (e.g., excavation support, formwork, dewatering) and faces semantic barriers (e.g., inconsistent IFC attribute naming), causing significant carbon underreporting. A dynamic ontology-driven framework was proposed to overcome this. Its semantic core is a multi-module ontology, shifting assessment from static elements to context-aware construction processes. An automated pipeline transforms OpenBIM data into a carbon knowledge graph, capturing permanent and temporary emissions. A federated neuro-symbolic multi-agent system, combining LLM-based probabilistic reasoning with deterministic ontology constraints, enables natural language querying and scenario simulation for interactive decision support.

Introduction

As urbanization accelerates, metro systems are pivotal for sustainable mobility. In China, as of March 2025, 304 metro lines span 6,530 stations, with 157 lines under construction (He et al. 2025). While operation offers environmental benefits, construction is energy-intensive: a kilometer of open-cut metro emits 39,000–84,000 t CO_2e (Wang et al. 2023; Gan et al. 2024; Zhang et al. 2024). This intensity is comparable to constructing approximately 46 kilometers of highway paradigms y(Chen et al. 2023a). Therefore, calculating and reducing greenhouse gas emissions during the materialization stage is a critical priority for industry (Geng et al. 2022; He et al. 2025).

Early-stage design decisions lock in >80% of emission reduction potential (Gao et al. 2024b), but comprehensive LCA requires detailed data only available later (Roberts et al. 2020), leaving a gap between decision needs and data availability (Hollberg et al. 2020). BIM-LCA integration automates quantity extraction and scenario simulation (Gao et al. 2024a; Kim et al. 2024), yet remains ill-equipped for underground metro complexities (Li et al. 2024).

Current methods face three technical limitations for metro stations. First, the element-centric paradigm omits temporary works (excavation support, dewatering, earthwork logistics) rarely modeled in IFC files, causing significant underreporting. Second, tools lack domain-aware reasoning; early-stage low-LOD models cannot infer implicit construction sequences or backfill requirements. Third, semantic disconnect between design models and environmental databases forces error-prone manual mapping (Cavalliere et al. 2019; Abbasi and Noorzai 2021; Cheng et al. 2022).

To overcome these, we propose an ontology-driven OpenBIM framework that shifts from data extraction to knowledge-enabled inference. It harmonizes structural, enclosure, and geological data via formal logic rules that deduce implicit construction processes from explicit design geometry (e.g., inferring excavation zones from foundation pit design). The framework is validated on six open-cut metro stations with three contributions: (1) the Metro Station Carbon Assessment Ontology (MSCA-Onto) decoupling geometry from construction logic; (2) an automated inference mechanism reconstructing implicit work quantities from sparse geometry; (3) a neuro-symbolic cognitive interface combining LLM reasoning with deterministic ontological constraints, turning the tool into an interactive engineering copilot.

Methodology

Overview

Conventional BIM-LCA methods are constrained by an element-centric paradigm, relying on static bills of quantities from explicit geometry. This causes three shortcomings: (1) data incompleteness – omission of temporary works (formwork, excavation support, dewatering); (2) semantic interoperability barriers – inconsistent IFC naming conflicts with LCA databases, requiring manual mapping; (3) static post-hoc reports – no interactive "what-if" simulation. To address these, we propose a dynamic ontology-driven framework with three integrated layers, each targeting one gap.

The Semantic Foundation Layer (Layer I) redefines the underlying assessment logic to resolve semantic ambiguities. Instantiated by the Metro Station Carbon Assessment Ontology (MSCA-Onto) and based on a System-Element-Process-Resource-Carbon (S-E-P-R-C) architecture, this layer shifts the focus from static elements to context-aware construction processes. By establishing a unified vocabulary, it bridges the semantic gap between heterogeneous design data and environmental databases. Building upon this foundation, The Automated Computational Layer (Layer II)

operationalizes the ontology to quantify emissions comprehensively. It transforms OpenBIM data into a computable Carbon Knowledge Graph (CKG) by automating semantic alignment and geometric enrichment. Crucially, this layer utilizes ontological inference rules to deduce the consumption of unmodeled temporary works from permanent structures, thereby ensuring a complete system boundary and correcting the underreporting inherent in conventional methods.

While the first two layers establish a rigorous and complete data repository, a cognitive interaction layer (Layer III) is implemented to bridge the final cognitive gap between structured data and human decision-making. Designed as a federated neuro-symbolic Multi-Agent System (MAS), this layer synergizes the probabilistic reasoning of Large Language Models (LLMs) with the deterministic logic of the ontology. It transforms the CKG from a passive database into an active decision-support engine, enabling stakeholders to synthesize optimization strategies and perform various scenario analysis through natural language interaction. Collectively, this framework not only ensures accurate quantification during the design phase but also establishes a scalable, semantic continuum for lifecycle carbon management.

Metro station carbon assessment ontology

The MSCA-Onto serves as the semantic foundation of the proposed framework, engineered to facilitate a paradigm shift from static, element-centric accounting to dynamic, process-aware carbon assessment. The development of this ontology follows a hybrid methodology that integrates the structural rigor of METHONTOLOGY with the lifecycle flexibility of the NeON framework. Spanning six stages from specification to evaluation, the process involved a comprehensive synthesis of construction standards, IFC schemas, and project documentation. To ensure high interoperability, ontology strategically reuses established schemas such as QUDT for units and PROV-O for provenance, ultimately formalizing domain knowledge into OWL 2 DL expressions supplemented by SWRL rules for advanced automated reasoning.

The structural core of MSCA-Onto is the S-E-P-R-C framework, which establishes a unified semantic layer to decouple static geometric data from dynamic resource consumption. Within this architecture, the System and Element modules decompose the metro station into functionally distinct engineering systems and specialized subtypes, such as diaphragm walls and bracing, effectively bridging the semantic gap between generic IFC schemas and underground engineering practice. The Process module represents the framework's primary innovation by utilizing WorkPackageTemplate entities as semantic adapters. These templates function as inference engines that automatically deduce implicit construction activities, such as formwork or excavation, from sparse BIM geometry. This process-based logic subsequently connects to the Resource and Carbon modules, which map activities to material descriptors and emission factors from external databases to enable multi-level carbon aggregation across lifecycle stages A1 to A5. The overall architecture is illustrated in Figure 1. Six competence questions validated MSCA-Onto's ability to quantify material consumption, evaluate low-carbon substitution, analyze temporary structure recycling, identify carbon hotspots, and assess logistics footprints, proving its utility for early-stage carbon management.

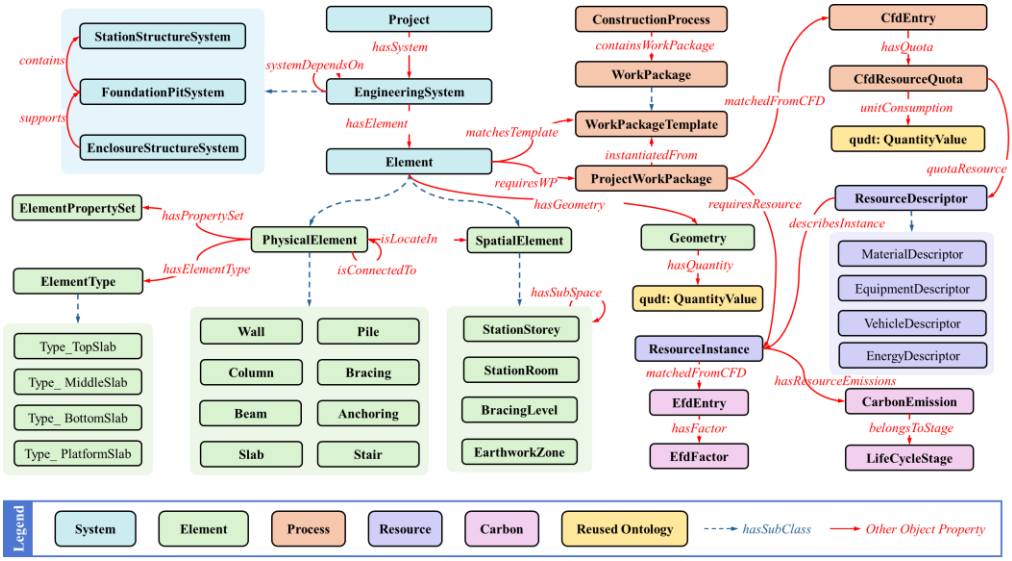

Figure 1: Overall architecture of MSCA-Onto

Table 1 summarizes the six competence questions used to validate MSCA-Onto, along with the SPARQL query patterns and expected outcomes. For instance, CQ5 identifies carbon hotspots via a grouping and ranking query; the results across six stations consistently ranked diaphragm walls and slabs as the top two contributors (42% and 28% of structural carbon, respectively). CQ6 quantifies logistics emissions by joining material supply distances with transport emission factors, yielding a contribution of 8–12% of A1–A3 emissions. The full

executable SPARQL queries and result datasets are provided in the supplementary material.

Table 1 Ontology validation competency questions

Competence Question	Validation Objective	SPARQL Pattern
CQ1: What are the material consumptions and total carbon emissions generated by waterproofing engineering in the main structure?	Material Consumption and Carbon Quantification	Process→Resource→Carbon chain with material filtering
CQ2: How much carbon reduction can be achieved by substituting conventional concrete with GGBS-based low-carbon concrete in primary structural elements?	Low-carbon material decision support	Comparative analysis with emission factor lookup from EFD
CQ3: What is the carbon impact of temporary support system demolition activities, including recycling credits?	Temporary structure lifecycle assessment	Temporal process analysis with negative emission accounting
CQ4: What is the carbon emission comparison between vertical retaining systems and horizontal bracing systems in the enclosure structure?	Comparative System Analysis	Cross-system comparison with intensity metrics calculation
CQ5: What are the top 10 carbon hotspots among structural components, and what is their carbon intensity ranking?	Component-level carbon hotspot identification	Multi-criteria ranking with statistical aggregation
CQ6: What is the carbon contribution of material transportation in construction logistics?	Construction logistics carbon analysis	Distance-weight-emission calculation per transport mode

Automated carbon assessment pipeline based on OpenBIM

Based on the MSCA-Onto, this study establishes a systematic automated pipeline designed to transform heterogeneous OpenBIM data into a comprehensive Carbon Knowledge Graph (CKG) suitable for high-precision embodied carbon assessment. The workflow begins by anchoring the assessment in two hierarchically structured reference databases: a construction process database (CPD) for resource inventory and an emission factor database (EFD) for environmental impact, which are strategically decoupled to ensure data flexibility and fitness for purpose. To resolve the semantic ambiguity inherent in raw IFC data, the pipeline employs a hybrid topological reasoning engine. By utilizing spatial indexing and geometric algorithms, such as ray casting and collision detection, the system infers critical spatial relationships to accurately classify elements based on their functional roles, such as distinguishing a generic slab from a specific station platform. For instance, an unclassified IfcSlab instance is resolved as a "Platform Slab" via three topological checks: normal vector orientation (ray casting), vertical position (R-tree query), and adjacency to passenger spaces (collision detection). Simultaneously, to address the omission of temporary earthworks in standard BIM, the module executes a rigorous geometric reconstruction of the foundation pit. Using a "profile-sweep-trim" operation, the system synthesizes horizontal enclosure envelopes with vertical structural surfaces to generate precise volumetric domains for excavation and backfill, which are then intersected with geological layers for quantification.

The pipeline culminates in an automated element-process-resource mapping mechanism that operationalizes the ontology's inference logic. Through domain-specific SWRL rules, semantically enriched elements are matched with WorkPackageTemplate adapters. For example, the following SWRL rule triggers an excavation support work package when the depth of a foundation pit exceeds 5 meters:

```
StationPit(?pit) ∧ hasDepth(?pit, ?depth) ∧ swrlb:greaterThan(?depth, 5.0) → requiresWorkPackage(?pit, ExcavationSupportWorkPackage)
```

Figure 2: An example of the SWRL rule

These adapters dynamically retrieve construction methods from the CPD and associate emission factors from the EFD, instantiating ProjectWorkPackage and ResourceInstance entities. This enables bottom-up aggregation of carbon emissions across stages A1–A5 (material production, transport, on-site construction), ensuring full traceability from individual resources to the project footprint. The complete workflow is shown in Figure 3.

A Multi-agent system for interactive carbon intelligence

To bridge the critical cognitive gap between the static Carbon Knowledge Graph (CKG) and the dynamic, unstructured nature of engineering decision-making, this study proposes a federated neuro-symbolic Multi-Agent System (MAS). Designed around a rigorous divergence - convergence workflow, the MAS strictly decouples cognitive planning from domain-specific execution across three logical layers: cognitive planning, semantic execution, and decision synthesis. This hierarchical architecture ensures that the probabilistic reasoning of Large Language Models (LLMs) is constrained by the deterministic logic of the MSCA-Onto, enabling reliable

support for information retrieval, knowledge correction, and strategic analysis entirely through natural language interaction.

The workflow is governed by the Cognitive Planning Layer, where the Orchestrator Agent (A_{orch}) functions as the central reasoning engine. Upon receiving a user query, A_{orch} utilizes a fine-tuned LLM for intent classification and employs Chain-of-Thought (CoT) reasoning to decompose the request into a machine-readable Task Dependency Graph (TDG). To constrain the LLM's probabilistic reasoning without exceeding context window limits, the system does not parse the entire OWL ontology as a raw prompt. Instead, a compressed schema dictionary—containing only the permitted S-E-P-R-C core classes, taxonomic relations, and operational properties—is dynamically injected into the LLM's system prompt to grant it structural awareness. Meanwhile, strict semantic verification (e.g., SWRL rule checking) is deferred to the downstream symbolic agents.

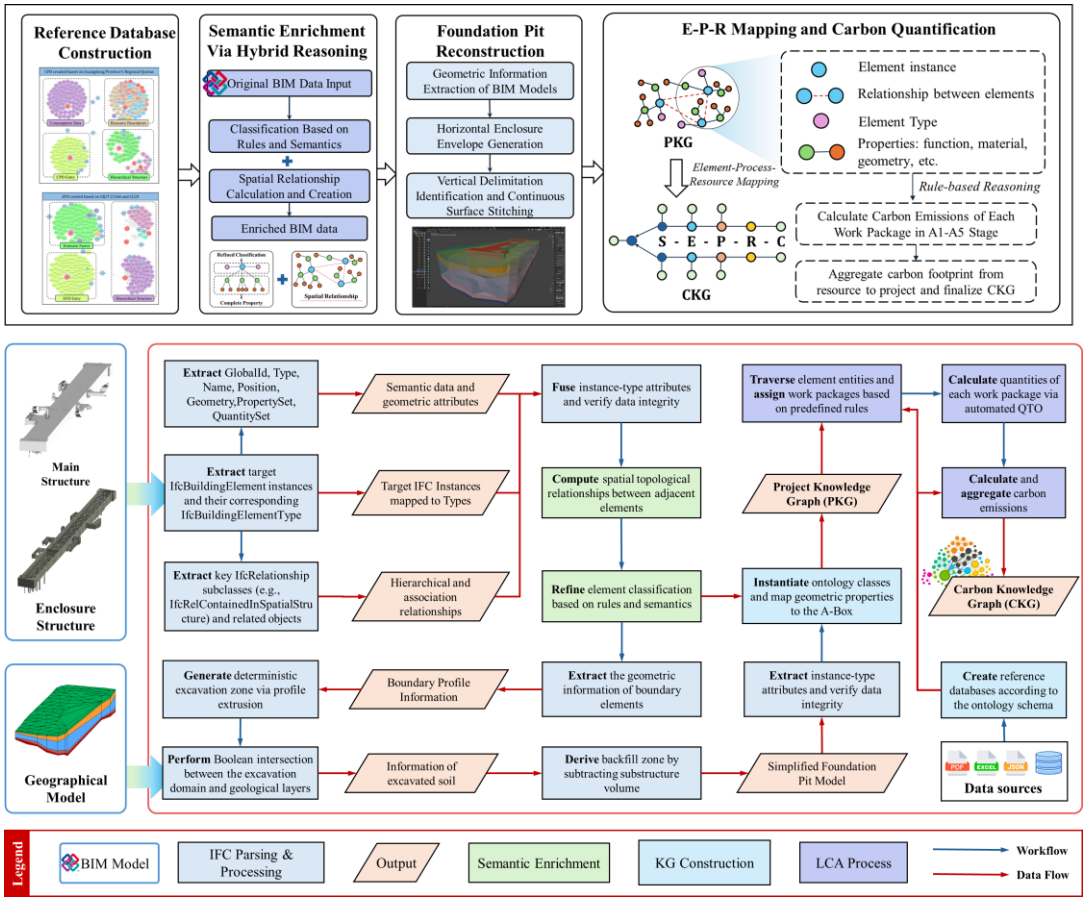

Figure 3: Workflow of automated carbon assessment pipeline

The LLM performs orchestration only: it maps natural language to a predefined set of task templates and produces a TDG. It does not generate SPARQL or numerical parameters directly. For example, given " Replace C30 with C40 concrete in the bottom slab" , CoT produces: (1) Intent: Strategic Analysis; (2) Entity: bottom slab → Type_BottomSlab; (3) Parameter: C30→ C40; (4) TDG: [Extraction→Reader→Calculation]. All formal queries and calculations are executed by symbolic agents using deterministic templates. The LLM's reasoning is confined to intent classification, ambiguity detection, and workflow planning. To optimize efficiency, the system implements a hybrid shared-state architecture: control signals are dispatched asynchronously to trigger downstream agents, while data artifacts are managed via a global "blackboard" pattern. This ensures that agents read from and write to a validated, synchronized context, minimizing communication overhead while maintaining strict data consistency.

The Semantic Execution Layer operationalizes these tasks through a suite of functionally atomized agents. The Metadata Agent ($\boldsymbol{A}_{\text{meta}}$) serves as the semantic bridge, parsing complex queries into atomic propositions and mapping ambiguous terms to precise ontology entities via a "decomposition-retrieval-verification" pipeline. For hypothetical scenarios, the Extraction Agent ($\boldsymbol{A}_{\text{extr}}$) translates user intents into a "delta graph specification" ($\boldsymbol{G}_{\text{spec}}$), a provenance annotated artifact that prioritizes user-defined parameters over system defaults while filtering out invalid structural alterations. Simultaneously, the Unified Reader Agent ($\boldsymbol{A}_{\text{read}}$) executes a dual-path retrieval strategy-using deterministic SPARQL for project

data and hierarchical semantic search for external reference databases-to construct a composite data context ($\boldsymbol{D}_{\mathbf{comp}}$). These inputs converge at the Calculation Agent ($\boldsymbol{A}_{\mathbf{calc}}$), which performs a sandboxed semantic overlay operation $R = f_{\text{template}}\left(D_{\text{comp}} \oplus G_{\text{spec}}\right)$. By dynamically superimposing user constraints onto the baseline context, this agent ensures that all quantitative derivations are mathematically rigorous and fully traceable.

Finally, the Decision Synthesis Layer ($\boldsymbol{A}_{\text{syn}}$) acts as the system's executive interface and safety valve. It adaptively formats heterogeneous outputs-ranging from visualization of carbon hotspots to comparative scenario matrices-into coherent, human-readable responses enriched with provenance annotations. Crucially, for tasks involving persistent modifications to the CKG, $\boldsymbol{A}_{\text{syn}}$ enforces a strict "human-in-the-loop" protocol. Rather than executing updates immediately, it generates a comprehensive impact assessment forecasting the cascading effects of the proposed changes. The system then pauses to solicit explicit user adjudication, executing the final SPARQL UPDATE statements only after receiving authorization, thereby guaranteeing that stakeholders retain ultimate sovereignty over data integrity. The structure of MAS is shown in Figure 4.

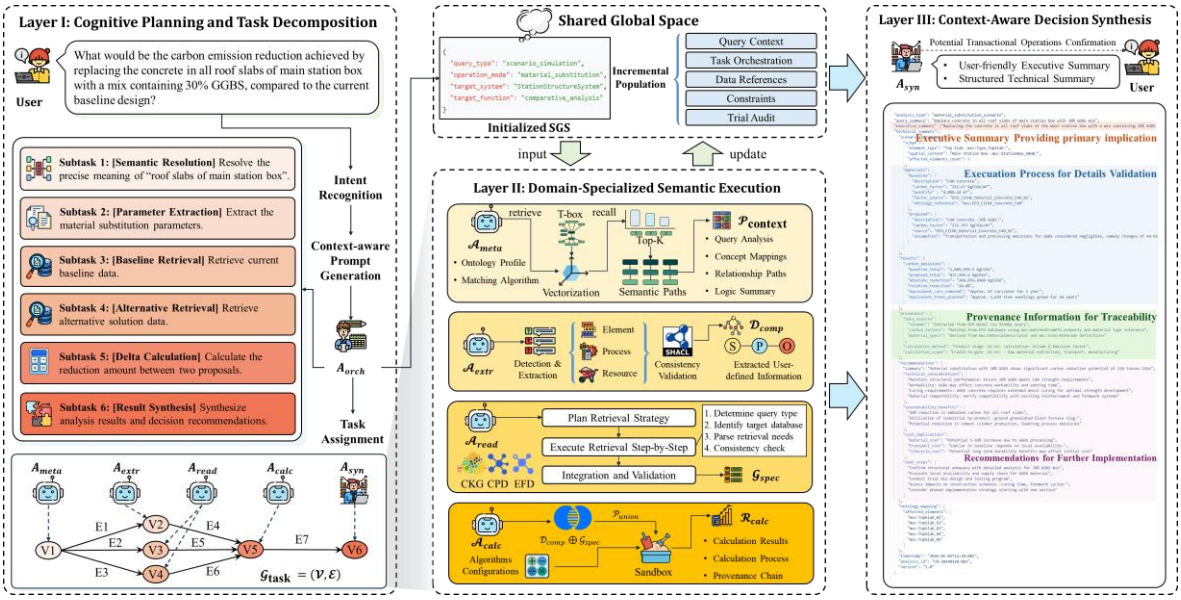

Figure 4: The workflow of MAS proposed

Implementation and results

Evaluation of the automated assessment pipeline

The empirical validity of the proposed framework was established using a diverse dataset comprising six open-cut metro station projects located in Guangdong Province, China. These projects represent a comprehensive range of structural typologies. The excavation depths vary significantly from 16.5 meters to 22.3 meters. This diversity ensures that the validation encompasses different geological conditions and construction complexities.

The input data for each project consisted of the original Industry Foundation Classes design models and the corresponding structural drawings. To rigorously test the scalability of the automated pipeline, we maintained the BIM models at a high level of fidelity. The dataset contains a total of over 44,000 individual geometric components. All three methods, including Manual Calculation (Baseline), Typical BIM-LCA Software, and the Proposed Framework, operated on these identical IFC datasets. They also referenced the exact same data infrastructure for construction processes and emission factors. This rigorous control ensures that any observed performance variance is attributable solely to methodological differences rather than data discrepancies. The CPD was populated using Guangdong Province's municipal construction quotas, covering 124 construction activities (e.g., diaphragm wall excavation, concrete pumping, formwork erection). The EFD (Emission Factor Database) combines Ecoinvent 3.8 for background processes (e.g., cement production, diesel combustion) and region-specific factors from the China Life Cycle Database (CLCD) for materials like steel and concrete. Transportation distances were set to default regional averages (50 km for concrete, 200 km for steel) unless specified otherwise in the BIM properties.

To rigorously quantify the performance of the ontology-driven pipeline, the evaluation was structured around three key performance indicators designed to assess mathematical precision, statistical correlation, and operational efficiency. The first metric, mean absolute percentage error (MAPE), measures the average magnitude of error between the automated results C_{auto} and the manual ground-truth C_{man} across the n test projects, calculated as:

$$MAPE = \frac{100\%}{n}\sum_{i=1}^{n}\left|\frac{C_{man,i} - C_{auto,i}}{C_{man,i}}\right| \quad (1)$$

This provides a normalized assessment of accuracy where lower values signify higher alignment with expert standards. The second metric is the coefficient of determination (R^2), which evaluates the proportion of variance in the manual baseline that is predictable from the automated pipeline. Finally, temporal efficiency is assessed through the total end-to-end processing time required for a complete assessment.

To rigorously quantify the reliability of these generated profiles, we compared the automated results against the expert-verified manual baseline. We employed Mean Absolute Percentage Error as the primary accuracy metric. This measures the average magnitude of deviation between the automated results and the ground truth. Additionally, we used the coefficient of determination to evaluate linear consistency. The automated pipeline demonstrated exceptional alignment with the manual baseline. It achieved a project-level MAPE of 2.8% and an R^2 value of 0.983. This confirms that the rule-based, ontology-driven workflow can reliably replicate complex engineering logic without the significant deviations observed in standard BIM-LCA plugins. Standard tools often suffer from errors exceeding 23% due to their inability to account for the unmodeled auxiliary processes described above. The detailed accuracy comparison is summarized in Table 2.

Table 2: Accuracy comparison of carbon assessment methods

Metric	Manual Calculation (Baseline)	Typical BIM-LCA method	Ours
Project-Level Accuracy (MAPE)	N/A	23%	2.8%
Component-Level Accuracy (MAPE)	N/A	12%	5.5%
Correlation (R^2)	1.00	0.81	0.983

In terms of operational efficiency, the framework demonstrated a transformative reduction in assessment latency. The manual calculation process required an average of 7.5 person-hours per project. This duration was dominated by tedious quantity take-off and Excel-based mapping. In contrast, the automated pipeline completed the entire end-to-end assessment in an average of 22 minutes.

To understand the computational cost, we decomposed this 22-minute duration into its constituent phases. The semantic enrichment and reasoning phase consumed most of the time, taking approximately 12 minutes. This reflects the computational intensity of the topological algorithms used to resolve element relationships such as containment and adjacency checks. The geometric reconstruction of the braced foundation pit required an average of 8 minutes. This represents a necessary trade-off to capture the implicit earthwork quantities accurately. The final mapping and calculation phase was highly efficient and completed in under 2 minutes. Although the Typical BIM-LCA method was faster at approximately 5 minutes, this speed resulted in the significant accuracy penalty noted in the previous section. Consequently, the proposed framework offers an optimal balance. It delivers professional-grade accuracy with industrial-scale efficiency that is approximately 20 times faster than manual workflows.

Evaluation of the Neuro-Symbolic MAS

To evaluate the efficacy and safety of the proposed Neuro-Symbolic MAS, a comprehensive performance assessment focusing on its interaction reliability across diverse engineering tasks was conducted. The evaluation utilized a benchmark suite of 120 standardized engineering queries distinctively categorized into three operational modes: information retrieval (IR), knowledge correction (KC), and strategic analysis (SA). To assess the framework's adaptability and model-agnostic robustness, the experiments were replicated using three distinct LLMs as the reasoning backbone: DeepSeek-V3, Gemini 3 Pro, and Qwen 2.5-14B.

To strictly quantify the system's engineering capabilities, we introduced a "trap mechanism" within the benchmark suite. Approximately 15% of the queries were intentionally designed with missing parameters or ambiguous intents, such as requesting a material update without specifying the target component. For these queries, a correct outcome is defined not as executing an operation, but as halting execution and requesting clarification. This tests the system's meta-cognitive ability to detect ambiguity, which is a critical safety feature in engineering.

Accordingly, the system's performance was measured using a quantitative net reliability score (R). Unlike subjective fluency metrics, this score is strictly grounded in the quantitative accuracy of the output. The metric rewards correct answers and penalize unsafe errors while neutrally treating safe failures where the system correctly refuses to answer due to ambiguity. The metric is formalized as:

$$R = \frac{1}{N}\sum_{i=1}^{N}\left(I_{\text{correct}}^{(i)} - \lambda \cdot I_{\text{unsafe}}^{(i)}\right) \quad (2)$$

where $I_{\text{correct}}^{(i)}$ is a binary indicator set to 1 if the system's output strictly matches the ground truth or correctly identifies a trap. $I_{\text{unsafe}}^{(i)}$ is a penalty indicator set to 1 if the output contains a constraint violation, such as returning a physically impossible parameter or hallucinating a value for an ambiguous query. The safety penalty coefficient λ is set to 1.0, reflecting the engineering principle that providing erroneous data is as detrimental as the value of a correct insight. To ensure statistical robustness, the benchmark suite was executed three times for each configuration resulting in a total of 360 independent trials.

The experimental results, summarized in Table 3, demonstrate that the proposed neuro-symbolic architecture effectively standardizes performance output

enabling even smaller models to achieve engineering-safe reliability levels.

Table 3: Comparative Performance of LLM Backbones within the MAS Framework

Operational Mode	Metric	Qwen 2.5-14B	DeepSeek-V3.2	Gemini 3-Pro
Information Retrieval	$I_{correct}$	68.2%	85.3%	92.1%
	I_{unsafe}	3.0%	2.0%	0.0%
	R	0.65	0.83	0.92
Knowledge Correction	$I_{correct}$	58.0%	82.5%	91.3%
	I_{unsafe}	6.0%	3.5%	0.0%
	R	0.52	0.79	0.91
Strategic Analysis	$I_{correct}$	50.0%	66.6%	86.4%
	I_{unsafe}	9.5%	4.0%	3.0%
	R	0.41	0.63	0.83
Global Performance	Avg. R Score	0.53	0.67	0.86
	Avg. Latency	18.5s	28.8s	34.2s

Using DeepSeek-V3 as the backbone, the system achieved a robust global R score of 0.91. It exhibited exceptional performance in Strategic Analysis tasks with a success rate of 92.0%, successfully decomposing complex "what-if" scenarios into valid delta specifications. The constraint violation rate was kept extremely low at 1.8%, proving that the orchestrator's planning logic effectively restrains the model's generation within ontological bounds.

The integration of Gemini 3 Pro yielded the highest reliability with a global R score of 0.86. Its superior reasoning capabilities minimized the errors in complex multi-hop queries. Notably, in KC tasks, it achieved a 100% success rate demonstrating perfect alignment with the feasibility protocol when parsing complex user directives. The absence of unsafe errors across all trials highlights the model's rigorous adherence to the provided prompts and its ability to correctly identify all trap questions.

Crucially, the lightweight Qwen 2.5-14B model demonstrated the structural value of the framework. While its raw reasoning capability is lower than the flagships resulting in a lower raw success rate, the MAS architecture successfully mitigated the risks. Instead of generating plausible hallucinations for ambiguous queries, the model frequently defaulted to "safe failures" when uncertain. Although its global R score (0.67) is lower, the constraint violation rate was contained at 3.5%. This is significantly better than the typical instability of unconstrained small models confirming that the framework functions as a cognitive guardrail that makes lightweight models viable for non-critical engineering tasks.

Discussion

The empirical results show that the element-centric BIM-LCA paradigm is insufficient for underground infrastructure. About 12.4% of total embodied carbon comes from unmodeled temporary work, revealing systematic scope leakage and confirming that geometric explicitness is a poor proxy for construction reality. Our ontology-driven pipeline bridges this gap using the S-E-P-R-C model as an active inference engine. The 2.8% error rate proves that semantic reconstruction is necessary for professional-grade accuracy, suggesting that future standards should mandate procedural logic beyond geometric LoD.

A key architectural insight from the MAS evaluation is that the reliability of generative AI in engineering depends more on system architecture than on model size. Lightweight local models achieved operational safety when constrained by the framework, implying that highly reliable, privacy-compliant tools do not require expensive cloud models. The neuro-symbolic architecture decouples probabilistic intent understanding from deterministic execution and defaults to safe failures on ambiguous queries, defining trustworthiness as the ability to recognize knowledge boundaries.

The framework reduced assessment latency twenty-fold (from 7.5 hours to 22 minutes), shifting engineers' cognitive load from tedious quantity take-off to high-value strategic analysis. This enables real-time carbon budgeting alongside cost and schedule during design. Accuracy depends on database granularity; missing methods fall back to generic averages. Geometric reconstruction is optimized for cut-and-cover stations and may need adaptation for tunnels or complex nodes. The human-in-the-loop step ensures safety but adds latency. The S-E-P-R-C architecture is domain-agnostic: extending to tunnels or bridges only requires domain-specific work package templates and geometric threshold rules. The manual baseline may contain expert bias; future work will validate it with real-world construction data.

Conclusion

This research addressed the systemic limitations of conventional BIM-LCA for underground infrastructure—specifically the omission of auxiliary processes and the lack of interactive decision support. A dynamic assessment framework based on a neuro-symbolic MAS was proposed and validated, marking a paradigm shift from static element-based carbon reporting to interactive, process-aware engineering intelligence.

The primary contribution is a robust computational methodology that harmonizes sparse design data with deep engineering knowledge. The MSCA-Onto, built on the S-E-P-R-C model, decouples geometry from resource consumption, enabling dynamic inference of typically invisible work packages (e.g., excavation support). The automated pipeline transforms OpenBIM data into a computable CKG, capturing the full life-cycle inventory with near-expert precision. Most significantly, integrating

LLMs with deterministic ontologies provides a viable pathway for reliable engineering AI. The federated MAS acts as a cognitive copilot, interpreting complex intents, executing rigorous simulations, and enforcing safety via safe-failure mechanisms. Empirical results show a 12.4% completeness improvement and high reliability across diverse backbones, validating the neuro-symbolic approach as a scalable industry solution.

Future work will focus on agent learning from user corrections and integrating real-time schedule data for dynamic carbon forecasting. This framework lays the foundation for intelligent, holistic carbon management, moving sustainability assessment into an integral, effortless part of infrastructure design.

AUGMENTED REALITY AND COMPUTER VISION TO SUPPORT SCHEDULING AND MONITORING IN CONSTRUCTION: A MEP CASE STUDY

Patrick Dallasega[1], Marco Lanzone[1], Andrea Revolti[1], Alessandro Sottovia[1], and Oswald Lanz[1]
[1]Faculty of Engineering, Free University of Bozen-Bolzano, Italy

Abstract

Mechanical, Electrical, and Plumbing (MEP) systems require complex spatial coordination and installation sequences, making scheduling and progress monitoring challenging. This paper presents a framework that integrates Augmented Reality (AR) and Computer Vision (CV) to support MEP scheduling and progress tracking. BIM-based plans are visualized on-site through AR to guide installers, while CV algorithms detect MEP components from images to measure progress and identify schedule deviations. A prototype developed in Unity for HoloLens 2 was tested in laboratory and construction site environments. Results demonstrate its potential to improve construction managers' situational awareness.

Introduction

Mechanical, electrical, and plumbing (MEP) construction projects are among the most complex phases of building delivery because they require the installation of numerous interdependent components within constrained spatial environments. As buildings become more technologically sophisticated, the density of MEP systems has increased, placing significant demands on coordination, sequencing, and precision during installation. Prior research highlights that MEP works often involve intricate spatial relationships and tolerance requirements, which make them particularly susceptible to coordination problems and rework if not managed carefully (Eastman et al., 2011). Moreover, these activities typically occur at later stages of a project, when structural and architectural elements are already in place, thereby limiting flexibility and amplifying the consequences of any errors or clashes discovered on-site.

Despite advances in Building Information Modeling (BIM) and digital design workflows, construction errors such as geometric clashes or incorrect installations are still frequently detected only at late stages of construction. Several studies have shown that while BIM-based clash detection is widely adopted, its benefits are reduced when updates to the model are not timely or when discrepancies between the as-designed and as-built conditions are not systematically captured (Hartmann et al., 2008). In practice, field conditions deviate from planned information for a range of reasons, for example design changes, unforeseen site constraints, or human error. These deviations are often discovered only during installation or inspection. By the time such issues emerge on-site, corrective actions may be costly, disruptive, or infeasible. This temporal gap between planning and execution remains a persistent challenge for effective project control.

The consequences of late error detection manifest in well-documented industry-wide problems of delays and cost overruns. Global construction performance studies indicate that time and budget deviations are widespread, with a significant portion of construction projects exceeding planned durations and costs (Flyvbjerg et al. 2002; Cantarelli et al., 2013). Highly integrated scopes such as MEP are particularly prone to such deviations because misalignments accumulate across trades and require iterative rework cycles. Furthermore, traditional monitoring techniques, such as manual inspections, paper-based checklists, or 2D drawings often limit the ability of project managers to obtain an accurate, real-time understanding of construction progress or emerging risks. As a result, decision-making tends to be reactive rather than proactive, reducing opportunities for early intervention.

In recent years, Augmented Reality (AR) has received growing attention to improve visualization and communication in construction environments. By superimposing digital information directly onto physical space, AR can provide workers and managers with intuitive insights into planned tasks, component locations, and spatial constraints (Billinghurst et al., 2015). Earlier research has demonstrated that AR can support construction activities such as layout, inspection, training, and safety management by making complex information easier to comprehend on-site (Kamat et al., 2011). When combined with sensor data or computer vision capabilities, AR systems can also help detect discrepancies between planned and actual conditions, thereby creating opportunities for early error identification. The integration of AR with BIM and progress monitoring tools has thus emerged as a promising direction for enhancing construction project management.

This paper proposes an integrated AR and CV approach aimed at supporting the scheduling and monitoring of construction projects, with a particular focus on MEP-intensive environments. The approach combines AR-

based visualization of the construction schedule with automatic detection of installed components through CV techniques. This integration facilitates users to compare the planned and actual states of construction, facilitating earlier detection of deviations and more informed decision-making. The objective is to move beyond traditional, document-based progress tracking toward an immersive, data-driven project control system that can reduce errors, minimize rework, and improve adherence to schedule.

To demonstrate the feasibility and usefulness of the proposed approach, a prototype system was developed and tested partly in a laboratory setting and partly on-site within the construction of a large winery production and storage facility in northern Italy. This project provided a particularly relevant testing environment due to its complex MEP installations, tight construction timelines, and stringent quality requirements typical of industrial facilities. The pilot test allowed for an evaluation of the system's usability, accuracy, and potential benefits in supporting field operations. Preliminary findings suggest that AR-CV technologies can enhance situational awareness, streamline progress verification, and support proactive project control.

Overall, this research contributes to ongoing efforts to digitalize construction management by offering a practical solution for integrating AR and CV into project scheduling and monitoring workflows. By focusing on the challenges characteristic of MEP-intensive environments, the proposed approach addresses a critical gap in current construction management practices and offers new avenues for improving productivity, reducing errors, and enhancing coordination on construction sites.

Related works

In recent years, the literature on construction progress monitoring has increasingly focused on the development of digital pipelines integrating CV, BIM, Digital Twin (DT), and AR to support near real-time project control, effectively rendering traditional manual, episodic, and subjective approaches obsolete. Recent review studies highlight that the topic is no longer limited to the automation of data capture but is increasingly oriented toward the development of closed-loop control systems, in which as-built observations directly inform the comparison with as-planned data through BIM. Within this context, traditional monitoring methods based on site inspections and manual reporting are still widely used but are considered inadequate for complex and dynamic projects, particularly when frequent and objective assessment of progress is required (Reja et al., 2022; Pal et al., 2023; Samsami, 2024).

Research on CV applied to the construction industry primarily focuses on the comparison between as-built and as-planned conditions through BIM models. Recent advancements show a shift from simple recognition of whether an activity has been completed to more granular, activity-based methods. A representative example is the work of Yang et al. (2023), who proposed a YOLOv8-based system for the automated monitoring of window installation progress. Several studies emphasize that the reliability of CV models is strongly influenced by site conditions, such as lighting variations or the presence of occluding objects that may interfere with visual inspection, as well as by the limited availability of annotated datasets and the difficulty of recognizing partially installed elements (Yu et al., 2025; Yue et al., 2025). In the MEP domain specifically, point cloud-based approaches have shown that deep learning networks can accurately segment pipe components even from poorly scanned data, provided that the domain gap between BIM generated synthetic training data and real as-built scans is explicitly addressed through feature and label alignment strategies (Yu et al., 2025). In particular, point clouds of MEP scenes are inherently affected by severe occlusions due to the dense overlapping of components, which degrades the performance of downstream recognition and classification tasks if left unaddressed (Yue et al., 2025). Both Yu et al. 2025 and Yue et al. 2025 demonstrate that BIM models can serve as a scalable and cost-effective source of synthetic annotated training data, directly mitigating the scarcity of labeled industrial datasets that represents one of the primary bottlenecks in applying CV to MEP environments (Yu et al., 2025; Yue et al., 2025).

Pal et al. (2024) propose a framework, which combines BIM, semantic segmentation, and ortho-view synthesis, also leveraging Neural Radiance Fields (NeRF), to estimate activity completion percentages with an average error below 6%, overcoming the limitations of methods that only detect the presence or absence of elements. Many studies aim to optimize the acquisition of point clouds for integration and comparison with BIM models. Some approaches involve SLAM-based mobile mapping devices to capture point clouds and panoramic images in indoor environments. Vassena et al. (2023) highlight the potential of more continuous workflows but also the persistence of issues related to semantic interpretation and automated understanding of point clouds, which negatively affect the real-time capabilities of DT systems. Other research explores neural rendering techniques and lightweight, photorealistic 3D representations. Studies on NeRF show that construction site scenes can be used not only for visualization but also for BIM comparison and progress estimation, often relying on handheld smartphone-captured video (Jeon et al., 2024). More recent work is also exploring 3D Gaussian Splatting and hybrid workflows to improve coordination, immersive visualization, and the quality of as-built versus as-planned comparison (Liao et al., 2025). These developments indicate that CV for monitoring is no longer limited to 2D image detection and segmentation but is increasingly merging with scene representation techniques, digital twin systems, and visual analytics.

Regarding AR technologies, recent literature confirms that their main value lies not only in the visual overlay of BIM models onto the real environment, but also in their ability to make project information, construction sequences, geometric deviations, and coordination issues immediately interpretable on-site (Sidani et al., 2021). The review by Bhatarai et al. (2025) describes BIM-AR

integration as a digital-physical bridge extending across the lifecycle, with expected benefits in design optimization, rework reduction, and contextual data access. At the application level, recent studies show that AR integrated with scheduling and BIM can support real-time progress tracking (Arvikar et al., 2025), while in the MEP domain AR has proven particularly promising for verifying complex installations, enabling direct comparison between the as-built condition and design geometry within the physical environment (Girgin et al., 2023).

More recently, research has addressed the convergence of CV, BIM, DT, and AR. These technologies are no longer treated as independent modules but as components of a unified monitoring and inspection architecture. For instance, Tao et al. (2024a) propose a passive AR inspection framework that integrates object detection, 3D projection, digital twin-driven recognition, and AR visualization. Tao et al. (2024b) investigate different methods and their combinations for recognizing construction progress directly through AR, by overlaying BIM models onto captured images. At a broader scale, recent studies show that the integration of CAD, BIM, immersive technologies, and advanced scanning techniques can yield measurable benefits even in highly complex structural and MEP coordination scenarios, reducing rework and review times (Liao et al., 2025).

Within this context, the present work aligns with the most recent research direction by proposing an integrated AR-CV framework, in which AR is not used solely as a visualization tool, but as an operational interface for construction progress recognition, task visualization, and real-time monitoring, contributing to a more immediate and integrated connection between site conditions, BIM-based planning, and decision-making support.

AR-CV based Construction Management

The proposed approach consists of three modules: 1) Planning with AR, where the structure and level of detail is defined. 2) Scheduling with AR, where based on module "1 Planning" the components/objects that are scheduled for installation are visualized in AR. 3) Monitoring with AR and CV where the scheduled objects/components in AR are compared with the installed objects in reality by means of CV. In the proposed approach scheduling is based on monitoring implementing the so- called "rolling scheduling" approach. In this way, the construction work is scheduled in increasing levels of detail as the project progresses, rather than defining the entire schedule in detail from the start. The system was developed in Unity 2020.3.42f1 by using the Mixed Reality Toolkit (MRTK) 2.8 and deployed on the Head Mounted Display (HMD) Microsoft Hololens 2. Figure 1 shows the AR-CV based approach for construction management.

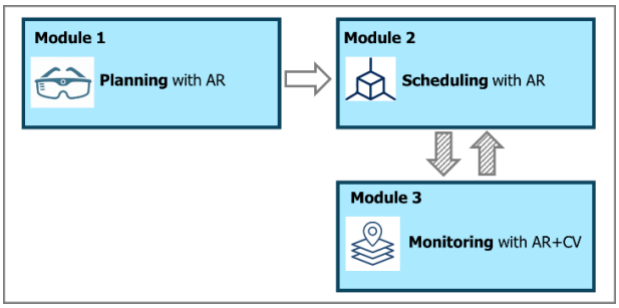

Figure 1: Schematic representation of the AR-CV based approach for construction management

Module 1 – Planning with AR

Module 1 is used to structure and define the Level of Detail (LoD) of the BIM, ensuring consistency between data acquisition, modelling, and downstream visualization processes. The definition of LoD within this module establishes clear modelling requirements aligned with the intended use of the digital model, particularly for AR visualization and CV–based monitoring. As a first step, a digital point cloud of the existing environment was generated using the Leica BLK2GO 3D laser scanner. This mobile scanning device enabled rapid acquisition of high-density spatial data while maintaining sufficient geometric accuracy for BIM modelling purposes. The resulting point cloud served as the primary geometric reference for the creation of the BIM model, which was developed using ArchiCAD version 27. The modelling process adhered to the LoD specifications defined in Module 1, ensuring that only the necessary geometric and semantic information was included.

The point cloud–based BIM model constitutes the foundation for the digital model used in AR visualization. By directly deriving the BIM geometry from the scanned data, spatial coherence between the physical environment and the virtual model is preserved, which is essential for accurate AR alignment and user interaction. This approach supports both visualization and spatial validation. In parallel, the planning module was employed to define the object structure and coding system required for AR visualization and monitoring. Each BIM object was assigned a standardized classification and unique identifiers, enabling seamless integration with the CV based monitoring approach. This structured coding framework allows selected elements to be visualized in AR and subsequently monitored in real time, supporting object recognition, status tracking, and progress analysis.

Module 2 - Scheduling with AR

Figure 2 shows the interface for scheduling and monitoring the construction project by using the HMD Microsoft HoloLens 2. The buttons on the left side are used to show the scheduling for a specific week (KW = calendar week in German), the "tig" indicates if the installation of the scheduled week had been completed and by using the "Undo" sign the completion can be revoked. An important aspect is the accurate aligning and anchoring of the digital model to the real-world environment so that virtual objects appear in the correct

position, orientation, and scale. This is also called AR registration. For this purpose, the Microsoft QR Code Tracking Package in Unity was used and 2 QR codes were set for the AR registration.

Figure 2. Interface for scheduling and monitoring by using the HMD

Module 3 - Monitoring with AR and CV

Module 3 is used to monitor the installation of the components on-site based on the scheduling. The complete system operates as a spatial correspondence estimator to quantify physical construction progress relative to the digital model through a multi-stage computation pipeline. The workflow begins with QR code detection, which establishes a spatial anchor that links Windows Perception Spatial Graph coordinate system to Unity's reference frame. This alignment ensures that the reference BIM and the spatial reconstruction produced are expressed in a common coordinate frame. Such normalization is essential as overlap estimation, and voxelization requires the same origin, orientation, and scale. To represent the real world, we used the HoloLens's 2 SLAM algorithm that generates view-dependent spatial mesh representing partial observations of the physical environment (SLAM, 2026).

In contrast, the reference BIM is deterministic and hierarchically structured, consisting of multiple geometric components that together encode construction elements, assemblies, and sections. Upon user-triggered comparison, both the reference geometry and the sensed spatial reconstruction are discretized through voxelization at a fixed spatial resolution of 5 centimeters. This process converts continuous surface meshes into discrete spatial occupancy representations that enable efficient comparison. Voxelization relies on the triangle-box intersection based on the Separating Axis Theorem (SAT), ensuring accurate surface coverage (Ericson, C., 2004). The SAT is a collision detection method, which determines intersection by testing for the existence of a separating axis such the projected intervals of the objects do not overlap. The system then computes the intersection over union (IoU) between the aggregated reference representation and the sensed environment to quantify spatial correspondence. Specifically, for each hierarchical node n , IoU is defined as the ratio between the number of voxels shared by the reference and sensed representations and the total number of voxels belonging to either representation. The reference voxel set V_n represents the aggregated spatial occupancy of node n in the reference hierarchy, while V_s denotes the voxel set corresponding to the sensed environment. Matched and total occupancy information is subsequently propagated recursively from lower-level components to higher-level nodes through bottom-up aggregation in the scene graph. Equation 1 shows the IoUn metric where n indexes a hierarchical reference node.

$$IoU_n = \frac{(|V_n \cap V_S|)}{(|V_n \cup V_S|)} \quad (1)$$

This bottom-up aggregation can be interpreted as a completion metric that estimates the degree of spatial correspondence for each construction unit. The resulting completion values are interpreted as empirical indicators of construction progress rather than exact geometric truth, explicitly accounting for the downward bias introduced by incomplete sensing. Module 3 was tested exclusively under laboratory conditions due to constraints encountered during the case study implementation. Immediately after installation, the pipes were covered as part of the standard construction process, preventing direct visual access required for the deployment and validation of the proposed approach on-site. As a result, laboratory testing was adopted to ensure controlled conditions for evaluating the functionality and performance of module 3.

Testing

The proposed approach was pilot tested partly in a laboratory setting and partly on-site within the construction of a large winery production and storage facility, where the construction intervention was focused on the realization of large underground cellar spaces dedicated to bottle storage. The case study company is a small enterprise located in Northern Italy and specialized in Heating, Ventilation and Air Conditioning (HVAC). The project considers the execution of technical installations within extensive subterranean open-plan environments. The industrial partner involved in the study was responsible for the on-site assembly of building services systems MEP, within these spaces.

Figure 3 shows the structuring of the BIM model as basis for the scheduling and monitoring of the case study. The size of section 1 is 17.80 m x 21.70 m, section 2 has a size of 13.50 m x 39.00 m and section 3 has a size of 13.00 m x 36.00 m.

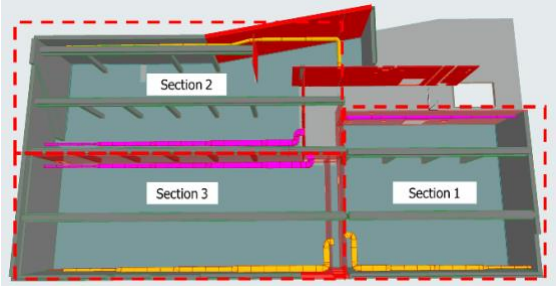

Figure 3. BIM model and structure of the case study

This case study introduced two main challenges: (i) the exceptionally large scale of the environments, characterized by open spaces, and (ii) the limited lighting conditions present during on-site testing activities. The solution deployed on site demonstrated high accuracy in hologram-to-reality alignment, maintaining geometric consistency between the physical environment and the digital model. However, the HMD initially experienced reduced spatial tracking performance due to insufficient illumination. This critical aspect was successfully addressed by installing temporary artificial lighting, which restored stable tracking conditions and enabled the continuation of the experimental activities.
Figure 4 shows module 2 and specifically the weekly scheduling in AR of the installation of air exchange pipes in sector 3 by using the Microsoft Hololens 2 HMD.

The results demonstrate that the AR–based visualization has great potential, even when applied to large-scale construction sectors. The spatial alignment between the digital model and the physical environment enables immediate identification of clashes and intersections among building elements, supporting rapid detection of potential conflicts. Furthermore, according to the foreman of the case study company, the integration of scheduling information into the visualization environment made construction sequencing tangible, allowing temporal aspects of the project to be intuitively understood and facilitating improved comprehension of planned activities and their spatial implications.

Figure 4. Module 2 weekly scheduling in AR of the installation of air exchange pipes in sector 3

Figure 5 shows the testing of module 3 in the laboratory environment.

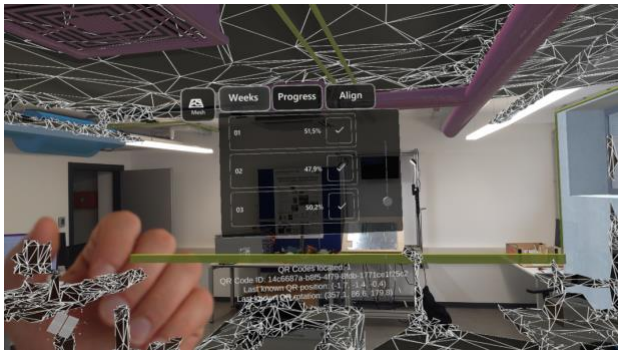

Figure 5. Testing of module 3 in laboratory settings

Figure 6 shows the 5 main component groups that were used to test module 3: A) The fan coil unit, B) the fan pipe supply connected to the unit, C) the wall channel for covering electrical wires, D) electrical pipes for the ventilation system and the writing desk plugins and E) the air exchange pipe system.

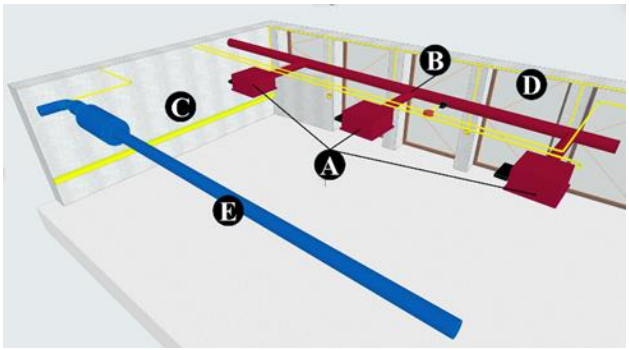

Figure 6. Component groups used for the testing of module 3

Table 1 shows the results of the lab tests where the IoU indicator was used according to Equation 1. Two tests in August 2026 were done.

Table 1: Lab test results of module 3

Object name and acronym	Intersection over Union IoU [%] – test 1	Intersection over Union IoU [%] – test 2
Fan coil unit (A)	48.00	77.80
Fan pipe supply (B)	78.10	62.30
Wall channel (C)	75.00	37.50
Electrical pipes (D)	54.7	45.60
Air exchange pipe (E)	91.4	63.60

According to the test results, electrical pipes D) and wall channels C) exhibit comparatively lower values of the Intersection over Union (IoU) ratio, indicating greater difficulty in achieving accurate spatial overlap for these elements. This behaviour can be attributed to their reduced cross-sectional dimensions and partial occlusions within the scene. In contrast, air exchange pipes E) and fan supply components B) demonstrate relatively high IoU values, reflecting more reliable detection and spatial correspondence. The larger geometric dimensions and clearer visibility of these elements contribute to improved detection, confirming the sensitivity of the IoU indicator to object scale and visual accessibility.

Discussion

The results indicate that the proposed AR–CV system enables a significantly faster detection of potential planning and execution errors when compared to traditional inspection and coordination methods. By superimposing digital information directly onto the physical environment, discrepancies between the planned and the as-built conditions can be identified in real time,

supporting prompt corrective actions and reducing the risk of error propagation during construction.

The findings further demonstrate that the visualization approach remains effective even in large-scale construction projects. Despite the increased spatial complexity and scale, the system maintained sufficient clarity and spatial accuracy, allowing users to navigate extensive construction sectors while preserving meaningful contextual information. This highlights the scalability of the AR-based visualization framework for complex construction environments.

The proposed AR–CV system addresses key limitations in current methods for scheduling and monitoring MEP construction projects. Unlike traditional approaches that rely heavily on large, annotated datasets, which are often scarce or costly to obtain in construction contexts, the proposed approach operates without the need for pre-labeled training data, enhancing its scalability and practical deployment. Furthermore, the AR–CV system tightly integrates scheduling with real-time monitoring, enabling dynamic adaptation to the inherent variability and uncertainty of construction processes. This interlinking facilitates more responsive progress tracking and decision-making. Additionally, while existing CV approaches struggle to accurately recognize partially installed components, Module 1 of the proposed system introduces a flexible level-of-detail definition, allowing robust detection and classification even in intermediate installation states. Collectively, these features contribute to a more adaptable and reliable solution for managing complex MEP construction workflows.

However, the analysis also reveals that the perspective of visualization plays a critical role in the evaluation of the IoU indicator (Table 1). Variations in viewing angle and distance influence the apparent overlap between detected objects and their corresponding digital representations, thereby affecting IoU values. This becomes also evident considering the discrepancies between test 1 and test 2 visualized in Table 1. This suggests that IoU-based performance assessment in AR–CV applications should account for viewpoint-dependent effects.

Moreover, the performance of the AR–CV construction management system was found to be highly sensitive to low-light conditions. Insufficient illumination negatively impacts image quality and feature extraction, leading to reduced detection accuracy and lower IoU values. This limitation highlights the need for controlled lighting conditions or the integration of additional sensing modalities to improve robustness in real-world construction environments.

Finally, the results indicate that the IoU indicator is particularly sensitive to objects that are not spatially free or detached on all sides, such as elements attached to walls or partially occluded components. In such cases, limited visible surfaces reduce the measurable overlap between detected and reference objects, leading to lower IoU values. This observation suggests that complementary evaluation metrics may be required to fully assess system performance for attached or constrained building elements.

Conclusion and outlook

Mechanical, Electrical, and Plumbing (MEP) systems involve spatial coordination and often complex installation sequences, making schedule adherence and progress monitoring particularly challenging in construction projects. This paper proposes a framework that leverages Augmented Reality (AR) and Computer Vision (CV) to enhance scheduling support and real-time monitoring in MEP construction. The approach combines BIM-based planning data with on-site AR visualization to provide field personnel with intuitive, context-aware guidance on installation tasks and sequencing constraints. By using CV algorithms an automatically detection of MEP components from site images and video streams becomes possible. This enables objective progress measurement and early identification of deviations from planned schedules. By fusing AR-enabled human-centric decision support with automated CV-based performance tracking, the system facilitates more accurate schedule updates, reduces rework caused by miscoordination, and improves communication on-site. The paper proposes a prototype that has been developed in Unity for the Head Mounted Display HoloLens 2. The AR-CV prototype had been pilot tested partly in a laboratory setting and partly on-site by using as case study the construction of a large winery production and storage facility in northern Italy.

Future research will focus on further enhancing the monitoring capabilities of the proposed system. First, Module 3 will be improved to understand the user's point of view, increasing robustness to viewpoint misalignment and occlusions during on-site data capture. Second, complementary evaluation metrics will be investigated to more comprehensively assess system performance, particularly for attached or geometrically constrained building elements where standard detection measures may be insufficient. Finally, extensive empirical testing of the monitoring module will be conducted on active construction sites to evaluate its accuracy, reliability, and practical usability under real-world conditions.

Acknowledgments

The authors would like to express their acknowledgement to the company Ruedl Hans OHG for valuable contributions to this research. The research was co-funded by MIMIT - Ministero delle Imprese e del Made in Italy in the context of the project Digital Innovation Hub South Tyrol (DIS-HUB 28-31), CUP B57H22006510001 - B57H22006500008.

PROPOSAL OF HUMAN-SENSORED ARCHITECTURE FRAMEWORK BY INTRODUCING MIXED REALITY

Kyung-Tae Lee[1]
[1]Kangwon National University, Chuncheon-si, Republic of Korea

Abstract

Remote work has increased the need to understand how indoor spatial design affects occupants' cognitive performance and physiological states. This study proposes a Human-sensored Architecture framework integrating Mixed Reality (HoloLens 2) for real-time spatial manipulation and EEG (Emotiv EPOC+) for physiological measurement. Following a network analysis of 124 publications, experiments with 30 participants revealed that red walls enhanced short-term executive function through stress-induced arousal, whereas preferred, low-stress settings improved long-term memory and productivity. These findings demonstrate the value of human-centered spatial design tailored to specific cognitive tasks and provide a foundation for personalized, adaptive architecture.

Introduction

Since the onset of the COVID-19 pandemic in 2020, the prevalence of remote work has increased significantly. As individuals spend more time indoors, there is a growing demand for environments that facilitate diverse tasks and activities effectively. Given that changes in the indoor environment profoundly affect the emotional and physiological states of occupants, research is continuously being conducted to identify which spatial configuration factors enhance user convenience and task efficiency (Lee et al., 2022). Historically, researchers have primarily focused on analyzing human states relative to environmental variables such as building facilities, temperature, and humidity to determine optimal conditions (Banaei et al., 2020). However, there remains a critical lack of analysis regarding the physiological responses to fundamental design elements—such as wall and floor colors, ceiling heights, and materials—that dictate the overall ambiance of a space (Lee et al., 2022). This gap is largely attributed to the technical limitations previously associated with modifying indoor designs in real-time.

Nevertheless, with the emergence of Extended Reality (XR) technologies, particularly Virtual Reality (VR) and Mixed Reality (MR), it has become possible to alter spatial designs instantaneously while incorporating real-time client feedback (Han et al., 2021). As a bridge between digital experiences and physical reality, these technologies—encompassing both AR and VR—serve as powerful tools for visualizing structures and environments (Portman et al., 2015). MR, in particular, has emerged as a significant paradigm in user interface systems, augmenting human perception by overlaying computer-generated information onto the real world. In this context, user interaction and immersion within the virtual environment are vital parameters that must be optimized for practical application (Chamilothori et al., 2019). While virtualization in MR enhances efficiency and productivity while mitigating risks (Portman et al., 2015), the most critical factor is interoperability. Since visual designs are superimposed on reality, maximizing interaction is essential. Furthermore, as MR devices often operate without external trackers or remotes, gesture-based recognition is paramount. Despite the potential of Head-Mounted Displays (HMDs) to enable accurate task performance and convenient daily life through 3D information, challenges remain. Mismatches or conflicts during the brain's information processing can induce cybersickness, leading to visual fatigue, anxiety, nausea, and disorientation (Im et al. 2022). Physical discomfort, such as the weight of the device, also necessitates further technological refinement (Rehring et al., 2019). Consequently, the MR market is expanding, with increasing adoption in the construction industry due to its interoperability and the convenience of controller-free operation.

To evaluate the physical and mental states of individuals within these spaces, psycho-physiological indicators are utilized. These indicators facilitate the assessment of human states through biological responses, identifying sympathetic and parasympathetic nervous system reactions to visual stimuli via metrics such as EEG, heart rate variability (HRV), and electrocardiogram (ECG) (Lee et al., 2022). Previous studies applying these metrics to the architectural field have found that white or green walls tend to induce a sense of psychological comfort, characterized by increased Alpha wave activity associated with reduced tension (Lee, Shin, and Lee, 2020). However, prior research has frequently focused on isolated components (e.g., a single wall or material) rather than the holistic design of a space. Moreover, while studies have analyzed physiological indicators to maintain a state of rest, research aimed at proposing optimal spatial designs for high task performance based on such indicators remains scarce.

Accordingly, this study aims to elucidate the relationship between indoor spatial design and human affective-physiological responses through empirical analysis. Since modifying physical indoor environments in real-time is practically infeasible due to construction and material constraints, Mixed Reality (MR, Microsoft HoloLens 2) was adopted as a specialized experimental apparatus. MR serves as a medium to overcome these limitations, enabling the instantaneous and controlled manipulation of spatial configurations to observe their direct impact on human states. To establish a robust theoretical foundation for the experimental design, a *bibliometric analysis* and network analysis were conducted. Based on the clusters derived from core descriptors, a theoretical framework was proposed, which subsequently guided the experimental protocol. Based on this framework, experiments were conducted with 30 participants across four spatial configurations: a baseline white space, a preferred space, a non-preferred space, and a self-selected space. During each session, two cognitive tests were administered to assess task efficiency. Concurrently, EEG data were collected and preprocessed to calculate Mental Stress and Mental Workload indices using established neuroscientific formulas. Through repeated measures statistical analysis, this study identifies fluctuations in affective-physiological indicators and task efficiency, ultimately proposing the optimal spatial configuration for specific task types.

Research Design

Methodology

This study aims to elucidate the intricate relationship between humans and spatial environments through empirical analysis. To achieve this, a theoretical framework was established via a literature review, followed by the development of an experimental environment capable of real-time modifications to indoor spatial designs. The review process involved curating scholarly publications from Web of Science and Scopus, with a subsequent network analysis performed on the extracted keywords. By identifying and synthesizing key thematic clusters, a comprehensive framework was constructed to map the connectivity between human subjects and spatial variables. Based on this framework, an experimental protocol was implemented. Technically, HoloLens-based mixed reality was utilized for spatial selection and manipulation. Human physiological responses were captured using electroencephalogram (EEG) to assess cognitive states, while spatial activities were defined and evaluated through task performance, enabling a multi-dimensional understanding of human reactions within diverse spatial configurations.

Establishment of experimental environment

Development of Theoretical Framework

To develop the proposed framework, research papers were extracted in accordance with a four-stage process. This process consists of the following: Stage 1, the selection of search engines and keywords; Stage 2, the screening and extraction of literature based on the selected keywords; Stage 3, quantitative literature analysis; and Stage 4, the analysis of results and the subsequent discussion process (Kim and Hyun, 2019). Initially, papers were retrieved from Web of Science and Scopus, which are recognized as representative academic databases. The temporal scope for the literature search was set from approximately 2000 to 2023. Specifically, in Web of Science, papers were extracted using the search string: TS=(interior AND space AND building) AND AK=(design) NOT AK=(Thermal AND Ventilation AND Energy). For Scopus, the search was conducted based on the query: ALL ("space" AND "building" AND "interior") AND KEY ("design") AND KEY ("interior") AND NOT ("Thermal") AND NOT ("ventilation") AND NOT ("energy").

Following this systematic screening as previously mentioned, a final total of 124 papers were selected, which provided the foundation for constructing the framework. In conducting the network analysis, a keyword co-occurrence network was constructed from the abstracts and keywords of the selected papers, and PageRank centrality (Brin and Page, 1998) was computed using the R programming environment. PageRank centrality was originally developed for ranking web pages based on hyperlink structures; however, it has been increasingly adopted in bibliometric research to evaluate the relative importance of keywords within co-occurrence networks, as the structural logic of interconnected nodes applies analogously to both domains (Ding et al., 2009). Through this approach, core keywords were identified based on their centrality scores, and the resulting network was subsequently visualized to delineate thematic clusters. Finally, after identifying the core values of the major clusters, the theoretical framework was established based on the synthesis of these cohesive factors.

Experiment Plan

The experimental protocol was meticulously designed to comprehensively reflect the components of the proposed framework. To investigate the fluctuations in affective-physiological indicators relative to indoor spatial design, it was essential to establish an experimental environment capable of real-time modifications. In this study, a Mixed Reality (MR) environment was introduced—a technology that enhances realism by superimposing virtual holographic information onto the physical environment (Im et al., 2022; Han et al., 2021). For the implementation of this MR setting, Microsoft HoloLens 2 was utilized, allowing for the manipulation of wall colors, materials, floor textures, and ceiling heights within a standardized indoor space measuring 5,500 mm × 7,000 mm × 3,600 mm.

Specifically, the wall color palette included white, blue, beige, green, and red. Flooring materials ranged from epoxy, stone, and wood to carpet, tile, and PVC, while wall finishes included brick, wood, paint, stone, concrete, and wallpaper. Additionally, the ceiling height was adjusted between high and low configurations. Based on a preliminary survey, participants were presented with three distinct spatial scenarios: a baseline white space, a

preferred space, and a non-preferred space. Furthermore, participants were encouraged to engage in decision-making by directly configuring their own preferred spaces. Findings indicated that participants predominantly preferred a configuration consisting of beige walls, PVC flooring, a wooden ambiance, and high ceilings, citing a sense of comfort and warmth. In contrast, a configuration featuring red walls, concrete and tile textures, and low ceilings was identified as non-preferred, with participants describing it as visually overstimulating and oppressive.

Subsequently, task efficiency within each spatial configuration was evaluated while concurrently measuring affective-physiological indicators. EEG data were collected using the Emotiv EPOC+ device, with 14-channel signals recorded in accordance with the international 10-20 system. This enabled the measurement of brainwave activity across four regions: the frontal, temporal, occipital, and parietal lobes (Lee, Shin, and Lee, 2020). Task performance and corresponding EEG patterns were analyzed through the Stroop test, which assesses short-term executive function, and the Reading Span Test, which evaluates working memory and long-term performance efficacy.

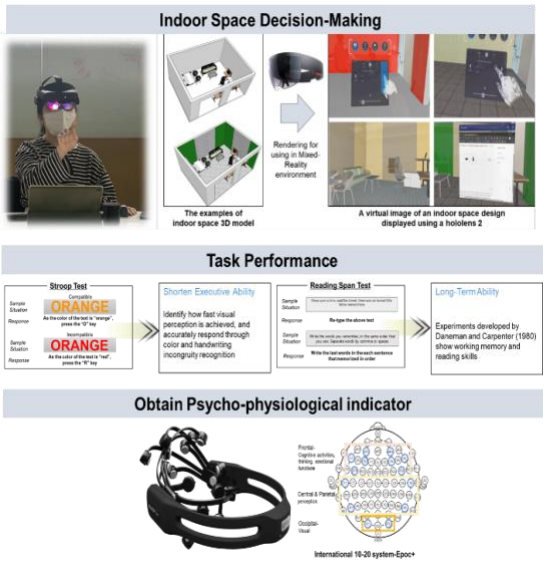

Figure 1. Process of experiment and activities

Data Collection

Experiment Participants

The experimental protocol of this study was conducted following approval from the Institutional Review Board (IRB) (Approval No. HYUIRB-2022202-005), after which participants were recruited. A total of 30 participants in their 20s and 30s were enrolled. The sample size was determined using G*Power 3.1 software and validated with reference to prior research in the field (Banaei et al., 2020). The participant pool comprised 30 Architectural Engineering students, balanced by gender (N=30; 15 males and 15 females). To eliminate potential bias arising from prior exposure, the selection was restricted to individuals who had never experienced Mixed Reality. Prior to the data collection phase, an introductory session on the MR device was conducted, followed by a 10-minute period for participants to independently adapt to the virtual environment. To ensure the integrity of the physiological data, all participants were screened to confirm they had no history of mental illness, were not suffering from sleep deprivation, and had no visual impairments. Furthermore, they were required to abstain from alcohol and smoking for 24 hours prior to the experiment. The Short Portable Mental Status Questionnaire (SPMSQ) was administered to verify that all participants possessed normal cognitive function. The SPMSQ, a 10-item screening instrument developed by Pfeiffer (1975) to detect cognitive impairment, was administered to all participants. The SPMSQ evaluates basic orientation, memory, and general knowledge through brief verbal questions of relatively low difficulty, serving as a preliminary screening tool rather than a comprehensive cognitive assessment. In this study, all 30 participants answered all items correctly (i.e., zero errors), confirming that the entire sample possessed intact cognitive function suitable for the experimental tasks. Before proceeding the experiment, participants wore the Microsoft HoloLens 2 and the Emotiv EPOC+ device, allowing them to engage in spatial decision-making tasks while their EEG signals were concurrently collected and recorded throughout the activities.

Data Pre-processing

First, to evaluate the task performance data obtained from the experiments, accuracy (%) and response time (ms) were recorded for each session. These metrics were subsequently converted into a 'Learning Ability Index' for comparative analysis, as defined in Equation (1).

$$\text{Learning Performance} = [(Accuracy)^{0.5} * \frac{1}{(Response\,time)^{0.5}}]^2 * 100 \quad (1)$$

Following this, electroencephalogram (EEG) was utilized as an affective-physiological indicator to analyze human responses. As a non-invasive method, EEG facilitates the practical measurement of neuronal activity and synaptic signals within the brain. The captured brainwaves were categorized into specific frequency domains to identify the underlying relationship between emotional states and indoor spatial configurations. For data processing, the frequency and spatial coordinates of each electrode were initially identified using the EEGLAB toolbox in MATLAB. Given that EEG signals are prone to artifacts such as eye blinks, muscle movements, and respiratory cycles, a rigorous preprocessing stage was essential to isolate the 2–39 Hz frequency range suitable for empirical analysis. As illustrated in Figure 2, this study employed the Blackman Window, characterized by low side-lobe levels and high frequency resolution. Through Independent Component Analysis (ICA) and Fast Fourier Transform (FFT), the signals were decomposed into distinct bands: Theta ($4-8$ Hz), Alpha ($8-13$ Hz), Beta ($13-30\ Hz$), and Gamma (30-39 Hz). Since lower frequencies are typically associated with resting states, these values were converted into 'Relative Power' to ensure an objective comparison of cognitive activity

(Kamzanova et al., 2014). Finally, two key indices established by previous researchers—Mental Workload and Mental Stress—were calculated to perform a spatial comparison, based on Equations (2) and (3), respectively.

$$\text{Mental workload} = \frac{(Relative\ Beta)_{Frontal}}{(Relative\ Theta)_{Frontal}+(Relative\ Alpha)_{Frontal}} \quad (2)$$

$$\text{Mental Stress} = \frac{(Relative\ Theta)_{Frontal}}{(Relative\ Alpha)_{Parietal}} \quad (3)$$

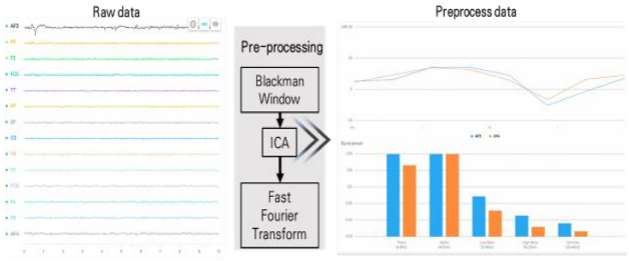

Figure 2 Data pre-processing method

Data Analysis

Statistical analysis in this study was performed using SPSS version 26.0 (IBM Corp., Armonk, NY, USA). To determine the appropriate statistical methods, the Kolmogorov-Smirnov (K-S) test was first conducted to assess the normality of the data distribution. For datasets that satisfied the normality assumption, a Repeated Measures Analysis of Variance (RM-ANOVA) was employed to compare EEG responses and task efficiency across the different indoor spatial configurations. Prior to the RM-ANOVA, the fundamental statistical assumptions were verified. First, the homoscedasticity of the dependent variables was confirmed, with all variables satisfying the requirement ($p \geq .05$). Second, Mauchly's test was employed to assess the assumption of sphericity. In instances where sphericity was violated, the Greenhouse-Geisser correction was applied to adjust the degrees of freedom and ensure the validity of the F-statistics (Yang et al., 2021). In instances where the normality assumption was violated, the non-parametric Friedman test was utilized for the comparative analysis (Han et al., 2021). To further identify specific differences between spatial conditions, post-hoc analyses were performed: Tukey's Honestly Significant Difference (HSD) test was applied following RM-ANOVA, whereas the Bonferroni correction was implemented for pairwise comparisons following the Friedman test.

Results

Proposal of theoretical Framework

As illustrated in Figure 3, the network analysis results reveal that the data are structured into four distinct primary clusters. Within each cluster, the size of the nodes (circles) corresponds to the frequency of the terms, indicating their significance as core keywords. As previously discussed, by employing PageRank centrality, the underlying main topics of each cluster were identified based on the inter-node connectivity between terms. Table 1 defines the representative keywords for each cluster, focusing on those descriptors that exhibit large node diameters and high degrees of connectivity as depicted in Figure 3.

Furthermore, terms associated with each primary keyword were systematically organized, providing a comprehensive basis for synthesizing the thematic focus and intended subjects represented by each individual cluster.

Figure 3 Result of Network Analysis

Based on a bibliometric analysis centered on Table 1, this study analyzed the interplay between humans and spatial design, called human-sensored architecture. The human component is broadly categorized into two dimensions: the cognitive dimension and the psycho-physiological reaction. Within the cognitive dimension, perception encompasses both innate temperament and accumulated experience, representing the diverse knowledge and empirical background individuals develop throughout their lives. Simultaneously, humans exhibit various psycho-physiological reactions in response to spatial configurations.

Table 1 Main topic of each cluster

Cluster	Main keyword	Other keyword	Main topic
Cluster 1 (red)	color	furniture object, light, textile, wall, height, surface, aesthetic, ceiling	Space Configuration Component
Cluster 2 (green)	experience	perception, psychology, behavior, decision, creativity, trait	Temperament of Human
Cluster 3 (blue)	technology	computer, quality, building information modeling, artificial intelligent, virtual reality technology	Smart construction technology
Cluster 4 (yellow)	human	comfort, satisfaction, safety, privacy, productivity, health	Status of human in indoor space

Specifically, as indoor environments undergo modifications, fluctuations are observed not only in physiological markers—such as electroencephalogram (EEG) and heart rate variability (HRV)—but also in psychological emotional states. Consequently, this study identified the cognitive dimension (conceptualized as the x-axis) and the psycho-physiological response (conceptualized as the y-axis) as the fundamental pillars influencing human spatial decision-making. Ultimately, the human state, which is modulated by the indoor environment, dictates the nature of human activity. These activities, typically manifested as work productivity or rest, necessitate that environmental configuration be proposed based on a comprehensive understanding of human factors. The resulting theoretical framework synthesized from these relationships is illustrated in Figure 4.

Differences in work efficiency by space

The results of the comparative analysis regarding short-term executive function and long-term working memory across the four spatial configurations (Baseline, Preferred, Non-preferred, and Self-selected/Decision-making space) are as follows. To determine the appropriate statistical method for evaluating task efficiency, the Kolmogorov-Smirnov (K-S) test was conducted. The results yielded p-values of 0.200 (D(30)=.113) for executive function and 0.178 (D(30)=.136) for working memory, confirming that both datasets satisfied the normality assumption. Consequently, a Repeated Measures ANOVA (RM-ANOVA) was performed to examine the differences based on spatial design, the results of which are summarized in Table 2. The RM-ANOVA revealed significant differences in both executive function and working memory depending on the spatial configuration. Regarding executive function, the highest performance levels were observed in the non-preferred space. Subsequent Tukey post-hoc analysis further elucidated that while performance was significantly higher in the non-preferred environment, no statistically significant differences were found between the baseline, preferred, and self-selected spaces. Conversely, the analysis of working memory showed that performance was lowest in the non-preferred space, whereas the highest performance was recorded in the self-selected (decision-making) space. Post-hoc results for working memory indicated that while no significant differences existed among the non-preferred, baseline, and preferred spaces, the self-selected configuration yielded a significantly superior performance outcome. In summary, the impact of indoor spatial design on task efficiency varied by cognitive demand: short-term executive function was enhanced in non-preferred environments, whereas long-term working memory performance was optimized in self-selected spatial configurations.

Differences in Psycho-physiological indicators by space

Following the preprocessing of EEG data, the physiological indicators derived from Equations (2) and (3) were subjected to normality testing. The Kolmogorov-Smirnov (K-S) test revealed that while Mental Stress satisfied the normality assumption ($D(30)=.109$, $p > .200$), Mental Workload violated it ($D(30)=.168$, $p = .030$). Consequently, Mental Stress was analyzed using RM-ANOVA, whereas the Mental Workload was evaluated via the non-parametric Friedman test. Regarding Mental Stress, Mauchly's test indicated that the sphericity assumption was satisfied for the executive function test. In contrast, the assumption was violated for the working memory test; consequently, the Greenhouse-Geisser correction was applied to adjust the degrees of freedom for the subsequent analysis. Figure 5 presents box plots illustrating the distribution of Mental Stress and Mental Workload across the different spatial configurations. In the case of Mental Stress during the executive function test, the highest levels were observed in the preferred space, followed by the self-selected and non-preferred spaces. Post-hoc analysis indicated no significant difference between the non-preferred and

Table 2 Statistical analysis of taskperformance among space design

Task Performance	Interior design	Mean	Standard deviation	Tests of within subject effects					Post hoc
				Type Ⅲ Sum of squares	Df	Mean square	F-Statistics	Sig.	Tukey HSD
Executive ability	Basic	9.349	4.063	549.384	2.572	213.564	27.966	.000**	1=2=4<3
	Prefer	12.203	3.960						
	Non-Prefer	14.790	4.088						
	Personal	12.275	4.044						
Working Memory	Basic	1.046	0.753	2.319	2.600	.892	2.815	.042*	3=1=2<4
	Prefer	1.055	-.656						
	Non-Prefer	0.916	0.660						
	Personal	1.301	0.492						

Note *: p-value<0.05, **: p-value<0.001

baseline spaces; however, participants experienced significantly higher stress in the preferred space. Similarly, significant spatial variations in Mental Stress were observed during the working memory test. Post-hoc comparisons confirmed that the preferred space induced the highest stress levels. Notably, in contrast to the executive function results, stress levels in the self-selected space during the working memory task were found to be lower than those in the non-preferred space. Regarding Mental Workload, analyzed via the Friedman test, the results for the executive function test showed the most intense workload in the non-preferred space. Bonferroni-corrected post-hoc analysis confirmed that these differences were statistically significant, indicating that the non-preferred environment imposed a substantially higher cognitive load, while the workload in the self-selected space was relatively low. Conversely, although the workload during the working memory task appeared higher in the non-preferred space, this difference did not reach statistical significance.

Discussion

With the increasing emphasis on Digital Twin technology, interest in Mixed Reality (MR) has grown significantly. In the construction industry, MR has primarily been utilized for spatial visualization, often limited to safety training and education. This study, however, expands the application of MR by redirecting its focus toward spatial decision-making. A key differentiator of this research lies in its integrated presentation of fluctuating physiological indicators alongside task efficiency across diverse spatial configurations. While traditional approaches have focused on subjective impressions and qualitative expressions of space, future spatial planning will likely transition toward more complex, biometric-centered proposals (Lee et al., 2022). As evidenced by this study, the evolution of MR enhances the decision-making process for stakeholders, fostering greater coherence and streamlining communication (Zaker and Coloma, 2018). Despite current technical limitations—such as resolution constraints and sensitivity to lighting—these challenges are expected to be overcome in the long term. Given its capacity for real-time interaction and 3D visualization, MR is poised to become an efficient tool, particularly in the early stages of construction projects.

The findings confirm that visual information significantly influences biometric responses, which in turn affect behavioral and task performance. Interestingly, the preferred space showed the highest Mental Stress values. This result suggests that Mental Stress should not be interpreted solely as indicating a more adverse or uncomfortable condition. Rather, the non-preferred condition was more consistently associated with elevated Mental Workload, suggesting increased cognitive demand, whereas the preferred space may have elicited greater emotional arousal or attentional engagement. Notably, the superior task performance observed in non-preferred spaces regarding short-term concentration can be elucidated through the 'fight-or-flight response' theory (Cannon, 1915). This theory suggests that when individuals experience stress, the autonomic nervous

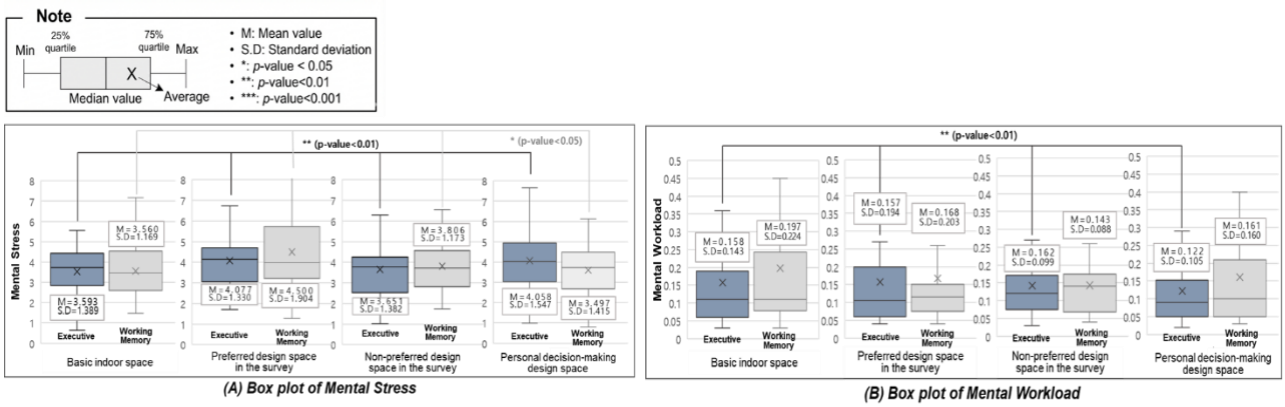

Figure 5 Boxplot of psycho-physiological index

system is activated to heighten focus on the stressor as a survival mechanism. Specifically, exposure to environments with red walls or low ceilings imposed a significantly higher cognitive workload, as evidenced by elevated Mental Workload indices. This heightened cognitive demand can be interpreted through the lens of the fight-or-flight response theory. According to this framework, the autonomic nervous system is activated under demanding conditions to sharpen focus as a survival mechanism, which may paradoxically enhance short-term executive function (Duyan & Ünver, 2016). This explains why participants exhibited improved attention despite the taxing nature of the non-preferred environment. However, considering that long-term capacity is better manifested in preferred spaces due to spatial adaptation, this research underscores the necessity of configuring environments tailored to specific individual competencies and task types. Future interior design should prioritize the emotional responses and cognitive demands of users, ensuring that individuals can successfully adapt their behavior within these optimized spatial configurations.

Conclusions

In conclusion, this study sought to analyze the variations in human affective-physiological responses and task efficiency according to real-time modifications in indoor spatial design. By implementing a Mixed Reality (MR) environment for 30 participants, the research facilitated the collection of EEG data and the comparative analysis of task performance across diverse spatial configurations. The findings revealed that in the short term, although participants experienced a higher cognitive workload in non-preferred spaces, they paradoxically reported lower stress levels and demonstrated superior task performance compared to preferred or self-selected environments. This suggests that visually stimulating or non-preferred environments may heighten acute attention, leading to increased output in brief, execution-oriented tasks.

However, the temporal dynamics of these effects shifted during long-term engagement. While no significant difference was initially observed between spatial design and workload during prolonged tasks, the non-preferred space eventually led to an accumulation of stress, resulting in a subsequent decline in task efficiency. In contrast, participants demonstrated a significant adaptation to self-selected (decision-making) spaces over time. In these configurations, stress levels decreased as individuals acclimated to their environment, which in turn facilitated higher long-term task efficiency. These results underscore that while non-preferred spaces may trigger higher short-term executive function, self-selected environments are optimized for sustained productivity and psychological well-being through spatial adaptation. Therefore, environmental configurations should be proposed dynamically, aligning with specific task types and the required levels of cognitive concentration (Cho et al., 2019).

Despite these insights, this study is subject to certain limitations, particularly its reliance on a Mixed Reality simulation. Future research should strive to validate these findings in full-scale physical environments through longitudinal action research. Furthermore, the scope of inquiry should be expanded by incorporating a broader array of affective-physiological indicators—such as heart rate variability (HRV) and electrocardiogram (ECG)—to achieve a more comprehensive understanding of human biological responses to the built environment.

CHAT WITH PRE-DEMOLITION AUDITS: KNOWLEDGE-GRAPH BASED INFORMATION RETRIEVAL

Ioanna Mitropoulou[1], Beril Önalan[1], and Catherine De Wolf[1]
[1]ETH Zurich, Switzerland
Circular Engineering for Architecture.

Abstract

Although pre-demolition audits (PDAs) provide early information on building materials, they are underutilized partly because their data require domain expertise to access and interpret. This raises the question: can natural-language querying enable non-experts to retrieve information from PDA datasets? We propose a knowledge-graph-based Retrieval-Augmented Generation (RAG) framework for natural-language querying of PDAs, applied to a case study of 40 French audits. Evaluated against a semantic RAG baseline across 21 queries, Graph-RAG achieves a success rate of 90% compared to 57% using vector-based retrieval, though at 2.34× higher cost, demonstrating its potential to making PDA content accessible to non-expert stakeholders.

Introduction

Pre-demolition audits (PDAs) are increasingly recognized as a key source of information for enabling reuse (Wu et al., 2026; Davis et al., 2025). Produced before the building intervention (refurbishment or demolition), they capture materials, quantities, conditions, and potential reuse pathways. However, despite their early availability and potential to inform design, PDAs remain largely disconnected from early-stage reuse decisions and design workflows. In practice, architects and clients rarely consult PDAs during conceptual design, when material selections and building configurations are most flexible.

The primary barrier to the effective utilization of PDAs is semantic accessibility. These audits often consist of vast quantities of fragmented information spread across extensive structured tabular inventories (material quantities, dimensions, conditions) with unstructured textual reports (building context, accessibility constraints, intervention plans). Extracting insights from these heterogeneous data currently requires users to understand schema conventions and to have the technical proficiency to formulate precise filters or database queries. For non-expert stakeholders, this technical overhead acts as a significant deterrent to data-driven reuse, limiting accessibility, user agency, and the practical use of PDA data in decision-making.

This paper aims to bridge this gap by developing a natural-language interface that enables easy and intuitive access to the contents of these large and complex documents through natural-language queries. We propose a Knowledge-Graph-based Retrieval-Augmented Generation (Graph-RAG) workflow structured to address specifically the typical formats of PDAs, so their information becomes more accessible and interpretable to non-expert users. We compare it against a baseline RAG workflow, as shown in Fig. 1), and conclude the strengths and weaknesses of each system. With the proposed Graph-RAG workflow, we enable users to extract specific material details and building-level context through natural language, effectively democratizing access to reuse data for the architecture, engineering, and construction industry.

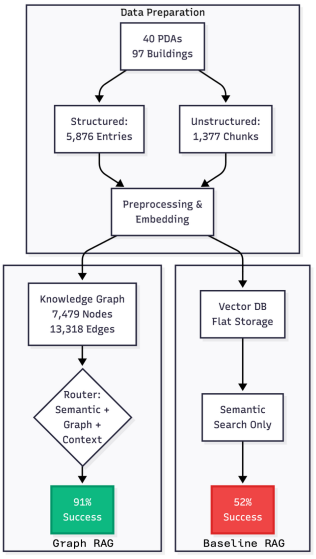

Figure 1: Overview of the proposed Graph-RAG framework for PDA data and its comparison with a baseline RAG approach.

Background

Pre-demolition audits in circular construction. PDAs have emerged as essential tools in circular construction for identifying, quantifying, and managing building materials at end-of-life stages to minimize end-of-life waste (Wu et al., 2026; Godina et al., 2025; Luciano et al., 2022). These audits systematically collect information about the type, quantity, quality, and accessibility of building materials, supporting selective demolition planning, material recovery pathways, and integration into digital building logbooks (Oluleye et al., 2023).

However, PDA datasets present significant challenges for

effective data retrieval. First, heterogeneity and inconsistency across different audits complicate data comparison, transferability, and generalization across different buildings (Akanbi et al., 2020). While recent research has addressed these issues through automated classification, structuring, and enrichment of heterogeneous data into unified schemas (Mitropoulou et al., 2026), challenges in querying remain. Second, PDAs consist of both structured data (tabular inventories with quantitative material information) and unstructured data (textual reports describing building conditions, accessibility, and contextual information), which are interlinked but difficult to query cohesively. This necessitates computational approaches that can jointly query both data modalities.

Natural-language interfaces for built-environment data. Natural-language interfaces have emerged as a critical mechanism for making complex built-environment data accessible to non-expert users. Retrieval-augmented generation (RAG) based on semantic similarity has been increasingly explored for knowledge-base querying (Li and Wang, 2026). RAG has become widely adopted in pre-trained language models to enhance performance in domain-specific tasks by dynamically accessing external knowledge bases, improving factual grounding and relevance in generated responses (Shang et al., 2025). However, standard RAG approaches face significant limitations when handling structured knowledge: they treat the data as isolated chunks of plain text, thus losing information about their relations. As a result, they fail to capture the global semantics and relational dependencies present in built-environment datasets (Procko and Ochoa, 2024; Xu et al., 2024).

To address these challenges, for tabular data specifically, recent methods have explored how LLMs can search, interpret, and reason over tables stored in comma-separated values (CSV) format. However, such LLM-to-CSV search methods suffer from similar loss of semantic information and high failure rates on complex queries (Sequeda et al., 2024). Knowledge graphs offer a promising alternative by representing heterogeneous information through semantically meaningful nodes and relationships. Knowledge graphs preserve the hierarchies and connections present in source data (Shang et al., 2025), enabling more successful retrieval of information through Graph-RAG (Li and Wang, 2026; Sequeda et al., 2024; Xu et al., 2024). Recent advances in Graph-RAG have demonstrated substantial improvements over standard RAG: the Vector-Graph RAG framework for querying semantic web building data achieved a 20-40% improvement in accuracy over state-of-the-art LLMs using traditional RAG (Li and Wang, 2026). Similarly, graph-based approaches for Building Information Modeling (BIM) data showed 75% accuracy compared to just 16.7% for direct LLM querying (Hsiu Tung et al., 2025). Additionally, Graph-RAG has been implemented to enable natural-language interaction with digital twins, demonstrating how such technologies can democratize access to complex built-environment information for non-expert users (Pan et al., 2026). However, to date, Graph-RAG has not been applied to datasets in which structured and unstructured information are semantically interdependent, as in PDA datasets.

Summary. Despite advances in structuring heterogeneous PDA data and developing natural-language interfaces for built-environment information, a gap remains in retrieval frameworks capable of jointly handling semantically linked *structured* data (e.g., tables) and *unstructured* data (e.g., textual reports). This paper addresses these limitations by proposing a Graph-RAG workflow that integrates structured and unstructured PDA data within a graph-based retrieval framework, enabling non-expert users to query this information in natural language.

Methods

We first describe the initial preprocessing of PDA data and the subsequent construction of the knowledge graph that combines structured and unstructured data. Following this, we introduce our retrieval algorithm, which uses a router to decompose the query into smaller steps. Each step is then executed through either semantic search or graph search. Finally, we present a comparative evaluation of our retrieval framework against a baseline semantic RAG interface (lacking access to the knowledge graph) by testing both strategies on a set of 21 questions.

Data preprocessing

The goal of the preprocessing step is to transform the raw PDAs into an accessible format suitable for subsequent knowledge-graph creation. Our case study consisted of a set of 40 PDAs sourced from different buildings across France that collectively describe entries from 97 distinct buildings. The information in these audits consisted of both structured data (tables), which describe building materials and products, and unstructured data (textual reports), which describe contextual information (Fig. 2).

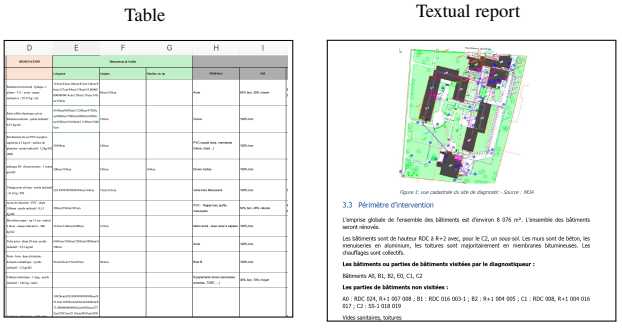

Figure 2: Example of the contents of a PDA. Left: structured input (table). Right: unstructured input (textual report).

Structured data preprocessing. To address the heterogeneity of the structured tabular data across different PDAs, we applied the methodology proposed by Mitropoulou et al. (2026). This process structured and classified the

entries according to a unified schema and classification system. This resulted in a CSV file containing over 7000 entries translated to English in a unified format. Following Mitropoulou et al. (2026), the entries were initially categorized into *Materials* and *Products*, each using a different classification system. For simplicity in the current study, we focused exclusively on the Product entries to maintain a single classification system, specifically the Uniformat II schema (Charette and Marshall, 1999), which provides a hierarchical structure consisting of three classification levels.

Unstructured data preprocessing. A subset of PDAs contained unstructured textual reports. These reports were first translated from French into English using OpenAI GPT-4o. Subsequently, the translated text was segmented into discrete text chunks, each limited to a maximum length of 1200 characters, with an overlap of 200 characters between neighboring chunks.

Knowledge-graph creation

Schema. To create the knowledge graph, we first defined the schema, which specifies the nodes, how they are connected, and which attributes each node stores. The schema includes the nodes *Project*, *Building*, *Entry*, *Classification*, *Report*, and *Text Chunk*, connected as shown in Fig. 3. We developed this model by first clarifying the purpose of the graph, its intended users, and the types of queries it should be able to answer. In our case, the dataset was designed for non-expert stakeholders seeking reliable information on documented materials to inform early-stage reuse decisions. Based on this, we manually identified the core entities and relationships present in the dataset and iteratively refined the structure by testing it on a small data sample. The attributes associated with each node type are listed in Table 1. The nodes Project, Building, Entry, and Text Chunk each store an embedding vector, enabling their contents to be retrieved through semantic search.

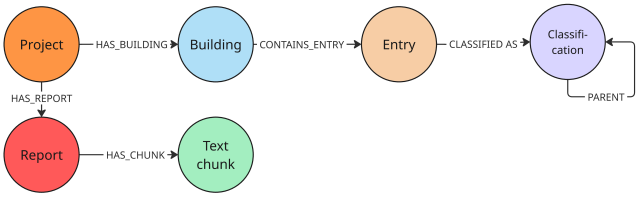

Figure 3: Schema of knowledge graph containing the following nodes: Project, Building, Entry, Classification, Report and Text chunk, connected with semantic edges.

Graph creation. The knowledge graph was constructed using the Graph Data Science Python Client (Neo4j, Inc., 2025a) to connect to Neo4j (Neo4j, Inc., 2025b), a web-based platform for building and querying knowledge graphs. We imported both the structured data (a CSV file containing the processed entries) and the unstructured data (text chunks), and created nodes for each entity defined in the schema, including their embedding vectors. We then added the semantic edges specified in the schema. An example of the resulting graph for a subset of entries belonging to a single building is shown in Fig. 4.

Table 1: Node types and their attributes in the knowledge graph. The nodes Project, Building, Entry, and Text Chunk each contain an embedding vector, so that their contents can be retrieved through semantic search.

py

Node	Attributes
Project	name, zipcode, **embedding vector**
Building	name, total area, usage, year of construction, **embedding vector**
Entry	entry id, assembly type, condition, description, notes, hazardous, quantitative data (mass, volume, dimensions, etc.), **embedding vector**
Classification	code, level
Report	report id, project name
Text Chunk	chunk id, chunk index, **embedding vector**

The full knowledge graph consisted of a total of 7,479 nodes and 13,318 relationships. Querying was performed using the OpenAI GPT-4o, while semantic representations were generated with the OpenAI `text-embedding-3-small` model, which produces 1,536 dimensional embeddings.

Knowledge-graph-based information retrieval

Our workflow for retrieving information using the knowledge graph is shown in Fig. 5 (proposed Graph-RAG) and compared with the baseline RAG workflow. The process begins with the user submitting a natural-language query. In the Graph-RAG, the query is routed through a sequence of steps, described below, aiming to assemble a comprehensive context that will produce an accurate answer.

LLM Router. The query is first handled by the router, an LLM-based function that decomposes the user query into a sequence of smaller retrieval steps. Each step is assigned to either a *graph search* or a *semantic search*, depending on which method is better suited to retrieve relevant context. The purpose of this decomposition is not to answer the question directly, but to make a plan for how to construct a maximally informative context that will enable answering the question at a later step. A few-shot router prompt instructs the LLM on the available tools, the criteria for selecting each tool, and examples of how complex queries should be broken down. For every generated sub-step, the router specifies:

- *Tool*: semantic search | graph search
- *Prompt*: a concise description of what to retrieve
- *Report context*: true | false (whether to also retrieve the most relevant linked report text chunks)

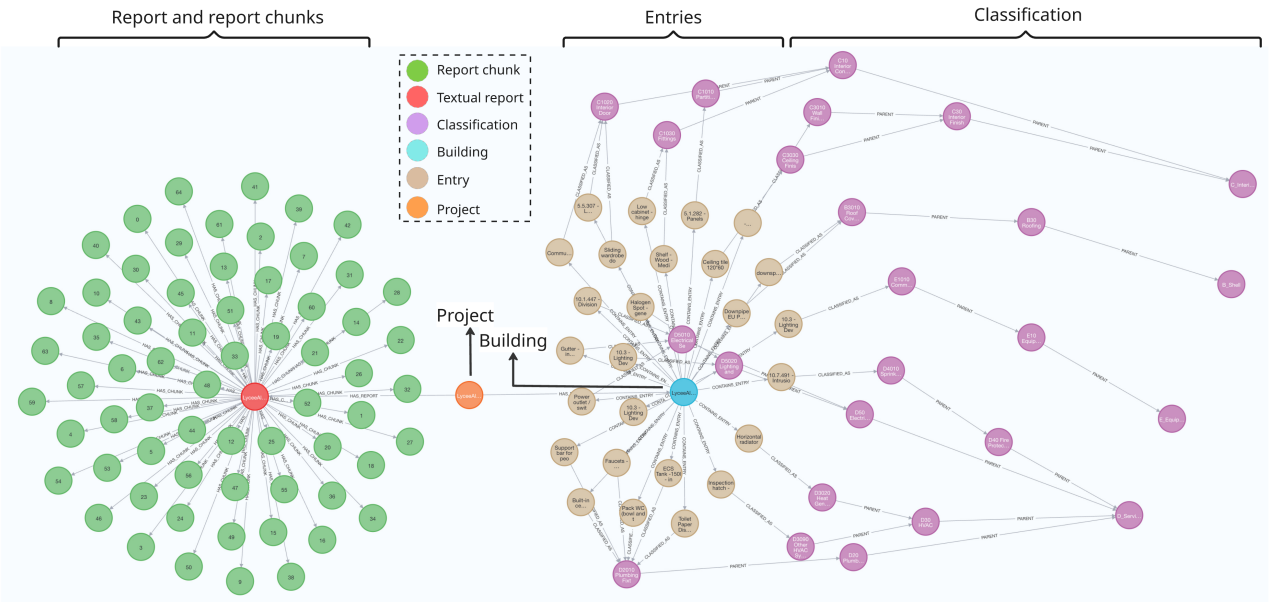

Figure 4: Example of a graph created for a subset of entries of a single building. Left: The Textual report chunk nodes (green) contain unstructured text parts of a Report node (red). Middle: A Building node (blue) is connected to a Project node (orange) and contains Entries (brown). Right: The Entry nodes are connected to their Classification nodes (purple).

Semantic search. The semantic-search component follows a standard RAG workflow. All nodes that contain embeddings (Projects, Buildings, Entries, and Textual Report Chunks) are searchable. For each step, the LLM semantic router determines which node type(s) should be queried. A similarity search is then performed, ranking nodes according to embedding similarity and selecting the top-k most relevant items, with $k = 20$.

Graph search. Graph search uses an LLM that generates Cypher code to traverse the knowledge graph, filter nodes, count elements, or retrieve specific relationships. The prompt for generating the Cypher code includes a description of the graph schema, relationships, and attributes, so that the generated queries are syntactically correct. Once generated, the Cypher query is executed to retrieve the required data.

Linked report context. For each retrieval step, the router may indicate that linked report information should also be included. In such cases, the algorithm starts from nodes obtained via semantic or graph search and traverses the graph to collect all linked textual report chunks. For example, when starting from a Building node, the traversal proceeds via the corresponding Project and its linked Report to retrieve all associated text chunks. If such chunks exist (not all projects have reports), they are semantically ranked, and the top-k most relevant fragments are added to the context.

Answering. Once the final context has been assembled by combining results from graph search, semantic search, and optionally linked report content, it is passed to the LLM along with the original user query and an answer prompt that instructs the model to base its output strictly on the provided context. The LLM then produces the final answer.

Evaluation

To evaluate the performance of the proposed approach, we designed a set of representative questions organized into five categories testing different competencies: (A) simple filtering, (B) counting, (C) more complex queries, (D) queries requiring report context, and (E) unanswerable questions (Table 2). Ground-truth answers were established through manual inspection of the dataset. The evaluation focused on end-to-end question-answering performance, that is, how well the final generated answer agreed with the established ground truth, without separately assessing the success of the intermediate retrieval steps. We compared the performance of our model against a baseline RAG system, described below.

Baseline RAG. The baseline consists of a standard RAG pipeline, illustrated in Fig. 5 left. Given a user query, the LLM semantic router determines which type(s) of searchable nodes containing embeddings to search (Projects, Buildings, Entries, or Textual Report Chunks). These nodes are then ranked according to semantic textual similarity. The top-k most relevant nodes are retrieved and incorporated into the context. For all semantic searches that retrieved the top-k most relevant nodes, we used $k = 20$.

Results

Evaluation questions

The evaluation questions, shown in Table 2, are organized into five categories that test different competencies.

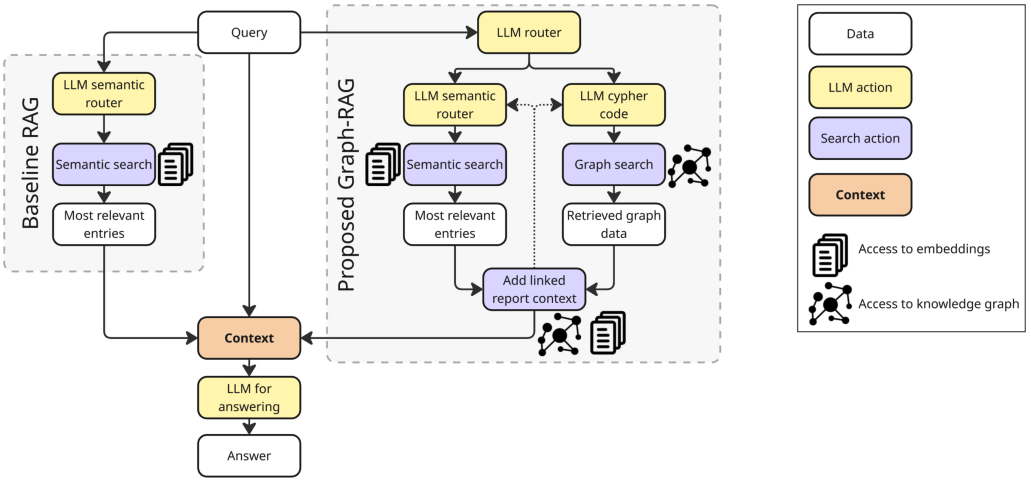

Figure 5: Diagram comparing two information-retrieval workflows for building the context that enables answering natural-language queries; baseline RAG (left), and the proposed Graph-RAG (right). The baseline RAG uses a single semantic search to retrieve relevant nodes by checking their embeddings for semantic similarity. The proposed graph-RAG first sends the query to an LLM router, which decomposes it into sub-steps executed through either semantic or graph search. The retrieved results, together with any linked report context selected by the router, are aggregated into the context.

Category A: Simple filtering. These queries involve retrieving specific entities based on explicit attribute matches, such as material condition or safety status. The baseline RAG performed well on basic listing tasks. The Graph-RAG successfully resolved these logical constraints but occasionally struggled with precise attribute filtering, such as in question A3: ‘‘Find windows in good condition”. There, it produced an invalid filter which returned zero entries, leading to failure in answering this question.

Category B: Counting. This category requires the system to aggregate and count information across the entire dataset to provide quantitative totals. Here, the baseline RAG failed in every query because it relies on local chunk similarity, which cannot capture a global count. In contrast, Graph-RAG demonstrated high competency by using graph operations to provide accurate totals.

Category C: More complex queries. These questions require both filtering and semantic search, and may also include multi-step retrieval. Graph-RAG answered all questions, whereas the baseline failed in half of the questions. This underscores a fundamental limitation of standard RAG: if the information needed is not contained within the same text chunk, the vector search cannot reliably link data from different chunks. Further, question C5, which required a global comparison of window counts across all buildings, was not successfully answered by baseline RAG. This is because this method only sees the top-k chunks it retrieves and has no way of knowing which building has the most windows. Graph-RAG successfully answered the questions by combining semantic search and graph traversal. It also handled semantic variations, such as identifying that ‘‘residential buildings” and ‘‘houses” in C1 and C2 refer to the same category. However, this accuracy came at significantly higher token consumption and cost as the retrieval required more steps and generated more extensive context.

Category D: Queries requiring report context. These queries evaluate the system’s ability to retrieve information from the reports and link it to the corresponding entries. Both methods succeeded in questions D1 and D3, where building-level attributes like construction material or future use could be found in the report text chunks. However, in D2 the baseline RAG failed to link a specific component (glazing panels) to building properties (the heating system) found elsewhere in the report, illustrating the RAG’s inability to link information stored in different chunks. In contrast, Graph-RAG successfully resolved the query by following the graph edges from the identified nodes (glazing panels) to their parent building nodes and finally to their report text chunks where the information about the heating system is stored.

Category E: Answer cannot be found in the dataset. This final category serves as a robustness check to evaluate the systems’ tendency to hallucinate when faced with queries regarding information absent from the dataset, such as market values or carbon-footprint metrics. The baseline RAG demonstrated consistent reliability; it correctly identified the absence of data. In contrast, Graph-RAG failed in E1 by confusing a different numerical property (mass) with the requested market value. Although Graph-RAG successfully provided correct refusals for E2 and E3, it did so at a significantly higher token cost since the system performed a more extensive search before concluding that the data was missing.

Table 2: Comparison of performance across 21 query types for baseline RAG and the proposed Graph-RAG approach. The symbol ✓denotes success and ✗denotes failure. The total amount of tokens used and the total cost for the creation of the full answer are reported for each approach.

Evaluation questions	Baseline RAG			proposed Graph-RAG		
	Tokens	Cost $	Result	Tokens	Cost $	Result
A. Simple filtering						
A1. List five items that are in good condition.	6,475	0.012	✓	9,262	0.021	✓
A2. List five hazardous entries.	8,433	0.024	✓	4,657	0.010	✓
A3. Find windows in good condition.	7,615	0.022	✓	14,379	0.029	✗
B. Counting						
B1. How many buildings are in the dataset?	3,332	0.009	✗	3,872	0.006	✓
B2. Count all the residential buildings in the dataset.	3,795	0.014	✗	3,999	0.007	✓
B3. Count how many entries are in each building in the dataset.	3,733	0.013	✗	8,351	0.026	✓
B4. What percentage of entries are marked as hazardous?	6,327	0.016	✗	5,531	0.013	✓
C. More complex queries						
C1. Find five windows from residential buildings	6,499	0.020	✗	20,720	0.061	✓
C2. Find five windows from houses	6,302	0.019	✗	21,072	0.072	✓
C3. Show exterior cladding options from schools in good condition.	5,627	0.017	✓	23,716	0.062	✓
C4. Find acoustic ceiling panels from office buildings.	6,550	0.018	✗	17,473	0.049	✓
C5. Which building has the most available windows and what are its details?	3,452	0.010	✗	28,802	0.072	✓
C6. We need 30 sq. meters of exterior facade cladding in good condition, which options exist in the dataset?	6,676	0.021	✓	19,263	0.038	✓
C7. Find reusable double glazing windows with more than 2 units available.	6,458	0.019	✓	20,262	0.056	✓
C8. I'm looking for 10 identical toilet separator walls that can be reused.	7,645	0.022	✓	20,217	0.052	✓
D. Queries requiring report context.						
D1. Find a residential building in the dataset whose load-bearing system is made of reinforced concrete.	8,261	0.021	✓	16,322	0.058	✓
D2. I'm looking for available glazing panels. What kind of heating system does the building have that these panels originate from?	8,557	0.022	✗	21,371	0.056	✓
D3. Which building is undergoing transformation into offices?	7,705	0.020	✓	12,761	0.035	✓
E. Answer cannot be found in the dataset.						
E1. What is the market value of the double-glazing windows recorded in the dataset?	8,227	0.025	✓	21,228	0.064	✗
E2. Which reusable material in the dataset has the highest market value?	7,634	0.022	✓	25,592	0.069	✓
E3. What is the carbon footprint of the structural steel parts in the dataset?	7,707	0.023	✓	20,678	0.053	✓

Reasoning plans

Table 3 shows examples of the reasoning plan of sub-steps created by Graph-RAG to gather the necessary context to answer the given questions.

Table 3: Step-by-step reasoning plans followed by Graph-RAG for building the context that can help the LLM answer selected evaluation questions.

ID	Question and reasoning plan
A4:	**Find three entries from buildings constructed before 1970.** 1. *Graph search.* Find buildings constructed before 1970. 2. *Graph search.* Find entries from the buildings found in the previous step.
B4:	**What percentage of entries are marked as hazardous?** 1. *Graph search.* Count all entries. 2. *Graph search.* Count all entries marked as hazardous.
C4:	**Find acoustic ceiling panels from office buildings.** 1. *Semantic search.* Find office buildings. 2. *Graph search.* Find all entries from the buildings found in the previous step. 3. *Semantic search.* Find acoustic ceiling panels from the entries found in the previous step.
C6:	**We need 30 sq. meters of exterior facade cladding in good condition, which options exist in the dataset?** 1. *Semantic search.* Exterior facade cladding entries. 2. *Graph search.* Filter entries found in the previous step to those in good condition with at least 30 square meters available.

Discussion

Overall performance. The evaluation results demonstrate a clear performance-accuracy trade-off between the baseline RAG and the Graph-RAG methods. Across 21 queries, Graph-RAG achieved 90% success rate (19/21 successful queries) compared to 57% (12/21 successful queries) for baseline RAG. Graph-RAG significantly outperformed the baseline RAG on tasks requiring global knowledge of the dataset, multi-step retrieval, and counting, while the baseline RAG proved effective for simple, localized retrieval (Category A) and exhibited higher robustness against hallucination in the absence of data (Category E). However, this improved accuracy came at a 2.34× higher cost, with Graph-RAG averaging $0.0433 per query compared to $0.0185 for baseline RAG. The main strengths and weaknesses of each method are summarized in the following:

- **Relations.** Graph-RAG successfully used graph traversal to find relations between separate nodes and address the inability of baseline RAG to link information that is stored in different text chunks.

- **Global vs. local context.** The baseline RAG is inherently limited by its top-k retrieval mechanism, making it incapable of performing global aggregations

such as counting (Category B). Graph-RAG, conversely, was successful at answering questions that require global context.

- **Efficiency and cost.** The increased accuracy of Graph-RAG comes at a substantial cost. On average, Graph-RAG came at a 2.34× higher cost than the baseline, making standard RAG the more cost-effective solution for simple keyword-based retrieval.

- **Hallucination.** As seen in Category E, the baseline RAG was more conservative and better at identifying knowledge gaps, whereas Graph-RAG occasionally became confused by the retrieved information and failed to identify the lack of the requested data.

- **Flexibility.** Graph-RAG's modular approach, which builds a series of sub-steps, enables adaptive query decomposition, providing flexibility that baseline RAG lacks.

Retrieval methods overlap. Semantic search and graph search have overlapping capabilities. As a result, most queries can be answered through multiple retrieval paths, though with varying degrees of reliability. For instance, identifying a specific material category can be achieved either through vector-based semantic similarity or by querying specific nodes within the graph.

Reliability. When Graph-RAG fails, errors typically originate from the stochastic nature of the query-decomposition phase, inaccuracies in automated Cypher generation, or system implementation issues. For instance, Graph-RAG was unable to answer question A3 because the graph-search query for windows in good condition produced the invalid filter `entry.condition = "Good condition"`, whereas the correct encoding is `entry.condition = "good"`. This illustrates that, while the approach provides a robust foundation for PDA information retrieval, its practical performance remains dependent on the accuracy with which the LLM translates natural-language inputs into structured, executable operations.

Evaluation limitations. The question-based evaluation cannot capture nuances such as incomplete answers, varying response quality, or incorrect confidence levels in generated outputs. Additionally, the manual ground-truth verification introduces potential subjectivity for queries with multiple valid interpretations. Furthermore, the evaluation does not assess user-experience factors such as query formulation difficulty or result interpretability, which are critical considerations given that the intended users are non-experts. Finally, the study focuses on a single dataset of French PDAs with specific structural characteristics. Applicability to PDAs from other regulatory contexts or formats remains to be validated.

Outlook

Several directions could advance this research beyond the current prototype. First, enriching the knowledge graph with additional semantic relationships, such as explicit MENTIONS edges linking Report nodes to referenced Entry or Building nodes and implicit edges for relations such as spatial proximity, material compatibility, and dimensional similarity, would facilitate multi-step queries. Second, extending the system to support continuous conversations with memory would enable iterative query refinement (for example, ‘‘show me more details about that building,’’ ”now filter those to only non-hazardous items”) without re-specifying context. Third, incorporating multimodal data such as photos from PDA site visits would provide richer context; photographic documentation that many PDAs already contain could be leveraged but remains unexploited in text-only frameworks. Fourth, integrating external knowledge sources such as material databases, reuse marketplaces, or embodied carbon calculators would enable queries combining PDA inventory with market availability, pricing, or environmental impact assessments. Fifth, implementing explainability mechanisms that visualize which graph paths, semantic similarities, or retrieval steps contributed to answers would build user trust and enable systematic debugging of retrieval errors. Finally, human-centered deployment studies in real design workflows are needed to evaluate the system as a decision-support tool, including its effects on user trust, understanding, perceived agency, decision quality, decision-making time, and stakeholder engagement.

Conclusion

This paper presented a Graph-RAG framework to enable natural-language querying of PDA data. The approach integrates structured tabular inventories with unstructured textual reports in a knowledge graph to enable non-expert users to retrieve information using natural-language queries without requiring schema knowledge or technical skills. In this way, it improves the accessibility of PDA data and provides a foundation for more human-centered interaction with reuse information.

The evaluation across 21 queries demonstrated that Graph-RAG achieved a higher success rate than baseline RAG, with the performance advantage most pronounced in queries requiring counting, global aggregation, and multi-step reasoning. Both methods performed equally well on purely semantic queries, confirming that semantic similarity-based retrieval remains effective for concept matching when graph structure is not required. However, Graph RAG's higher accuracy comes at a higher cost, as it requires significantly more tokens to answer queries. The study demonstrates that knowledge-graph representations of PDA data enable more flexible and context-aware information retrieval compared to semantic search over unstructured text chunks. The framework's design provides a foundation for applying natural-language interfaces to heterogeneous built-environment datasets where structured

and unstructured information coexist.

COLLABORATIVE FACADE DESIGN WITH LLM-BASED MULTI-AGENT SYSTEMS USING RECLAIMED BUILDING COMPONENTS

Pritha Jacob[1], Ioanna Mitropoulou [1], Pei-Yu Wu[2] and Catherine De Wolf[1]
[1]ETH Zurich, Zurich, Switzerland
[2]TU Delft, Delft, Netherlands

Abstract

The potential for material reuse is restricted by the lack of methods for integrating reclaimed materials into facade design workflows. This paper presents a multi-agent pipeline using LLMs to support integrating reclaimed materials into facade design. Tested through a web application in two design modes: a *collaborative* mode, where human and LLM collaborate, and an *independent* mode, without human guidance; the users reported the collaborative mode to be more useful. The proposed AI-human collaboration framework improved the tasks of searching for materials, evaluating options, and visualizing design iterations, highlighting the value of AI-driven design frameworks in encouraging reuse in architecture.

Introduction

Designing with reclaimed components remains largely a task of trial and error, with designers manually assembling designs from available inventories, which makes them more hesitant to implement reclaimed materials in their design (Kawa et al., 2022). Much of the research to date aimed at facilitating circular design frames the integration of reclaimed materials as an optimization problem. As a result, researchers are pursuing fully automated deterministic methods to generate feasible design solutions (Moussavi et al., 2022). However, facade design, in particular, cannot be reduced to optimization alone: it involves aesthetic judgment, contextual reasoning, and qualitative considerations that are difficult to formalize computationally. When the human designer is incorporated into the loop, these qualitative dimensions can be addressed through interpretation, judgment, and situated decision-making, leveraging human expertise alongside computational reasoning. The present research aims to develop such a collaborative design workflow that integrates human expertise with generative AI methods, specifically large language models (LLMs), to support design with reclaimed materials. In doing so, it is guided by two key Human-Data Interaction (HDI) principles: *legibility*, meaning that the system's reasoning, suggestions, and use of data remain understandable to the designer, and *agency*, meaning that the designer retains informed control over decisions rather than being reduced to validating automated outputs (Durango et al., 2024).

We propose a workflow based on an AI multi-agent system, composed of multiple interacting AI agents capable of adaptation, learning, and reasoning. As such, this research advances the use of AI agents in construction as HDI mechanisms. It aims to support designers in real-world practice within the context of circular construction by facilitating material selection, application on the facade, and visualization of the result. This enables more iterations during early design stages.

Background

The background for this research was done using a scoping review to understand AI agents, their capabilities, types, and application in various fields. An AI agent is a system or program that is capable of autonomously performing tasks on behalf of a user or another system by designing its workflow and utilizing available tools (Gutowska, 2025). Core components of AI agents include capabilities for planning and task decomposition, memory, reasoning, decision-making, action execution, and tool utilization. AI agents can be classified into different types according to their level of autonomy and intelligence, decision-making processes, and interaction with the environment to achieve desired outcomes (Stryker, 2025). They are also distinguished by their reasoning methods, such as using conditional statements, ReAct (Reason + Act), ReWOO (Reasoning Without Observation), or self-reflection (Caballar and Stryker, 2025). In this study, we use ReAct agents that integrate LLMs, tools, and prompt design, and also take feedback from humans to achieve adaptive intelligence.

AI agents are increasingly used in business, personal, and specialized domains (e.g., healthcare, finance, research) to improve productivity, support decision-making, and enable innovation (Krishnan, 2025). A notable example is the Gemini 2.0–based AI co-scientist, which helps researchers generate knowledge and hypotheses aligned with their goals (Gottweis et al., 2025). In construction, autonomous, distributed multi-agent systems integrated into design software utilize stochastic algorithms (Cousin et al., 2023), performance metrics, and environmental data to collaboratively generate, evaluate, and optimize adaptive, performance-driven facade geometries (Pantazis and Gerber, 2018; Gerber et al., 2017). Today, construction-related research also demonstrates the use of AI applications centered on HDI principles (Pal et al., 2025). While these approaches do not explicitly rely on Generative AI (GenAI) techniques, recent studies highlight the signifi-

cant potential of GenAI methods such as LLMs in architectural design. Tools such as ChatGPT and Bard are transforming architectural workflows by supporting ideation, optimization, and collaboration (Rane et al., 2023). Research also shows the examples of AI-enhanced workflows for façade design. Hoeng et al. (2025) integrate computer vision, large language models, parametric modeling, and reinforcement learning with human expertise to optimize design outcomes and reduce planning time. Cheung et al. (2025) propose a conversational AI-enhanced design framework, featuring a multimodal agentic AI bot integrated with WeChat for design ideation, optimization, evaluation, and style testing. Building on this line of work, the present study adopts a conversational chatbot paradigm to develop an LLM-based multi-agent workflow that supports iterative concept development in façade design.

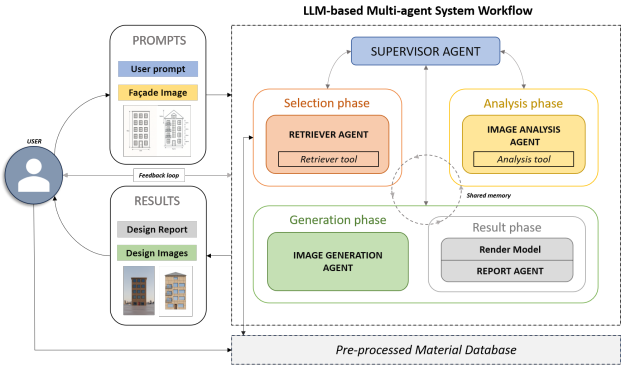

Figure 1: Overview of the workflow detailing the inputs, outputs, phases, and agents.

Methodology

Conceptual Model

We developed our proposed LLM-based multi-agent system using the AI agent framework LangGraph (LangChain, 2024). Our system takes as inputs, first, *a prompt*, which is a text prompt with an image of the design (sketch or render), and, second, *a database* of reclaimed materials. This database is pre-processed and converted into JSON files detailing the dimensions, quantity, material type, and other specifics of reclaimed components.
Our workflow, described in Fig. 1, includes:

Prompts: The prompts needed as inputs are text-based user prompts to assign tasks to the agents and a facade image to convey the user's design concepts.

Results: Aimed at designers and stakeholders, the results include a visual representation of the designs through generated renders (images) and compiled reports.

Specialized phases: The workflow is divided into phases, with each phase having its own specialized agents.

- *Selection phase*: This phase involves an agent that selects materials from the database based on user prompts.
- *Analysis phase*: This phase aims at analyzing the input facade sketch or image to extract its key features and dimensions.
- *Generation phase*: This phase integrates the selected materials into the façade to create new façade designs and reports according to the user's preference. It also generates renderings of the proposed designs.

Agent Types

Based on the conceptual model, the various agents that work in the respective phases of the workflow are as follows:

Supervisor agent: This agent is an LLM-based router that directs tasks to different agents in the workflow based on user prompts.

Retriever agent: As part of the Selection Phase of the workflow, this agent is a pre-built LLM-based LangGraph ReAct agent. It uses a retrieval augmented generation tool to semantically search the material database to retrieve elements that match the user prompts.

Image analysis agent: Part of the Analysis Phase of the workflow, this agent is also an LLM-based ReAct agent that analyses the input facade image to extract details such as the number of floors, windows, etc.

Image generation agent: This agent, part of the Generation Phase, creates N Matplotlib codes that describe design variations, using the materials from the retriever agent and facade analysis from the Image analysis agent. Its prompt includes example code templates, details from the other agents, and user instructions to generate multiple façade designs.

Report agent: Part of the result phase, a subset of the Generation Phase, this LLM-based agent compiles the results of all other agents into a structured technical PDF report.

Agent Evaluation

To ensure that the three main phases (Selection, Analysis, and Generation) of the workflow function as intended, evaluations were integrated into the workflow. These evaluations are essential to validate the agent's working and verify the results produced by the agents. We implemented the following evaluation strategies:

LLM-as-a-judge: With their ability to process diverse data formats and generate scalable, adaptable assessments, LLMs offer a strong alternative to traditional expert-based evaluations. The LLM-as-a-judge paradigm emphasizes that LLMs are auto-regressive generative models that produce follow-up content from prior context and derive evaluations from this generated output (Gu et al., 2025).

In the context of this workflow, this evaluation strategy involves the use of an LLM to validate the agent's performance by checking, first, that its answers are rooted in data generated by its tools rather than hallucinations, and, second, that it responds to the requirements of the prompt.

Human-in-the-loop (HITL): HITL systems enable integrating feedback from the nuanced contextual understanding of human users (Natarajan et al., 2024). In this context, HITL is the main way in which collaboration between humans and AI agents is introduced. Its goal is to ensure that the agents' outputs align with human expectations. Furthermore, it enforces explicit user validation of the generated content prior to its finalization. In this workflow, the HITL mechanism is implemented through the LangGraph "Interrupt" feature, which pauses LLM reasoning until feedback is given by the user.

Unit Testing

The development of the agent-based workflow started with testing each phase (unit) separately. The unit testing involved determining the most suitable LLMs for each agent and the best evaluation strategy for each of the three main phases; *Selection, Analysis, and Generation*.

Selection phase with retriever agent: The retriever agent often hallucinated in its final responses despite correct outputs of the retrieval-augmented generation-tool. Adding LLM-as-a-judge to the pipeline reduced these hallucinations by about 80%. Following this, a HITL evaluation step was introduced. Requiring explicit user approval of each final response enforced relevance and precision. Finally, both strategies, LLM-as-a-judge and HITL,were combined, as shown in Fig. 2. Each addresses complementary aspects of reliability and quality control.

The final agent framework operates as follows. The retriever first generates a response to the user prompt, which is checked by the LLM-as-a-judge for hallucinations. If the response is accepted, the HITL node requests user approval or triggers regeneration. If the response is rejected, the retriever produces a revised response. Feedback from the HITL node is incorporated as a new prompt, and the resulting output is again assessed by the LLM-as-a-judge and HITL nodes. This iterative workflow was tested using `Google's Gemini 2.5` and `OpenAI's GPT-4.0 mini`.

Analysis phase with image analysis agent: An analogous procedure was implemented for the image analysis agent, which likewise interfaced with an image-analysis tool, as shown in Fig. 2. This configuration minimized tool-agent inconsistency and mitigated hallucinations while simultaneously enabling human reviewers to act as the ultimate verification layer. The LLMs tested included `Gemini 2.5` and `GPT 4.0 mini`.

Generation phase with image generation agent: Since this agent's task involved comparatively complex reasoning, yielded inherently subjective outputs, and did not require the use of external tools, the inclusion of an LLM-as-a-judge component in the evaluation pipeline was deemed unnecessary. Instead, only the HITL evaluation was employed. The HITL process ensured that the design artifacts produced by the agent could be iteratively improved through user feedback, including targeted suggestions and corrective interventions. In this case, the tested LLMs include `Gemini 2.5 Pro, GPT 4.0 mini, Qwen 2.5 Coder 0.5B` and `Gemini 2.5 Pro, GPT 4.0 mini, Qwen 2.5 Coder 0.5B, and Qwen 2.5 Coder 7B`.

System Architecture and Testing

In this context, the term *system architecture* denotes both the way the various agents are connected to each other and how they interact with the user. The overall architecture (Fig.2) exhibits a graph-like structure in which the various agents and their associated tools, additional functions (routing and execution), and the evaluation strategies are encapsulated within *nodes*. These nodes comprise the agents mentioned previously as well as a non-agentic node called the "stylization node," as seen in Fig. 2. This node is part of the *Generation phase* and consists of a vision language model (VLM) that takes as input the plot images and creates photorealistic façade renderings. Two VLMs, `Google's Imagen 3.0` (capability 001) and `Google's Gemini 2.5 flash` (image-preview), were evaluated for this task.

The intermediate and final outputs from the different nodes are stored in a shared data structure, termed *State*, and inter-agent communication (i.e., state updates) is orchestrated via *Edges* as defined by LangGraph. These edges can be either conditional or fixed. Fixed edges (displayed with continuous arrows) connect a node to a single subsequent node, whereas conditional edges (displayed with dotted arrows) may route execution to multiple candidate nodes. With conditional edges, the specific node is selected according to the evaluation of the condition associated with that edge. For this workflow, two main system architectures were explored:

Collaborative workflow: As illustrated in Fig.2a, the graph structure of the system is organized around a supervisor agent, which is connected via conditional edges to four specialized agents: retrieval, image analysis, image generation, and report.

Operationally, when a user submits a query, the START node is triggered, which in turn activates the supervisor node. The supervisor node is responsible for determining the appropriate routing of the request within the graph. For example, for material-related queries, such as "Could you select some wooden flooring materials?", the supervisor node routes the request to the retriever node, which encapsulates the retriever agent and its associated tool. The retriever node then produces an output that updates the state. This output is subsequently evaluated

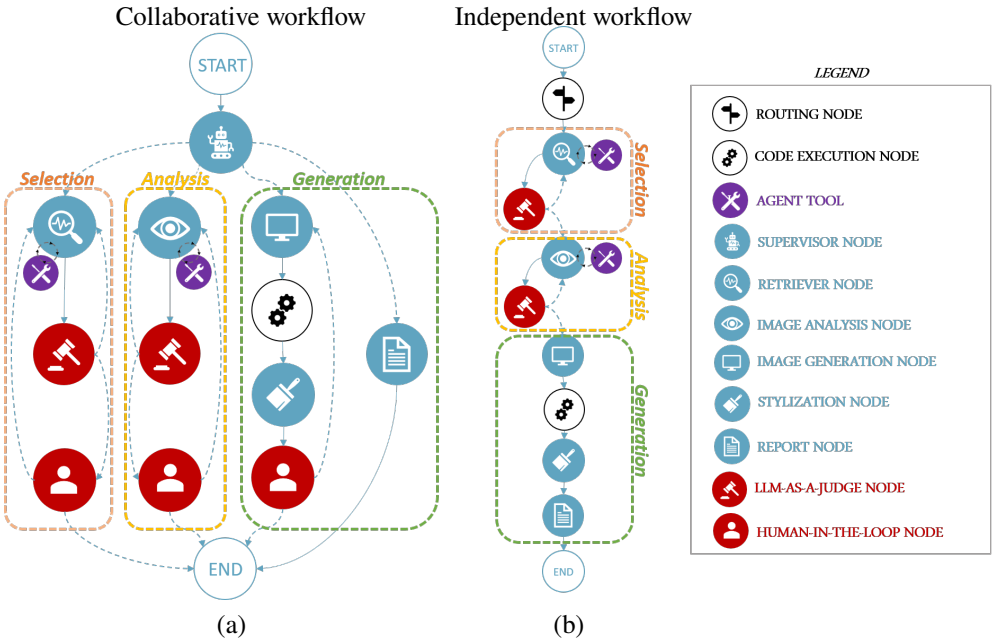

Figure 2: System architecture: (a) collaborative workflow, (b) independent workflow. The Selection, Analysis, and Generation phases each have their dedicated agent nodes (in blue), tools (in purple), assisting code-nodes (uncolored), and evaluation nodes (in red). The dotted blue arrows represent conditional edges, which may or may not be executed depending on the state of the system, while the solid blue arrows represent fixed edges that are always executed. The uncolored nodes (code execution node and routing node) consist of deterministic functions that do not include an LLM.

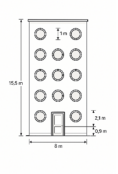
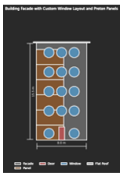
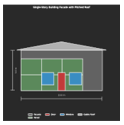
for potential hallucinations and must be validated by an LLM-as-a-judge module. Upon approval, the process advances to the HITL node, where the user may either approve the generated results, thereby terminating the process at the END node, or provide additional suggestions, which causes the entire workflow to recur. An analogous procedure is followed in the image analysis node, with the key difference that the user input in this case consists of both a text-based query and an uploaded image of the facade. In contrast, for the image generation agent, once the relevant code is produced by the image generation node, this code is executed in the execution node, resulting in generating the facade plots. These plots are then passed to the stylization node, where they are transformed into photorealistic renderings. The pipeline subsequently proceeds to the HITL node, where user approval or suggestion again determines whether the graph terminates or recurs. After all primary agents have been invoked and the user has expressed satisfaction with all intermediate results, the user may finally trigger the report node, which compiles and generates the corresponding PDF report.

Independent workflow: The system architecture depicted in Fig.2b represents a unidirectional pipeline in which each processing stage is executed sequentially. It focuses on minimizing human interaction by only including LLM-as-a-judge evaluation and no HITL. In this configuration, the routing function is implemented as a dedicated mechanism that decomposes the user query to update specialized keys in the state. These keys are subsequently used by the corresponding downstream nodes in the graph to perform their designated operations. Operationally, when a user query, such as retriever agent: "Could you select some wooden flooring materials?, analysis agent: analyze this image, generation agent: generate a facade design.", is submitted to the system, the routing function decomposes the input into its constituent segments. Subsequently, the graph-based workflow is initiated with the retriever agent as the first node in the sequence, as illustrated in Fig. 2. Upon completion of its task, the retriever agent's output is evaluated by the LLM-as-a-judge module. Once accepted, the graph updates the results in the state. The graph then proceeds sequentially through each subsequent node, with their respective tasks executed in turn, analogous to the architecture of the collaborative workflow. This process ultimately culminates in the generation of a consolidated PDF report.







These two architectures were specifically selected due to their modularity (facilitating the straightforward addition and removal of nodes), robustness (reducing the number of bottlenecks and potential points of failure), and their flexibility with respect to integrating agent evaluation mechanisms. Their suitability was subsequently examined through user testing, which was carried out to investigate user perceptions of the two fully implemented system architectures.

User Testing

The two system architectures were tested to gauge user perspectives. To gain user insight for this research, a web ap-

[3] This prototype can be shared for testing purposes under reasonable request to the author.

Table 1: Workflow showing retrieval, analysis, and generation prompts with base images, coded plots, and renders.

	Inputs			Outputs		
Trial	**Retriever agent prompt**	**Analysis agent prompt**	**Generation agent prompt**	**Base Image**	**Coded Plot**	**Render**
1	Can you suggest some wall cladding materials that have the highest CO_2 saved and are preferably wood?	What are the details of the façade in the given image? (*upload base image*)	Use the material details for the panelling and façade details for the overall façade. Using this information, generate the façade image.			
2	Can you suggest a lattice material that can allow ventilation within the interior spaces, with a height of 2.53m?	Describe the façade in the image? (*upload base image*)	Use the material details for the panelling and façade details for the overall façade. Using this information, generate the façade image.			

plication, *reFAC*[3], was created as a proof-of-concept for the research workflow. *reFAC* and its user interface (UI) were designed through *Streamlit*, a Python open-source application framework well-suited for hosting applications that involve AI agents and facilitate meaningful human interaction. This application has two pages: one that gives access to the collaborative workflow and one that gives access to the independent workflow, as shown in Fig. 3.

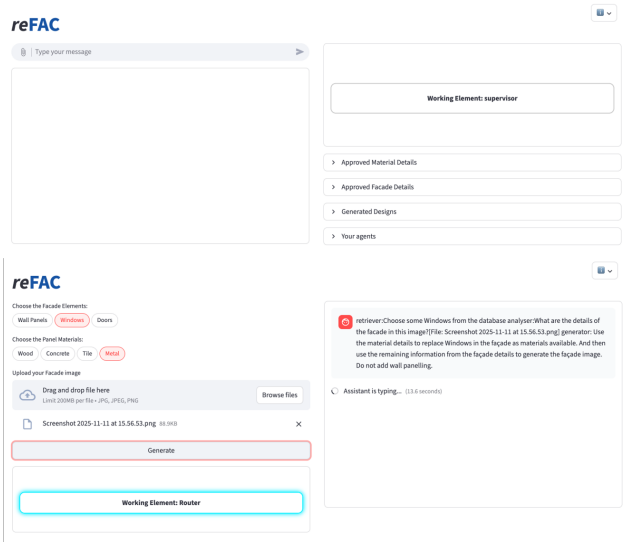


Figure 3: Pages of the UI corresponding to the different system architectures. Top: Page that gives access to the collaborative workflow. Bottom: Page that gives access to the independent workflow.

Results & Discussion

LLM models: The unit and integrated tests indicate that `Gemini` is the most suitable LLM for the agents' use cases, while for vision–language tasks the best-performing model was `Google's Gemini 2.5 flash` (image-preview). These models were used for the user testing.

Comparison of workflows: The collaborative workflow differs from the independent workflow primarily through its integration of the HITL node, which enables individual agent results to be verified and refined. In contrast, the independent workflow lacks such checks and risks propagating errors or requiring complete restarts. While the independent workflow offers a highly automated and rapid solution for design suggestions when the user has no specifications, the collaborative approach enables an iterative process where specific agents can be re-invoked with new feedback from the user without rerunning the entire pipeline. This modularity makes the collaborative system more token-efficient and cost-effective for targeted modifications. However, the flexibility of a supervisor-led architecture can occasionally lead to routing errors if user queries are ambiguous. For example, instead of the systematic querying carried out, if the user directly asks: "I would like to design a building with wooden slabs from the database," the supervisor may incorrectly route the request to the image-generation rather than the retriever node, interpreting it as a primarily generative task instead of first recognizing the need to retrieve relevant materials from the database. This limitation is largely avoided by the independent workflow's use of predefined, standardized prompt categories. The choice between these architectures involves a trade-off between the speed of autonomous execution and the granular control and resource optimization provided by a collaborative framework.

A trait common to both workflows is the low reproducibility of the results produced by them due to the stochastic nature of the LLMs, meaning that identical inputs will generally not produce the same outputs. This variability can be beneficial during conceptual design, as it supports rapid exploration of alternative ideas. However, it also

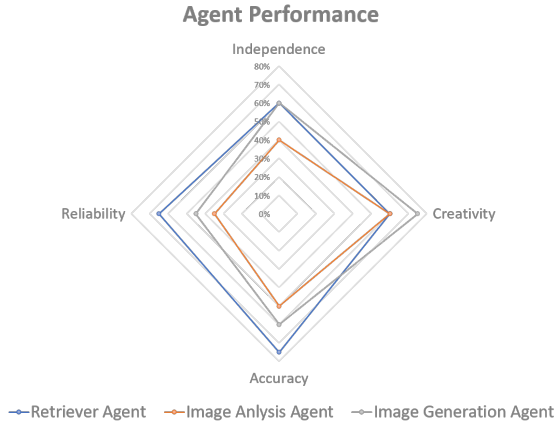
poses challenges for comparison and validation. To integrate such tools into systematic design processes, where iteration on the same design is needed, additional control strategies should be developed.

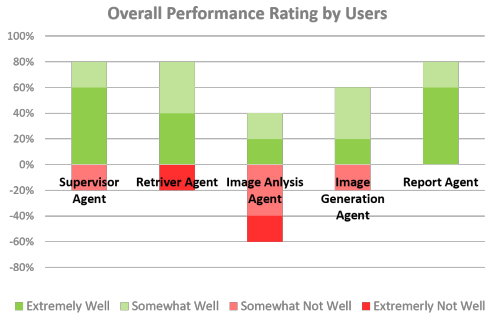
User testing: Both workflows, developed as a web application, were tested by five researchers in the field of architecture and engineering. User testing revealed that 60% of the users believe this application improves task completion, with 20% reporting that the generation is good but may require cross-verification of the results with the material database. 60% of the users report it took a lot more effort with respect to clarifying and repeating requests to the agents than expected, as shown in Fig. 4. This perception primarily arose from the heterogeneity of requirements across agents. The necessity for repeated clarification with these agents prompted the users to want an autonomous assistant that proactively orchestrates and manages a process, as opposed to one that executes externally specified instructions. This aligns with literature findings (Cheung et al., 2025) that emphasize the need for a conversational ideation process over directive interactions. To increase autonomy within the workflow, further improvements are needed, including refinements to agent-specific prompts and inter-agent coordination, in order to strengthen supervisor–agent communication and enhance the agents' ability to operate more independently. However, users did appreciate having the final say, indicating the value of collaboration in design. Future developments should aim for a balanced user-agent control ratio to foster co-designing. Fig. 4 also shows that 40% found the application to be overwhelming. These users felt like they were speaking to multiple agents as opposed to a system performing a single task. The workflow was intended to make users feel as if they are conversing with a unified Multi-agent System, with the supervisor agents assigning tasks to its worker agents. However, because each agent requires specific inputs from the users, the entire process can occasionally be experienced as question-answering rather than conversational.

(a) (b) (c)

Figure 4: Summary of the prototypes' user experience, with (a) human-AI collaboration, (b) expectation on effort, and (c) agent-human collaboration reception.

Fig. 5 shows the performance of the three major agents based on four main categories: independence, creativity, accuracy, and reliability. Among the agents, the retriever agent ranks the highest in accuracy, reliability, and independence. The image analysis agent ranks the lowest in all categories, while the image generation agent ranks the highest in creativity and independence.





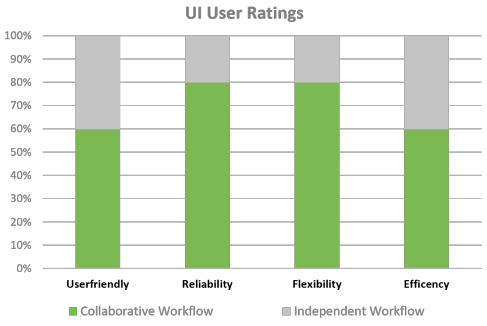


Figure 5: Comparison of Agent performance on various categories.

Fig. 6 shows that 80% of the users consider the collaborative interface to be reliable and flexible, with 20% preferring the independent interface. It is clear from the user ratings of the specific agents (see Fig. 6) that most of them perform quite well. Overall, the results show that the best performance is seen in the report and supervisor agent, while the least performative agent is the image analysis agent.

Limitations

Geometric fidelity. A current limitation of the system is the absence of hard geometric constraints that enforce strictly following the dimensions of the façade and the components used in its design. As a result, generated façades may appear to respect geometric proportions of the facade and the retrieved materials, but in reality they contain dimensional inaccuracies. Introducing explicit geometric constraints, rather than relying solely on the judgment of the LLM, could improve geometric fidelity.

Design flexibility. The system can exhibit reduced design flexibility in certain cases. Due to the prompts that guide code generation for façade synthesis, some outputs become oversimplified, resulting in generic or standardized façade typologies. While for some outputs the workflow is able to adapt well to the input (e.g., Fig. 7 top), other cases (e.g., Fig. 7, bottom) show excessive simplification, leading to the loss of salient architectural features.

Supervisor agent. This agent is more of an LLM router than a brain. If a query does not fit neatly in a specific phase, then the supervisor has difficulty assigning it to an agent. This limitation could be mitigated by giving further context, for example, the entire conversation history. The problem we observed when giving additional context to the supervisor is that the agent tries to answer the query by itself without routing to the other agents and using the available tools, despite being prompted to do so. Boundaries and guardrails should therefore be added to manage the additional context while fulfilling the supervisor's role.

Sensitivity to varied prompting. User testing indicates that the system's performance varies across different types of prompts. For instance, the function of the retriever agent is to choose a material from the database based on a user prompt. However, if the user prompt asks for a different type of retrieval, such as the retrieval of multiple materials, then the agent may fail to give a result. This is because it may or may not choose more than one material from the inventory based on requests relating to material types and properties, such as related emissions, type, color, or function, like windows or doors. A similar lack of flexibility was observed with the image analysis agent, which works best with elevation rather than render images, which should include dimensions. There were instances, as shown in Fig. 7, where the user input perspective images or sketches that did not have legible dimensions, leading to a poor analysis and evident optical character recognition errors by the agent. These issues can be mitigated by extending the system prompts for those agents to make them more flexible when dealing with more variable inputs, or by splitting their functionality down to more granular tasks that are carried out by separate agents.

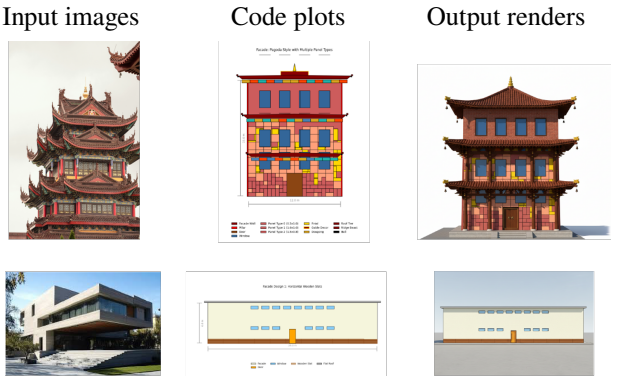

Figure 7: Comparison of final results: The top set shows a successful facade generation that follows the input image, while the bottom set represents an unsuccessful facade generation due to the unclear input image, where the details of the resulting facade have been overly simplified.

Outlook

This research demonstrates the potential of collaborative AI-based workflows. The proposed framework and its individual agents, such as data retrieval, image analysis, and generative design, can be adapted as versatile ideation tools for architectural offices exploring design alternatives, including variations in proportion, rhythm, and fenestration patterns. With further development, the system could also generate CAD- or BIM-compatible geometry, enabling a smoother transition from conceptual design to detailed documentation. Achieving this would require extending the current approach with parametric definitions of building elements, constraint-based geometric representations, and validation mechanisms to ensure compliance with CAD/BIM schemas. The current framework addresses conceptual design and ideation rather than detailed model generation. Such human-AI collaborative workflows have the potential to become integral to architectural design processes that incorporate reclaimed materials. They might support tasks such as efficient inventory search, rapid generation of design variants, and the structured arrangement of reused components on façades, while maintaining key HDI principles such as designer agency and the legibility of AI-supported decision-making.

Conclusion

This paper presented a collaborative LLM-based multi-agent system workflow for façade design with reclaimed materials, combining human expertise with generative AI tools. The proposed framework integrates LLM-powered agents and explores complementary validation strategies, including LLM-as-a-judge and human-in-the-loop approaches, to support accuracy, transparency, and effective collaboration. In doing so, it emphasizes HDI principles, especially legibility, by making the system's outputs and reasoning easier to understand, and agency, by keeping the designer actively involved in evaluating and guiding the design process. Through a comparative

user evaluation, the collaborative workflow was consistently perceived as more useful than a fully independent workflow, highlighting the importance of keeping designers actively involved in the design process. The proof-of-concept system, *reFAC*, demonstrates the potential of AI agents to operate with a degree of autonomy while remaining responsive to human input. It was positively received by users. Overall, this work establishes a modular and extensible foundation for future research on AI-assisted architectural design, particularly in the context of LLM applications, circular construction, and design with reclaimed materials.

Acknowledgments

This paper presents the results of the author's Master's thesis conducted within the Integrated Building Systems program at ETH Zurich. We gratefully thank the five participants from ETH Zurich for their valuable feedback in the user study, as well as Dr. Roxanne Goldberg for her insightful guidance and advice. This research was supported by the Bouygues Construction R&D and Innovation Department.

SERIOUS CONSTRUCTION GAME IN VIRTUAL REALITY: EMBEDDING HIGH-RESOLUTION TELEMETRY FOR LEAN PERFORMANCE ASSESSMENT

Kilian Speiser and Jochen Teizer
Technical University of Denmark, Denmark

Abstract

Existing Lean construction simulation games rarely provide detailed personalized feedback for participants but rely on coarse metrics like completion time or flow visualization. This paper investigates how high-resolution telemetry in active multi-role Virtual Learning Environment (VLE) supports lean assessment on teams in a staged introduction of process and automation improvements. We developed a VLE for 11 building trades using role-specific input devices and a telemetry pipeline that captures interactions to compute Lean indicators (flow discontinuity, production rate, waste). We found high potential of embedding high-resolution telemetry into VLE of data-driven evaluation of Lean principles, offering value to educators, trainers, and practitioners.

Introduction

Lean construction builds on concepts from the Toyota Production System, later described as the Lean Production System (Ohno, 1988). It aims to increase value while reducing waste, thereby improving productivity (Koskela, 1992). Lean construction emphasizes several principles: respect for people, value, flow, waste reduction, and continuous improvement. A central school within Lean is pull planning, in which work is released by downstream demand rather than pushed by a central schedule, most prominently operationalized through the Last Planner System (Ballard, 2000). To teach Lean principles, serious games have emerged as an active method, in both analog and virtual forms (Bhatnagar et al., 2023). Serious games enhance learning through structured challenges and feedback (Clark, 1970; Muntean, 2011) (Domínguez et al., 2013).

An early implementation of such lean construction games included the assembly of a building using Lego bricks, with and without pull planning (Warcup and Reeve, 2014). Such games introduce Lean principles over several rounds, and improvements between rounds highlight how users can improve through the adoption of Lean. However, quantifying these improvements requires clear performance indicators. In analog games, this is difficult to achieve based on objective data. For instance, players must record time and manually assess how many tasks were completed correctly. Virtual Environments (VEs) overcome this by automatically capturing task duration or errors at high resolution (Speiser and Teizer, 2024a; Wolf et al., 2022; Wolf and Teizer, 2022), and by visualizing progress or flow lines (Jacobsen et al., 2021; Sacks et al., 2007). However, while serious games in Lean construction enable automated data collection, a crucial gap remains: sub-second logs of user inputs, location updates, tool and material interactions, zone entries/exits, and task events are seldom used to compute Lean predictive Key Performance Indicators (KPIs). The remainder of this paper uses high-resolution telemetry to refer to such logs.

The idea investigated in this paper is the embedding of high-resolution, cross-role telemetry into a multi-user VR game to compute KPIs, thereby enabling actionable feedback at individual and team levels to enable cross-role and cross-round comparison. This work sits within Human–Data Interaction (HDI). The telemetry pipeline operationalizes three HDI principles for construction training: *legibility* (raw behavioral traces are rendered as indicators non-experts can read), *agency* (workers see indicators about their own work and can act on them within the round), and *negotiability* (cross-role indicators such as EWPT make coordination losses visible to the team that caused them rather than logged against the trade that absorbed them).

This paper addresses the following research questions based on the gaps identified before.

RQ1: How can role-specific lean performance be quantified and assessed in real time using in-game telemetry data?

RQ2: How can cross-role telemetry data be used to analyze collaboration patterns and detect coordination breakdowns in VR-based construction training?

A design science research (DSR) methodology iteratively develops and evaluates a networked VR artifact and its telemetry pipeline. The artifact derives a conceptual indicator framework to assess lean performance. In a study combining hoisting and apartment finishing in a high-rise building with 11 roles, role-specific interactions, and staged interventions across rounds, the research results in the following contributions:

C1: A theoretically grounded telemetry-based indicator framework with standardized lean performance indicators suitable for VR telemetry.

C2: An instantiated VR prototype and modular architecture demonstrating how realistic tasks, roles, and indicators can be adapted across multi-round scenarios to operationalize Lean principles.

Lean Performance Indicators

In construction projects, Lean performance is often assessed through outcome-focused indicators such as cost, schedule adherence, or percent complete, which serve as lagging indicators rather than true Lean metrics (Koskela, 1992; Ballard, 2000). Recent reviews highlight inconsistencies in their use that hinder comparison across projects and countries (Asmone et al., 2025). Process-oriented measures that capture flow, waste, and value have long been proposed in Lean research but are rarely applied systematically in practice, partly because collecting the fine-grained data required is difficult on active sites (Jacobsen et al., 2023). At its core, this is a HDI problem: data is fragmented across humans, devices, and trades, and translating it into legible indicators for workers and managers remains unresolved. The barriers are human-related (workers' attention demands), data-related (sparse, noisy site sensing), process-related (variable task definitions), and organizational-related (limited incentives to record). VLEs remove all four by capturing them automatically, offering an opportunity to measure Lean principles in new ways.

Flow is central to Lean thinking. Four indicators are particularly relevant (Rathnayake et al., 2023): (1) Level of Work Discontinuity (LWD), which quantifies crew downtime relative to work progress; (2) Mean Trade Production Rate (MTPR), which reflects the average completion rate of a trade; (3) Excess Work-in-Progress time (EWPT), which highlights inefficiencies between trades in the same location; and (4) Mean Location Production Rate (MLPR), which aggregates progress across trades at a given location (Rathnayake et al., 2023). Together, these provide diagnostic insights than higher-level indicators such as Percent Plan Complete (PPC), which is widely used but heavily dependent on the quality of the baseline construction schedule (baseline plan) against which progress is measured (Asmone et al., 2025).

Waste is another essential dimension of Lean, representing non-value-adding activities. The eight wastes are waiting, motion, inventory, extra processing, defects, overproduction, underutilised talent, and transport (Ohno, 1988; Liker, 2004). While it is difficult to measure waste on-site (Jacobsen et al., 2023), VR environments can automatically capture waste, linking low-level inefficiencies to overall productivity.

Value in Lean was originally defined as what the client is willing to pay for (Koskela, 1992). This concept has since broadened to include stakeholder benefit, end-user wellbeing, and quality-in-use (Salvatierra-Garrido and Pasquire, 2011). In VEs without client in the loop, quality and reliability serve as measurable proxies for the value the client would otherwise judge.

Research methods

The research presented in this paper follows a DSR methodology (Hevner et al., 2004; Kirk, 2013). DSR is appropriate here because the research question is not whether telemetry-derived Lean indicators correlate with productivity in the abstract, but whether such indicators can be constructed at all in a multi-role VR setting and made useful to learners and trainers. This is a design problem in the sense of Hevner et al.: it requires building an artefact, exercising it, observing where it breaks, and iterating. Pure observational or experimental designs cannot produce the artefact itself. The paper aims to produce a conceptually viable artifact as an instantiation of a serious Lean game in VR. The artifact is based on a relevant problem: Existing Lean games do not provide performance indicators across the different Lean principles from low-level data collection.

Recreation of the VR environment

The scene generation follows a mixed approach based on previous research. Two Building Information Modelling (BIM) models were obtained from contractors. The first project is a construction site in Munich, and the BIM model has been included using the IFC Importer (Speiser and Teizer, 2024a). The second BIM model represents a completed student dorm project in Denmark. The BIM model was included using the Unity Export plugin available in the Autodesk store. Using real projects rather than fabricated scenarios reduces authoring effort and avoids questions about ecological validity (Speiser and Teizer, 2024b).

The BIM models miss the construction site layout and machinery. Hence, these elements are added in Unity using Assets. Site equipment, including cranes, forklifts, guardrails, barriers, and materials, is manually added. On top of that, the elements that the users interact with are added manually, and scripts are assigned, like previously published research (Jacobsen et al., 2022). Generally, however, the materials that each trade needs are added. To further strengthen the real-world relevance, trajectory information for a forklift is included using an algorithm developed in previous work (Speiser et al., 2023).

Figure 1. Scene overview of the virtual construction site in Unity with zones highlighted.

The construction sequence integrated in this training environment is based on a handbook shared by a Finnish contractor. It outlines the construction of bathroom pods in residential housing in detail. The handbook was selected because it documents the bathroom-pod sequence at task-level granularity, which the German and Danish project documents lacked; pod-assembly logic is essentially country-agnostic, so the sequence transfers. This sequence was used to recreate the sequence. This sequence was also the baseline in identifying the trades required for the serious game. For simplicity, each trade represents one role, and each role is implemented as one user. Technically, there could be more users for each trade, and it would enhance the freedom during gameplay, but it has been chosen to stick with one per trade to enable smoother gameplay and implementation.

As the user study, which will be described later, includes three different rounds, the scene is also adapted for each of the rounds. The changes include moving the position of equipment, adding or removing safety equipment, or changing tools and interaction possibilities. These changes were chosen based on role-practicability. The objective was that each role had technological enhancements in each round and that Lean principles were included in each role. Hence, each trade receives information on how to reduce waste within their task, how to improve flow (for all trades), and how to improve quality as a proxy for value.

The virtual training environment combines observations from two real projects into one synthetic site encompassing four interdependent activities with eleven

Table 1. Role overview with tasks, required tools, and interaction setup.

Trade	Task description	Required tools and materials	Changes over rounds	Input devices and immersive displays
Crane Operator	Hoist bathroom pods to target units; coordinate with Riggers via signals	Tower crane, rig, bolts/rigging hardware, bathroom pods	R2: Crane repositioned; overhead-load proximity notifications; reminders to clear under load	HMD (optional desktop); Farmstick
Rigger Ground	Attach pod to rig; signal crane; prep/load boxes for forklift	Rigging points; two bolts/connectors; material boxes/pallets; ladder/ platform	R1: Ladder next to bathroom assembly R2: Safe platform replaces ladder; reminder to exit under-load zone	HMD (optional desktop); XR controllers (optional data gloves)
Rigger Top	Prepare the bathroom location with heel tabs and drainage; signal the final position; and disconnect the pod.	Heel tabs for placement; hand tools for disconnect (two bolts); ladder	R1: Manual material collection, no Lean board; R2: Overhead-load notifications; Lean board progress reporting	HMD (opt. desktop); XR controllers (opt. data gloves)
Plumber	Install four pipe runs (hot, cold, wastewater, ventilation); close opening with plasterboard.	Pipes; wrench for connecting pipes; plasterboard	R1: Manual material collection, no Lean board; R2: Materials pre-positioned; Lean board enabled	HMD (opt. desktop); XR controllers (opt. keyboard/mouse)
Screed Layer	Place self-leveling screed; level to finish	Screed; screed pump; levelling tool	R1: Manual material collection, no Lean board; R2: Materials pre-positioned; Lean board enabled	HMD (opt. desktop); XR controllers (opt. keyboard, mouse)
Glazier	Remove guardrail; install window; tidy debris	Window unit; guardrail components; self-retracting lifeline	R1: Manual material collection, no Lean board; R2: Materials pre-positioned; Lean board enabled	HMD (opt. desktop); XR controllers (opt. keyboard, mouse)
Carpenter	Cut and install floor elements; tidy waste	Pre-cut floor elements (by round); miter saw	R1: Cutting & fitting; R2: Pre-cut elements on pallets; Lean board	HMD (opt. desktop); XR controllers (opt. keyboard, mouse)
Painter	Paint two walls; dispose of trash	Paint buckets; brush/paint roller	R1: Bring/return bucket; R2: Bucket pre-staged; Lean board	HMD (opt. desktop); XR controllers (opt. keyboard, mouse)
Electrician	Verify power is off; Install two outlets, two switches, and one wall lamp;	Sockets; switches; lamp; drill	R2: Materials pre-positioned; Lean board	HMD (opt. desktop); XR controllers (opt. keyboard, mouse); 3d-printed drill
LEAN and safety manager	Inspect site; report defects/hazards; support coordination	N/A	R2: Progress visible on Lean board; dashboards between rounds	HMD (opt. desktop); XR controllers (opt. keyboard, mouse)
Autonomous forklift	Transport material boxes along predefined trajectories	Forklift; fork; material boxes; storage area	Trajectory constant; interacts with Rigger Ground workflow	N/A (autonomous)

roles. Table 1 summarizes each trade's tasks, tools, input devices, and round-specific changes. Together, these define the game structure and performance assessment.

Flow indicators as a proxy for productivity

Trade flow is measured through LWD and MTPR. LWD is defined as the ratio of total time spent in between locations to the floor area of the building (12 m² per apartment). It captures discontinuity in a trade's workflow as time per unit area. Since this indicator rewards consistency, even at a slow pace, MTPR is added to represent the average completion time of a trade across all locations. Together, LWD and MTPR provide a trade-level assessment of flow performance as an evidence-based proxy for productivity.

Team performance at the location level is measured through EWPT and the MLPR. EWPT quantifies the time lost due to unnecessary accumulation between crews, with lower values indicating smoother flow. However, as with LWD, steady but slow work is rewarded. To address this limitation, the mean location production rate is added, capturing the aggregated completion time of all trades working in the same location.

Waste indicators as a proxy for productivity

The VE tracks five waste types: motion, extra processing, inventory, defects, and waiting. Underutilized talent, overproduction, and transport are excluded due to their limited relevance in the developed game. For each user role and task, different aspects of waste are monitored. As with the flow indicators, waste is assessed both at the trade (individual) and location (team) level. To maintain consistency with flow terminology, these are referred to as trade waste and location waste.

In this paper, waiting is defined as time spent outside the apartments, which is treated as non-productive time. More advanced tracking methods could include continuous monitoring of worker movement, but here, waiting is only considered when users are not inside the apartments. Waiting is also a key input for the discontinuity indicator. For the tower crane operator, waiting is measured as the time between the Rigger's signal to hold and the subsequent signal to move the load after connection or disconnection. Motion waste captures unnecessary movement that results in lost time. Inventory waste is defined as carrying too many or too few elements. Too few elements result in additional trips, which are already classified as motion waste. Hence, only surplus inventory is considered, and a 10-second penalty is assigned for each excess item. Extra processing waste is defined as repeating activities without added value. In this game, it is only assessed for the Painter and screed layer. The Painter may repaint the same area multiple times, while the screed layer may repeatedly level the surface without improvement. The time spent on such redundant actions is aggregated as extra processing waste.

By combining these low-level contributors into higher-level indicators, the framework enables a new perspective on Lean performance in VR training.

Data collection and analysis

Unity provides robust data collection features. Specialized scripts are created and added to game objects, and for each role, the collected events are stored in the *UserDataCollector* component. Each script was tested individually during early tests of the training scene (Speiser and Teizer, 2024b).

Zones are modelled as colliders so that each avatar's entering and exiting can be detected. These events are sent to the *UserDataCollector*. The content of the virtual toolbox is also sent to analyze whether users brought the correct amount of materials to the rooms. Task completion is recorded based on the installation of the objects. Each trade has a certain number of elements to install. Elements snap into place once the user holds the correct item near its final position.

User studies

The study validates the technical and operational feasibility of the developed artifact to collect high-resolution telemetry data and convert it into performance indicators that enable comparison across roles. Based on previous experiences (Teizer et al. 2017, Teizer et al. 2019, Tagliabue, et al. 2020, and Teizer et al. 2020) the evaluation is structured in three parts. First, each role was tested individually with researchers through think-aloud sessions supported by expert feedback. Two evaluation sessions were then conducted with researchers as participants: Study 1 (n = 3, roles: Painter, Glazier, Plumber) and Study 2 (n = 3, roles: Rigger Top, Plumber, Crane Operator). The aim of this stage was to verify the data collection mechanisms and to confirm that the captured telemetry can be operationalized into indicator-based feedback using established Lean metrics. At this stage, verification and validation are limited to the Riggers, Crane Operator, Plumber, Electrician, Glazier, and Painter, while the Screed Layer and Carpenter roles are still under development.

Computed Role-level indicators

Figure 2 compares the trade-specific results for all indicators. LWD is an indicator of trade flow. At the trade level, the Glazier, Rigger, and Plumber in Study 1 showed much higher discontinuity compared to the Painter and Plumber in the Study 2. However, the Painter had a much lower MTPR. This highlights two findings: the Painter worked at a consistent pace, but at the lowest rate. The choice of combining indicators is therefore essential, since a pure flow metric cannot capture productivity.

Figure 2 illustrates this issue. The flow charts alone do not make the differences immediately clear. It shows the flow over time, and it's also visible that the trade spent most time in unit C3. Nevertheless, quantifiable units are more usable at first sight. While the graphs help, high-level KPIs provide quantification and decision support. Only with the numerical value discontinuity of 66 is an objective flow performance comparison possible.

MTPR for the Glazier and Plumber was comparable, while the Painter and Rigger lagged. Read alongside their LWD, this distinguishes two failure modes that flow

charts cannot: the Painter is consistent but slow (low LWD, low MTPR), whereas the Rigger is fast but discontinuous (high LWD, moderate MTPR). The two cases require different interventions, namely pacing support for the Painter and dependency smoothing for the Rigger. Because the Painter was scheduled last in the work sequence, downstream trades were not affected any more.

Waste indicators provide insights into non-value-adding activities across trades. In Study 1, extra processing dominated the Painter's waste profile (678 s of 848 s). Without task-level guidance, learners optimized for visible coverage rather than first-pass quality, identifying this as the primary lever for round-2 improvement. The Glazier's waste (466 s) was driven by motion (320 s), indicating that material staging rather than execution was the bottleneck. The Plumber's profile (367 s) combined inventory (190 s) and defects (100 s), pointing to logistics and standardization as separate addressable issues.

Study 2 totals were lower across all trades (Crane Operator 255 s; Rigger Top 318 s; Plumber 458 s), but the composition matters more than the total. The Rigger Top's profile is dominated by waiting (218 s), which reflects coordination loss propagated from the Crane Operator rather than Rigger performance. Trades downstream of slow signalers absorb their inefficiency, and only telemetry surfacing this dependency makes the loss attributable to its source. The Plumber's recurring inventory (210 s) and defect (100 s) waste across both studies indicates the issue lies in the task rather than the participant, with material logistics and installation standardization as the relevant levers. Figure 3 illustrates these differences. Charts help to show the spread of waiting, motion, inventory, defects, and extra processing, but numerical KPIs allow for easier comparison. Listing the waste types is important for identifying potential improvements in the next round. The Glazier mainly suffered from motion waste caused by repeated trips to storage. If they did not need to carry the window, they could transport more inventory in one trip and reduce this waste. The Painter's waste was driven mostly by extra processing, which is hard to see in flow graphs. The Rigger experienced the longest waiting time due to slow crane operations. The crane operator also showed high extra processing waste, which points to possible improvements through automated trajectory planning instead of manual operation, since they often deviated from the shortest path.

Computed Team-level indicators

Study 1 shows lower waste and shorter completion time, resulting in a higher production rate. The main waste contributor is extra processing, which is caused exclusively by the Painter (see Figure 4). The second-largest waste category is motion, driven mainly by the Glazier. In contrast, Study 2 eliminates motion waste but shows a higher waiting waste. This waiting time could be reduced if the crane operator worked faster. Inventory and defect waste are comparably high in both groups. The higher waste observed in Study 2 also results in longer completion time per unit.

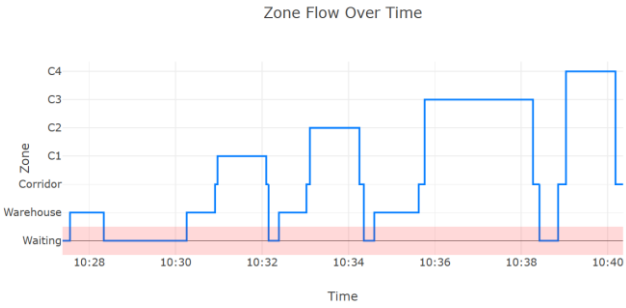

Figure 2. Plumber trade flow over four units.

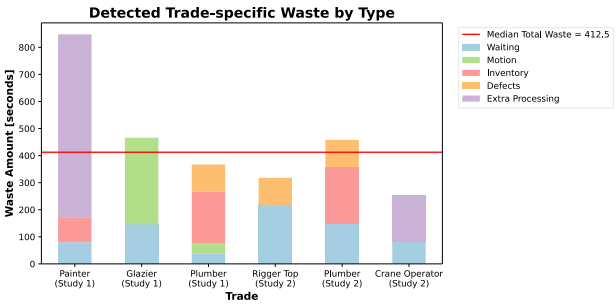

Figure 3. The detected waste for all trades by waste type.

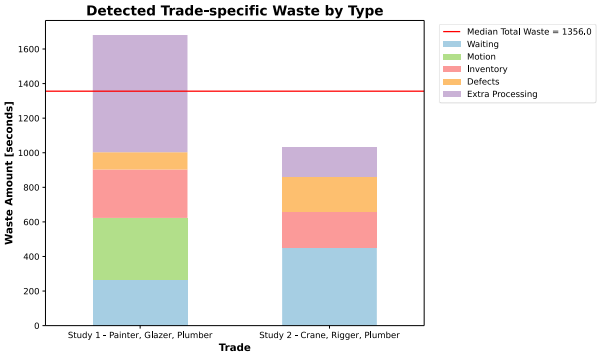

Figure 4. Aggregated team waste by waste type comparing Study 1 with Study 2.

EWPT quantifies what Figure 5 shows visually. Idle times between trades grow as the sequence progresses, most sharply between the Glazier and the Painter, totaling 389 s across locations (Figure 6). Three implications follow. First, EWPT exposes a lagging-trade penalty that PPC and completion time cannot, since locations sit unused even when each individual trade appears on track. Second, the metric is round-comparable: learners can be tasked with reducing EWPT and measure their own improvement quantitatively, which turns the dashboard into a learning instrument rather than a report. Third, the C1 value functions only as a relative baseline; calibrated thresholds remain a field-validation task (see Limitations). EWPT and LWD are interdependent, since a discontinuous trade upstream creates EWPT downstream.

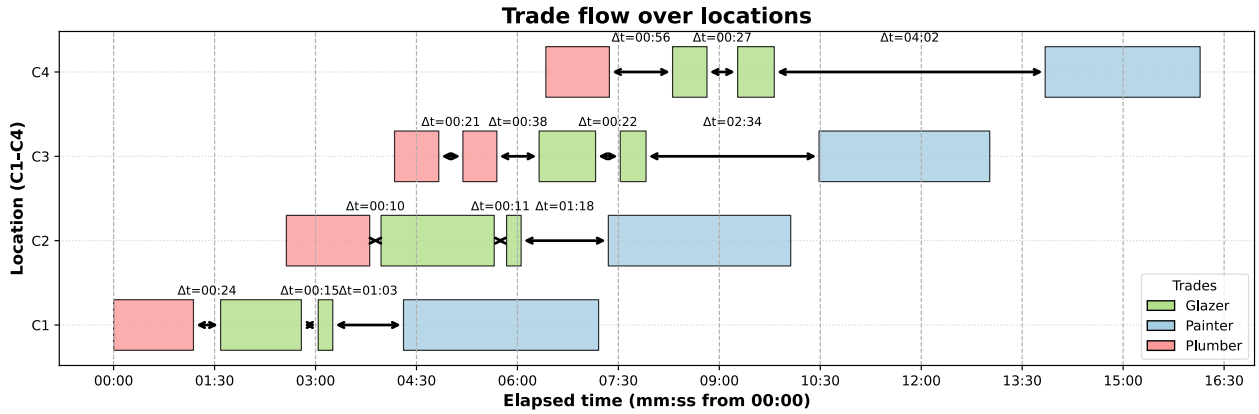

Figure 5. Location flow for group 1, where both motion waste and EWPT per location are included.

Bottlenecks and identified improvements

The Painter consistently worked at a much slower pace than the other trades. Unless their performance improves, subsequent activities will be delayed. A possible solution would be to either add a second Painter or redistribute the workload to balance the overall schedule. The Crane Operator's slower response times also created waiting waste for the Rigger. Improving crane operation speed, for example, through additional training or automation of trajectory planning, could reduce idle times and increase throughput. In addition, workers who arrived on site but could not start immediately contributed to unnecessary waiting and overcrowding. Adjusting arrival times or sequencing work differently would minimize idle presence and improve location utilization.

The Glazier experienced high motion waste due to frequent trips to storage. Improved material staging or delivery batching would reduce unnecessary movement. The Plumber repeatedly generated inventory and defect waste, suggesting systematic issues in material quality or installation practices. Standardizing installation procedures and improving material logistics could help mitigate these recurring inefficiencies. The Painter's extra processing waste points to inefficiencies in task execution. Clearer task planning or defined performance benchmarks could help prevent overworking the same areas.

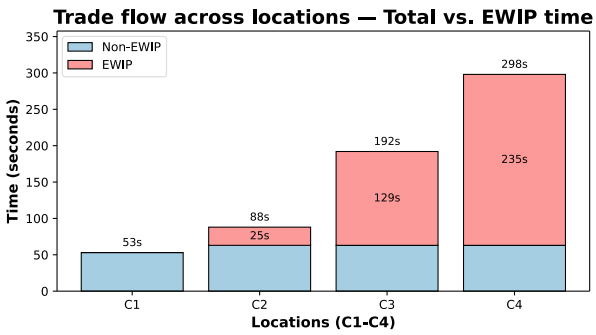

Figure 6. EWPT time by location.

The EWPT analysis revealed significant idle times between the Glazier and the Painter. This indicates a misalignment in trade sequencing that could be improved by staggering tasks or adjusting work areas. Monitoring and reducing EWPT times in subsequent rounds would allow teams to better visualize and quantify improvements in location flow. Moreover, providing real-time feedback on discontinuity (LWD) could enable trades to adjust pacing immediately and reduce downtime.

Conclusions

This paper developed a multi-user VLE that integrates lean indicators through high-resolution telemetry. The system shows how telemetry can turn low-level interactions such as signals, movements, and errors into actionable indicators that quantify flow and waste on both an individual and a team level. Linking role-specific and team-level data, the framework revealed coordination bottlenecks such as crane–rigger timing gaps and excess work in progress that remain hidden in single-role analyses. These results show that the telemetry pipeline enables a more comprehensive evaluation of construction workflows compared to pure completion tracking.

The study makes two main contributions. First, it provides an indicator framework to track lean performance in serious games. Second, it provides methods to collect data in VEs and compute the determined indicators, which support the assessment of both individuals and teams.

Compared to prior VR Lean games (Jacobsen et al., 2021; Sacks et al., 2007), which report aggregate completion or flow visualizations, this paper expands the knowledge through nuanced performance evaluation and eases the identification of coordination breakdowns or weak performance.

The HDI contribution lies in *who* the indicators are computed for. Conventional construction analytics produces dashboards for managers from data workers cannot see; here the same telemetry stream feeds back to the workers themselves during play. This shifts the indicator's function: LWD becomes a signal the trade can act on, not a post-hoc score; EWPT becomes a coordination signal visible to the team that caused it, not a report on them. The Rigger's 218 s of waiting in Study 2 is the clearest example: under conventional reporting, the waste is logged against the Rigger; under telemetry-mediated feedback, it is attributable to the Crane Operator's trajectory and visible to both in real time. This

is what makes pull planning measurable rather than aspirational: downstream readiness, the quantity the Last Planner System asks teams to commit to, becomes a continuous signal rather than a weekly self-report.

This paper is subject to several limitations. Interactions were simplified and limited to zone entries, tool pickups, install snaps, and signaling to ensure reliable measurement, which reduced ecological validity. The evaluation involved a small number of participants and only a subset of trades. The indicators do not yet have calibrated thresholds, so results can only be interpreted in relative terms. The framework has not yet been thoroughly tested in the field with construction workers, which restricts external validity. Telemetry collection from trades-people also raises privacy and ethical questions that this study does not yet address: data minimization, informed consent, and which indicators are appropriate to expose to whom remain open design questions for field deployment.

Practical implications arise for both education and industry. Trainers can use the framework to provide learners with immediate and data-driven feedback on lean performance. Cross-role visualizations, such as location-based flow charts and EWPT, also act as game mechanics that help players and trainers understand Lean principles in an active and engaging approach.

A priority future direction concerns HDI-aligned indicators for the respect-for-people principle. The current framework demonstrates that lean indicators can be computed from telemetry, but does not yet test whether they are meaningful to the people they describe. Future work will operationalize three HDI indicators: *trust calibration* (do users act on the indicator they see?), *perceived agency* over personal data, and *cognitive load* imposed by dashboards during play. These will be measured by pairing telemetry with short in-VR self-reports and post-session interviews. This direction also frames future integration of safety telemetry (Speiser et al., 2024, 2025; Speiser and Teizer, 2024c) and field validation as steps toward calibrated thresholds, benchmarks, and longitudinal evidence of behavioral change.

DEVELOPING A LINKED-DATA-BASED FRAMEWORK FOR REGULATION COMPLIANCE CHECKING IN ARCHITECTURAL DESIGN

Yutian Yi[1], Davide Lombardi[1], Zhelun Zhu[1]and Theodoros Dounas[2]
[1]Xi'an Jiaotong-Liverpool University, Suzhou, China
[2]Heriot-Watt University, Edinburgh, Scotland

Abstract

Manual regulation compliance checking remains common in architectural design, while BIM-based and semantic approaches operate outside the authoring environment, requiring specialist expertise, delaying feedback in iterative work. This paper presents a lightweight compliance-checking framework implemented as a pyRevit extension and prototyped in Autodesk Revit. The framework extracts model parameters, converts them to RDF aligned with ifcOWL and a project namespace, and validates constraints using Shapes Constraint Language. The case study shows non-compliances can be detected and reported via both documentation outputs and in-model graphical feedback. The contribution is an auditable linked-data mechanism for extensible regulation checking within BIM authoring tools.

Introduction

The Architecture, Engineering and Construction (AEC) industry is characterised by increasing project complexity, multidisciplinary collaboration, and fragmented information flows across design, approval, and construction stages (Michaud et al., 2019). Within this context, building regulations play a critical role in guaranteeing construction quality and safety. However, regulation compliance checking during architectural design remains largely manual and error-prone (Preidel & Borrmann, 2016). Architects frequently encounter situations where design proposals fail to satisfy specific code requirements because of misinterpretation, omission, or inconsistent misunderstanding of regulatory clauses. In addition, interpreting building regulations can often be subjective, as different practitioners may interpret the same clause in varying ways (Zheng et al., 2022). Such subjectivity often leads to drawings being returned by local authorities for rectification, triggering multiple cycles of revision. Furthermore, due to multiple revisions, data loss and format error might also occur. This extends the construction schedule and incurs additional consumption of labour and materials, as well as costs (Mäki & Kerosuo, 2015). Such ambiguity increases the risk of inconsistent compliance decisions and potentially opens up space for corruption. As a result, under such circumstances, designers struggle to enhance their work efficiency. Recently, smart supervision, which is defined as the application of digital technologies such as sensors and automation to monitor construction activities, has been increasingly adopted to enhance transparency and control (Mhmoud Alzubi et al., 2023). However, research and implementations keep focusing on construction and operation stages, leaving the design stage insufficiently supported. This gap highlights the need for a digital workflow that embed regulation checking directly into architectural design environments, enabling proactive and consistent compliance verification.

This study aims to build a direct link between architectural models and regulatory clauses by representing them in object-oriented and machine-readable forms. These encoded rules can be processed automatically, ensuring consistent and objective compliance checking directly within the Building Information Model (BIM) environment. Thus, this study develops a linked-data-based workflow that digitizes local building codes, automatically extracts corresponding element data from building model, and cross-checks design information against regulatory constraints. The resulting data is structured in a machine-readable format, facilitating the information interoperability and process automation (Zhong et al., 2019). Moreover, the framework is designed without requiring the users to possess advanced computer skills. All processing procedures are completed by providing the appropriate input data. The overarching goal of this research focuses on the minimisation of human errors, the prevention of wasted efforts from information discrepancies, and shortening the pre-construction process.

The remainder of the paper is organised as follows. In section two a brief overview of related work is presented so as to clearly identify the research gap. In section three, the linked-data based framework is introduced in detail. The framework is structured in four parts: code conversion, information extraction and semantic expression, and user-oriented performance. Section four validates the feasibility of the proposed framework by a real case, and section five provides the conclusion and highlights the future work emerging from this study.

Related Work

This study focuses on linked-data and automated compliance checking during architectural design phase.

The following sections elaborate on previous research of the relevant aspects.

Automated compliance checking

Automated Compliance Checking (ACC) is the process of using digital asset models and encoded contractual rules to automatically verify that the design model and as-built asset satisfy commissioning and operational readiness requirements, thereby enabling rapid and consistent compliance assurance (Dimyadi & Amor, 2013). Eastman et al. (2009) first summarised the rule checking process into four phases: Rule Expression Phase, Model Data Preparation Phase, Rule Enforcement Phase, and Check result reporting phase. Two main data sources are indispensable during a typical ACC process, namely the building model and normative knowledge (Amor & Dimyadi, 2021).

Recent papers show ACC progressing from rule execution prototypes toward more robust rule interpretation and institutional adoption. Early work demonstrated ACC for topologically complex requirements by combining model preparation with automated rule evaluation and clear reporting of non-compliances (Bloch et al., 2019). Building on this idea, Bloch et al. (2024) proposed graph-based semantic enrichment to improve robustness beyond hard-coded rule scripts. Doukari et al. (2021) proposed object-centred checking workflows and plug-in implementations that structure the pipeline from requirement definition through execution and result presentation. Furthermore, the recent growth trend indicates that many studies have applied artificial intelligence technology to compliance checks. Zhang & El-Gohary (2019) extract hierarchy information from building codes by dependency parsing based on deep neural network model training. Chen et al., (2024) leverages deep learning and Large Language Models to categorize categorise regulatory documents and conduct a preliminary screening of the text. From a regulatory standpoint, Fuchs et al., (2025) recognises that fully automated decisions may not be acceptable in regulatory contexts, and the need for human oversight still remains, thus, there is need for traceability and transparency. Being able to explain why a certain element passed or failed compliance plays a pivotal role particularly in audits. For better scalability and information sharing, Zhong et al., (2018) developed specific ontologies to represent varying building environmental information and interact it with SPARQL formed clauses.

Linked-data model

The vision of automated compliance checking in the AEC industry has long been limited by interoperability issues. In this vein, the Linked Data paradigm, built on Semantic Web technologies, presents a promising solution for meaningful data integration and machine interpretation (Boje et al., 2020). A key development is ifcOWL, a web ontology language of the IFC schema, which allows BIM models to be represented as Resource Description Framework (RDF) graphs, transitioning data from a closed format to an open, queryable knowledge graph (Pauwels & Terkaj, 2016; Tomczak, 2025). This semantic enrichment facilitates precise representation and reasoning about building information, enabling regulatory rules to be expressed in complex terms. The power of linked data is further demonstrated by its ability to integrate diverse data sources. For instance, the BRICK ontology offers a standardised schema for representing building equipment and their relationships within building automation systems, facilitating interoperable data exchange across platforms (Balaji et al, 2018; Brick Consortium, n.d.). Cerovšek & Omar (2025) illustrate how IFC-based semantic data can be aligned with operational datasets structured using BRICK, highlighting the role of RDF as an architectural layer for interoperability. Donkers et al. (2023) illustrate the dynamic interconnection of RDF data across knowledge domains through web-based applications.

Querying and validating these interconnected RDF graphs require specialised languages. For the specific task of regulation checking, which is inherently a validation process, the Shapes Constraint Language (SHACL) is applied as a standard for validating asserted RDF data, and was published as a W3C (World Wide Web Consortium, the main international standards body for the Web) Recommendation in 2017 (W3C, 2017). SHACL is designed for validating "what must be true" (Heimsbakk & Torkelsen, 2023). This provides a more declarative and direct method to formalise building codes as constraints against the ifcOWL representation. However, a significant gap remains between linked-data-based compliance checking and everyday architectural practice, as many research still depend on manual export-conversion-validation pipelines which interrupt iterative modelling and discourage routine use by design teams. In this study, lightweight refers to an operationally lean workflow that avoids full-model exchange and instead extracts only the minimum set of code-relevant elements and attributes required for checking selected quantitative clauses. In other words, the challenge is no longer how to represent codes and BIM data as knowledge graph, but how to configure and operationalise them as a live, in-context compliance helper inside BIM authoring environments. This leads to two research questions:

RQ1: What lightweight knowledge-graph representation and constraint configuration is sufficient to support reliable checking of quantitative residential-code clauses during design iterations?

RQ2: How can this linked-data checking pipeline be embedded into a BIM authoring workflow to provide real-time feedback for architects without requiring expert coding skills?

To answer these questions, this study bridges the gap by integrating ifcOWL-based data representing and SHACL validation directly within Autodesk Revit through a pyRevit extension which is an open-source add-in framework that enables custom Python-based tools to run directly inside Autodesk Revit, thereby turning semantic checking into a designer-centric tool rather than a separate post-processing task.

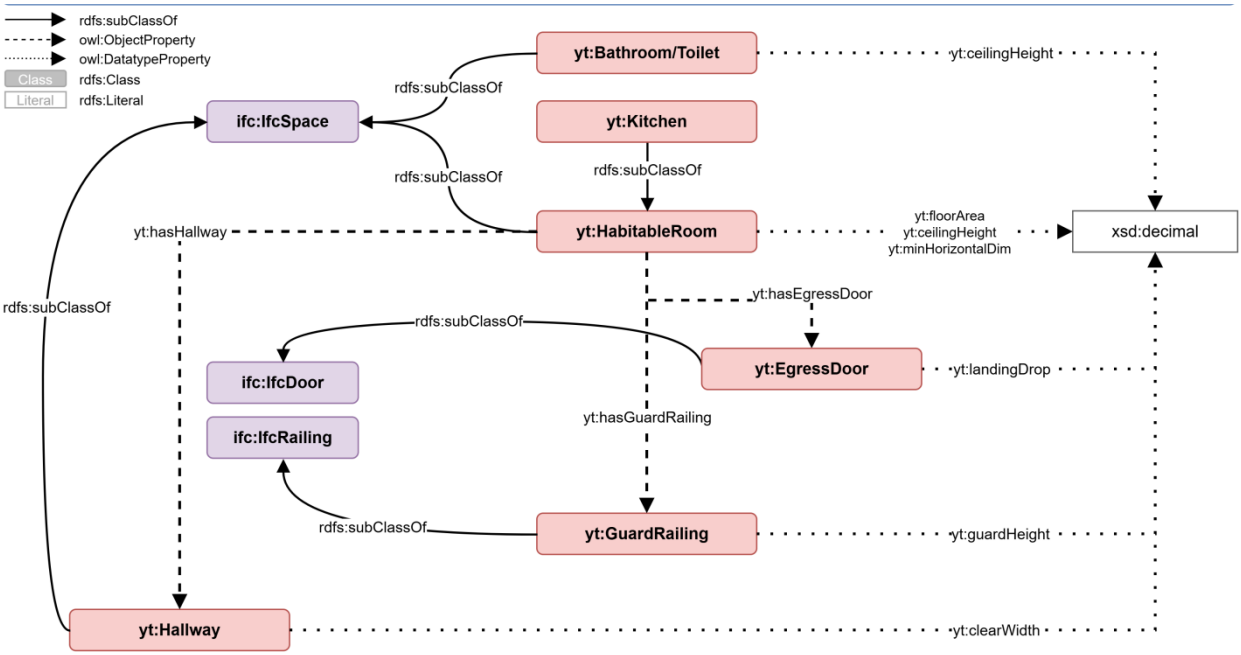

Figure 2: Snippet of the building regulatory ontology schema aligned with ifcOWL

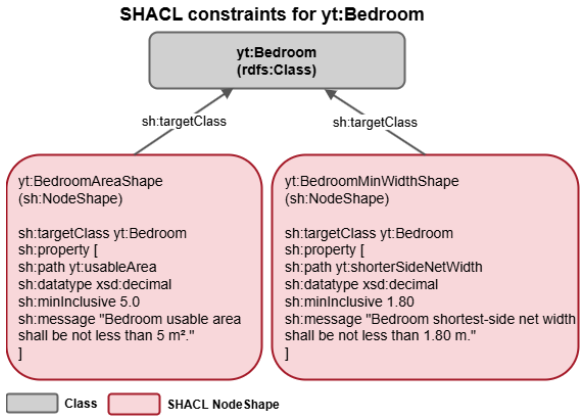

Figure 3: Example of SHACL rule definitions for compliance checking

Methodology

Scope definition and code sources

This study develops a flexible regulatory-checking framework aimed at the architectural design phase, where design teams need real-time, in-context feedback without relying on external consultants or expert programmers. To demonstrate feasibility of embedding code reasoning into the BIM operational environment, a subset of clear and quantitative requirements was extracted and encoded from the 2025 Edition China Residential Code (CRC2025), and it can be found on Github[1].

The framework is intentionally modular. The normative knowledge base acts as a replaceable code database which can be expanded or localised to other jurisdictions by updating the SHACL constraints and the associated regulatory terms. Each rule is expressed in a machine-readable format, enabling scalable adaptation as additional requirements are introduced and/or use of the framework for other regulations. By limiting the initial implementation to well-defined, quantitative provisions, the framework validates the workflow logic while ensuring its utilisation for non-technical design practitioners. This infrastructure provides a foundation for future inclusion of more complex and qualitative compliance criteria through the same linked-data structure.

Linked-data-based framework

This study proposes a linked-data based framework (shown as Fig 1.) for regulation compliance checking that is conceptually independent of any single BIM authoring platform, while being implemented and validated through a Revit-based prototype. The core idea is to decouple normative knowledge from software-specific model representations by first translating regulatory clauses into a regulatory ontology and then aligning model data with this ontology through shared semantic structures.

In the proposed framework, only the minimum required semantic information is extracted from the active BIM model and transformed into RDF with explicit mappings to ifcOWL and a project-specific regulatory ontology. This semantic abstraction enables regulation checking to be executed through SHACL validation at the ontology level, rather than being hard-coded to a specific BIM API. While the current prototype realises the workflow through a pyRevit extension, providing visual feedback, tabular summaries, and auditable reports within Revit, the same semantic rule set and validation logic can, in principle, be applied to models organising from other BIM environments that support IFC-based data exchange. Therefore, the use of IFC/ifcOWL and SHACL in this study is not intended to demonstrate cross-platform interoperability empirically, but to establish a software-agnostic regulatory reasoning layer, with Revit serving as a representative design environment for proof-of-concept validation.

Encoding the regulatory clauses with ontology

The proposed framework translates selected quantitative clauses from the China Residential Code into a machine-interpretable regulatory ontology aligned with ifcOWL. Each clause is formalised as constraints over (i) a target building element class (e.g., space, door, railing) and (ii) measurable attributes (e.g., area, clear width, ceiling height). In this way, legal requirements are expressed as explicit semantics that can be consistently validated over BIM-derived data.

Figure 2 presents a subset of the developed ontology. The visual schema in Figure 2 follows the Ontology Design Template by Donkers (2022) to ensure consistent notation and readability. The schema reuses ifcOWL classes to represent BIM entities (e.g., ifc:IfcSpace, ifc:IfcDoor, ifc:IfcRailing) and extends them through a lightweight project namespace "yt:" (Yutian Yi), publicly released on GitHub for reuse, extension, and transparent review. Domain-specific regulatory concepts such as "yt:HabitableRoom", "yt:EgressDoor", and "yt:GuardRailing". They are defined as subclasses of their closest IFC counterparts, preserving interoperability while allowing code-oriented distinctions. Quantitative requirements are then attached through datatype properties (e.g., "yt:floorArea", "yt:clearWidth", "yt:ceilingHeight") whose values are represented as xsd:decimal. Encoding the regulatory knowledge in RDF triples ensures the resulting rule vocabulary is linked, queryable, and reusable across projects, enabling a traceable connection between legal clauses and digital building entities.

In-model data extraction

Within Autodesk Revit, a dedicated pyRevit extension automates extraction of compliance-relevant information directly from the authoring model. Using the Revit API, the extension identifies target element categories (e.g., rooms/spaces, doors, railings) and retrieves only the parameters required by the rule set, avoiding unnecessary geometry export and reducing operational overhead during iterative design.

To support rule execution and semantic alignment, each exported field is annotated with two layers of correspondence. First, an ifcOWL-oriented mapping associates the extracted elements with established AEC semantics (e.g., Room is mapped to ifc:IfcSpace, BalconyRailing is mapped to ifc:IfcRailing, Door is mapped to ifc:IfcDoor). Second, a regulatory mapping links the same elements and attributes to the project's "yt:" ontology introduced above (e.g., habitable-space attributes to "yt:floorArea", "yt:minHorizontalDim", "yt:ceilingHeight"; egress-related attributes to "yt:landingDrop"; guard attributes to "yt:guardHeight"). This dual annotation enables reuse of standardized IFC semantics while preserving the code-specific vocabulary needed for regulatory checking. The extracted data are serialized as a compact JSON-LD payload, where numeric values are preserved alongside an explicit

semantic context that binds each field to ifcOWL and the "yt" regulatory vocabulary. This lightweight linked-data serialization avoids exporting a full IFC model while maintaining machine-interpretable interoperability across tools and rule sets.

Conversion to RDF graphs

The extracted dataset is first serialised as JSON-LD, where every Revit element assigned a stable identifier (e.g., "yt:Room_101") and an explicit semantic context that maps fields to the "yt" regulatory vocabulary and the ifcOWL schema. This means the payload is already a Linked Data representation rather than a purely syntactic JSON export. The workflow then materialises the JSON-LD into an RDF graph (and, when required by downstream tools, into a Turtle .ttl file). In this graph, element instances are represented as resources, attributes are expressed as RDF triples, and their conceptual types are connected to ifcOWL via rdf:type assertions. The conversion step automatically binds the "ifc:" and "yt:" namespaces and produces a standards-compliant RDF dataset for subsequent SHACL validation.

This semantic representation merges two domains that are usually separated in practice: BIM authoring data and rule-based knowledge graphs. By doing so, the building model can participate in the web of data—each wall, door, or space is no longer merely a 3D object but a node in a logically connected graph that can be validated, queried, and extended. The RDF layer therefore acts as a bridge between design tools and semantic reasoning technologies, while JSON-LD provides a lightweight and interoperable carrier format for moving data across components of the workflow.

Rules checking process via SHACL

Compliance checking is executed using the SHACL, which interprets the ifcOWL-encoded model as building model and normative knowledge as shape constraints. Each regulatory clause corresponds to a SHACL shape. Fig 3. presents an example, a "yt:HabitableRoomShape" enforcing sh:minInclusive 6.5 for "yt:floorArea", which means habitable room area must be greater than or equal to 6.5 square meters.

The SHACL engine (PySHACL library) parses the RDF graph, matches each instance of the target class, and then checks the relevant properties against the specified numeric thresholds. Non-conforming elements generate validation reports with precise pointers to both the violating node and the specific rule.

As both the data and the rules share the same ifcOWL backbone, reasoning occurs at the semantic level rather than through file-specific attributes. This alignment allows the framework to extend seamlessly to other jurisdictions or to add higher-order logic by simply appending new SHACL shapes.

Result Presentation

After validation, results are returned through two synchronised channels. On one hand, a textual report and an Excel summary are generated, listing all items and highlighting non-compliant element with its property values and the corresponding rule citation. These documents are automatically saved to the designer's local workspace and can be used for later verification or regulatory submission.

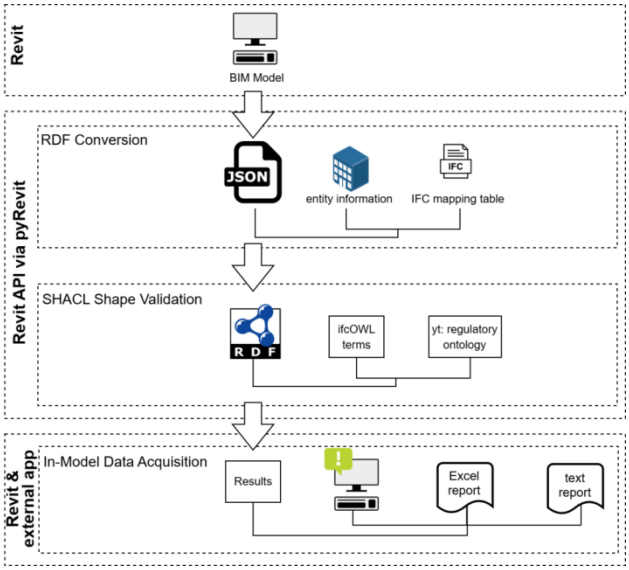

Figure 4: Overall data flow path of the prototype

More importantly, the pyRevit interface presents the feedback directly within the Revit user-side model. The script parses the SHACL report, identifies the offending element IDs, and visually highlights them in the active view using colour coding and annotations. This live feedback loop turns regulation checking into an interactive design activity, where architects can correct issues while modelling rather than after exporting or outsourcing verification. Fig 4. illustrates the data path across the whole framework. Through this integration, the traditionally disconnected processes of design and compliance merge together into a single continuous workflow governed by linked data semantics.

Case study

To demonstrate the feasibility and practical value of the proposed framework, a case study was conducted on a residential project comprising two-family dwellings currently under design development. The project type aligns directly with the applicability scope of the CRC2025, which governs low-rise residential buildings. The model was developed in Autodesk Revit 2026, and the pyRevit extension created in this study was used to perform data extraction, ontology conversion, and regulatory validation within the same digital environment.

Figure 5: The button of the developed pyRevit plug-in and the chosen case model

The chosen project represents an early-stage design model that is still undergoing iterative refinement, allowing the proposed framework to demonstrate its usefulness in real-time design evaluation rather than retrospective verification. Through the developed pyRevit plug-in shown in Fig 5., spatial and dimensional attributes of each building component were exported, converted into an RDF graph based on the ifcOWL schema and the extended "yt" ontology, and validated against the SHACL constraint set derived from local codes.

By suitable building model and normative knowledge input, the validation process successfully identified non-compliance instances, confirming the framework's capability to automatically trace code violations. For example, warnings in the SHACL validation report indicated in Fig 6.: usableArea: Missing or 0.

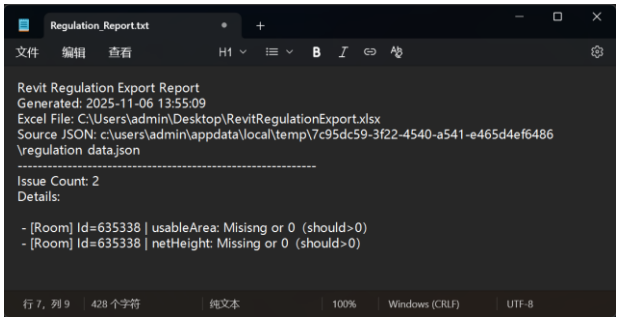

Figure 6: The generated result of regulation report text

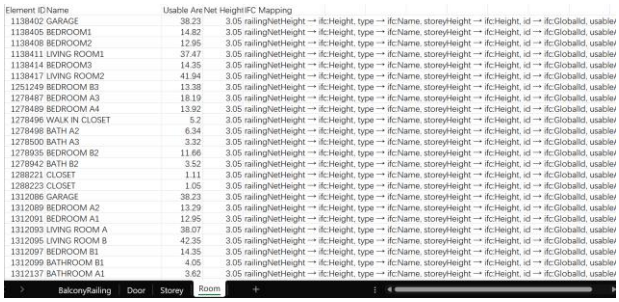

Figure 7: Example figure layout

Beyond textual validation, the framework produced two additional outputs that enhance its practical utility. First, it automatically generated a structured Excel file (Fig 7.), organising all model elements and their compliance status for item-by-item inspection by designers or reviewers. This tabular format enables traceability, documentation, and manual double-checking of design changes over time. Then the system delivered graphical feedback within Revit. Non-compliant elements were automatically selected and highlighted in the model view, enabling designers to visually identify and address each issue directly. If no violations were detected, a pop-up message appeared within Revit, indicating full compliance with the current rule set. Those are shown in Fig 8. This immediate interaction between reasoning output and model visualization underscores the system's lightweight, user-friendly nature.

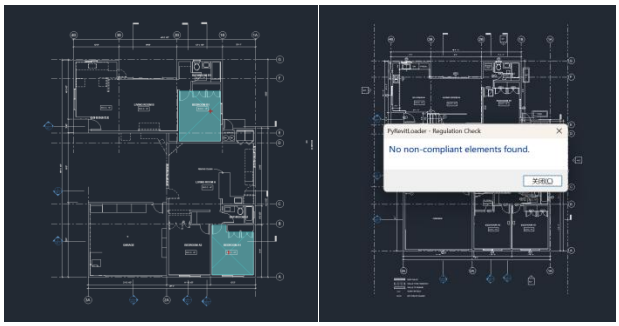

Figure 8: The graphical result shown inside Revit

Conclusions

This study presented a lightweight regulation compliance framework integrated within Autodesk Revit through a custom pyRevit extension. By linking BIM data with semantic web technologies with ifcOWL and SHACL, the system enables architects to perform specific regulation checks intuitively without leaving their design environment. The workflow automates data extraction, RDF conversion, and rule validation while providing both tabular and visual feedback, significantly improving accessibility for non-programming users.

Beyond its practical value, the study offers a theoretical implication by clarifying a reference architecture for "in-model semantic compliance": regulatory knowledge is treated as an explicit, modular layer which includes ontology and constraints that is conceptually separable from any particular BIM platform, while user interaction and feedback remain embedded in the authoring environment. This framing contributes to the Human-Data Interaction literature by positioning compliance checking as a human–data interaction problem where transparency, traceability, and actionable feedback are as critical as rule correctness.

A key limitation is that, at the current stage, a single prototype implementation was developed and validated in Revit; cross-platform interoperability across multiple BIM authoring tools will be empirically evaluated as primary goal in next step of the study. The current implementation is also restricted to quantitative and spatial clauses and still relies on manual encoding of regulatory knowledge. Future work will extend the rule set and test the workflow across additional BIM environments, as well as building on recent advances in AI-assisted code translation, natural language processing and large language models. Such integration of AI-driven knowledge modelling and semantic reasoning could significantly accelerate the creation of digital regulatory databases, improving adaptability, scalability, and adoption of compliance automation in the AEC industry.

Acknowledgments

The authors gratefully acknowledge BIM Engineer Hanqin TANG (WRNS Studio) for generously providing the Revit model used in the case study which enabled the practical validation of the proposed workflow within a real design project context.

BETWEEN ARCHITECTURAL DESIGNERS AND DEVELOPERS: EMPIRICAL DESIGN RESEARCH FOR COMPUTATIONAL DESIGN SUPPORT

Elien Vissers-Similon[1] and Theodoros Dounas[2]
[1]University of Antwerp, Belgium
[2]Heriot-Watt University, United Kingdom

Abstract

This paper addresses the gap between architectural designers and computational design support developers by proposing a Lakatosian framework grounded in empirical design research. Combining Peirce's reasoning modes with Schön's reflective practitioner, we extend Pauwels et al.'s (2013) framework by revising the hypotheses on design thinking and tool adoption. We derive three guidelines: computational design support as aides of reasoning modes, as artefacts for experimenting, and as collaborative reasoning agents. For each guideline, we formulate a primary empirical research question. We also propose two empirical instruments to help answer those questions.

Introduction

The architectural design process continuously becomes more complex due to an increase of collaborators, stakeholders, regulations, and client demands. This in turn leads to a growth of computational design support tools development. However, the adoption rate of such tools is rather low in architectural design practice. This is especially true for small and medium-sized architectural design firms, who do not tend to set the narrative on emergent technologies but do represent most European firms. (The Architects' Council of Europe, 2024) Surveys show that parametric modelling tools have particularly low adoption rates for small and medium-sized firms (Stals et al., 2018) despite having access to user-friendly tools such as Grasshopper since 2007. (Tedeschi, 2010) Other surveys show that even building information modelling (BIM) software faces low adoption rates in such firms (Burgess et al., 2026) despite BIM's proven value for the AEC sector. The common denominator for these surveys is that they capture the *designers' perspective* on these computational design support tools. The barriers and limitations observed in the surveys unveil that architectural designers and developers are lost in translation. On one hand, designers assume that computational design support restricts their creativity, they expect expensive implementation difficulties and fail to see sufficient added value for their designerly processes. On the other hand, developers approach design processes as homogeneous processes rather than heterogeneous thinking processes and fail to understand layered decision-making processes within a design task.

To bridge this gap, this paper argues for more empirical design research into architectural design processes, to develop computational design support that is compatible with design thinking. By critically extending Pauwels et al.'s (2013) theoretical framework into a Lakatosian research programme, we establish practical guidelines for design support developers and formulate relevant empirical research questions.

Our argument is grounded in an ongoing empirical research programme studying the adoption of diffusion models in small and medium-sized architectural practice (Vissers-Similon et al., 2026) and educational settings (Vissers-Similon and Dounas, 2026A), which provides situated evidence of how reasoning modes, design artefacts and design features interact in real design processes.

Specifically, we address four research questions:

1. Which Lakatosian framework on computational design support can bridge the gap between architectural designers and developers?
2. Which resulting guidelines are relevant for developers?
3. Which resulting empirical design research questions are relevant for future research on computational design support?
4. Which instruments can we use to pursue these research questions?

Traditionally, computational design support is either a means of representation, a tool, or both. We consider computational design support to be a tool for decision-making within design processes.

State-of-the-art review

Design thinking and computational design support

The relationship between design and technology has been theorised through multiple paradigms. Simon's (1969) *Sciences of the Artificial* first established design as a legitimate scientific inquiry. Schön's (1983) *Reflective Practitioner* introduced a paradigm shift by challenging the technical-rational model, arguing that designers engage in 'reflection-in-action': a process fundamentally different from technical knowledge application. This catalysed subsequent research by Dorst (2011) and Cross (2011) establishing "design thinking" as a distinct mode of cognition operating through iterative cycles of problem-framing and solution-finding. Contemporary

understanding of design thinking draws significantly on Peirce's (1931) triadic framework: abduction as generating hypotheses, deduction as deriving consequences, and induction as testing through observation. Dorst (2011) demonstrates how design problems involve 'frame creation': the abductive leap of simultaneously determining problem and solution approach. Kolko (2010) shows designers rely heavily on abduction during design synthesis, indicating that reasoning mode importance shifts during a design process. Garbuio and Lin (2021) further distinguish explanatory from innovative abduction, mapping abductive activities to problem search frames, hypothesis generation, and hypothesis evaluation.

When considering "computational design thinking", Oxman's (2017) *Thinking Difference* establishes parametric thinking as a distinct form enabling fundamentally different modes of design cognition. Terzidis (2006) extends this by distinguishing parametric from algorithmic thinking. These frameworks reveal a consistent pattern: new computational capabilities enable new forms of design thinking, not merely more efficient existing processes.

Alexander et al.'s (1977) *A Pattern Language* focused on "design knowledge" rather than design thinking, proposing codification through patterns. This work followed an unexpected trajectory: initially developed for architecture, pattern languages were adopted by software engineering (Gamma et al., 1994) and are still relevant for software developers today. From software engineering, pattern languages circled back to influence computational architectural design, at first through Stiny and Gips's (1972) shape grammars and their extensions (Stouffs and Krishnamurti, 1996) and through many applications that have followed since. This crosspollination reveals both the portability and context specificity of design knowledge.

We note that, despite the increasing theoretical understanding of design thinking, it is the more tangible and specific design knowledge that generally shapes the development of new computational design support tools.

Empirical evidence from protocol analysis and practice studies

The above claims on design thinking, that reasoning modes shift and tools shape cognition, are not merely theoretical. Goldschmidt's (2014) linkography method demonstrates that design thinking operates through networks of 'design moves' with identifiable critical moments. Her work shows measurable patterns of fore-linking (divergent thinking) and back-linking (convergent thinking) that fluctuate over design sessions, providing quantitative evidence for dynamic reasoning mode dominance. Gero and Kannengiesser's (2014) situated Function- Behaviour-Structure (FBS) framework has generated extensive empirical evidence through protocol studies comparing design cognition across tools and media, showing statistically significant differences when using hand sketching versus parametric modelling. Suwa and Tversky (1997) identified four cognitive levels (physical, perceptual, functional and conceptual) showing expert architects make significantly more functional inferences from sketches than students. Suwa et al. (1998) extended this, identifying distinct design phases with different cognitive profiles. Dorst and Dijkhuis (1995) empirically compared Simonian and Schönian descriptions of the same protocol, finding reflection-in-action better preserves the relationship between process and content. Cramer-Petersen et al. (2019) demonstrate that abductive-deductive patterns dominate early-stage ideation. Critically, recent empirical work by the authors' research programme provides situated evidence from contemporary practice. Vissers-Similon et al. (2026) conducted a year-long living lab with a small Flemish architectural design practice, studying the adoption of diffusion models across complete design processes. The analysis represents design data on three encapsulating levels: *design features* (such as style, texture, geometry, spatial relationships, feeling, lighting, details); *design artefacts* (such as floorplans, sketches, mood boards, 3D models, generated images) as sequences representing design processes; and *design thinking* (specifically Peirce's reasoning modes) representing reasoning between artefacts. The results show that: (a) reasoning mode dominance shifts measurably across design stages, with abductive reasoning dominant during presentation sketch creation and annotation/discussion moments, deductive reasoning during cost estimation and mood board assembly, and inductive reasoning during 3D modelling and floorplan iteration; (b) despite diffusion model adoption, design decisions were predominantly situated in analogue moments, through manual annotation and discussion, and coincide with abductive reasoning; (c) generated artefacts function as effective design artefacts in Schön's sense, 'talking back' to the designer. Short empirical experiments in education (Vissers-Similon and Dounas, 2026A) also corroborate this, showing students make design decisions based on 'moments of interpretation' that are textual, visual or spatial in nature.

Information systems and reasoning mode alignment

Pauwels et al. (2013) provide the key synthesis linking computational design support to design thinking through Peirce's reasoning modes. Their framework connects cognitive reasoning modes to practical requirements of digital tools, arguing effective support must align with natural reasoning patterns. They propose three application development approaches: computational design support as surrogates for reasoning modes, as tools for experimenting, and as autonomous reasoning agents. They then argue that traditional information systems typically target only one reasoning mode at a time, which may explain limited adoption.

Research gaps

The state-of-the-art review establishes crucial principles but also reveals critical gaps. First, computational design support is most often based on design *knowledge* rather than design *thinking*. Second, design thinking operates through reasoning modes that shift in dominance, as demonstrated by empirical evidence from both protocol

and practice studies. Third, Pauwels et al.'s (2013) framework treats the reasoning cycle as static rather than dynamic and does not accommodate design artefacts as catalysts for reflection-in-action. Fourth, no formalised representation maps Peirce's reasoning modes onto concrete design activities in a way that is both empirically grounded and machine-readable. These gaps motivate a revised Lakatosian framework and accompanying empirical instruments.

Methodology

This paper employs a dual methodological approach. Its primary method is *critical conceptual analysis*: we systematically extend an existing theoretical framework through gap identification and hypothesis revision, following Lakatos's (1970) methodology of scientific research programmes. Its secondary method draws on *design science research* (Hevner et al., 2004): we treat the revised framework and its accompanying empirical instruments as design artefacts, subject to evaluation against utility criteria. The complete methodological approach is visualised in Figure 1.

Selection and analysis of base framework

We select Pauwels et al.'s (2013) framework because it explicitly links computational design support to *design thinking* through Peirce's reasoning modes, rather than to design knowledge. Alternatives were considered: Hevner et al.'s (2004) design science framework focuses on information system artefacts rather than design cognition; Oxman's (2017) parametric thinking framework addresses a specific tool typology; Gero and Kannengiesser's (2014) Function- Behaviour-Structure ontology provides an empirical coding scheme but not a normative framework for tool development.

Gap identification

The base framework rests on two major hypotheses, regarding design thinking and tool adoption. We interrogate each hypothesis against two evidence sources: (a) established protocol analysis studies showing reasoning mode shifts (Goldschmidt, 2014; Suwa et al., 1998; Cramer-Petersen et al., 2019) and (b) situated empirical evidence from the living lab study (Vissers-Similon et al., 2026) mapping reasoning mode transitions across complete design processes in a real architectural practice. A hypothesis is revised when it cannot accommodate documented variability (criterion of flexibility) or when it treats support as replacement rather than augmentation (criterion of compatibility with reflective practice).

A Lakatosian framework for design thinking support

Lakatos (1970) introduced a structure for scientific research programmes distinguishing between a 'hard core' of fundamental commitments and a 'protective belt' of auxiliary hypotheses subject to modification. Applied to our case, this suggests computational design support should be developed as design research programmes: maintaining core commitments while allowing implementations to evolve based on empirical evidence. To accommodate empirical modification of the auxiliary hypotheses in the protective belt, our Lakatosian framework includes practical guidelines for developers of computational design support, and theoretical research questions to facilitate empirical design research.

Design science component: from framework to empirical instrument

Following Hevner et al.'s (2004) design science framework, which itself adopts Lakatos's structure, we propose an empirical instrument as a design artefact: a structured protocol-analysis coding instrument mapping Peirce's reasoning modes onto observable design activities. This instrument operationalises the revised framework and can be evaluated through the empirical studies we propose. Its design draws on Gero and Kannengiesser's (2014) Function- Behaviour-Structure coding scheme, Goldschmidt's (2014) linkography, and Vila-Henninger et al.'s (2022) abductive coding methodology, calibrated against Vissers-Similon et al.'s (2026) three encapsulated levels: design features, design artefacts and design thinking. The empirical instrument provides a formal structure into which findings can be encoded, closing the loop between the empirical observation of design thinking and machine-readable applications of design knowledge in computational design support.

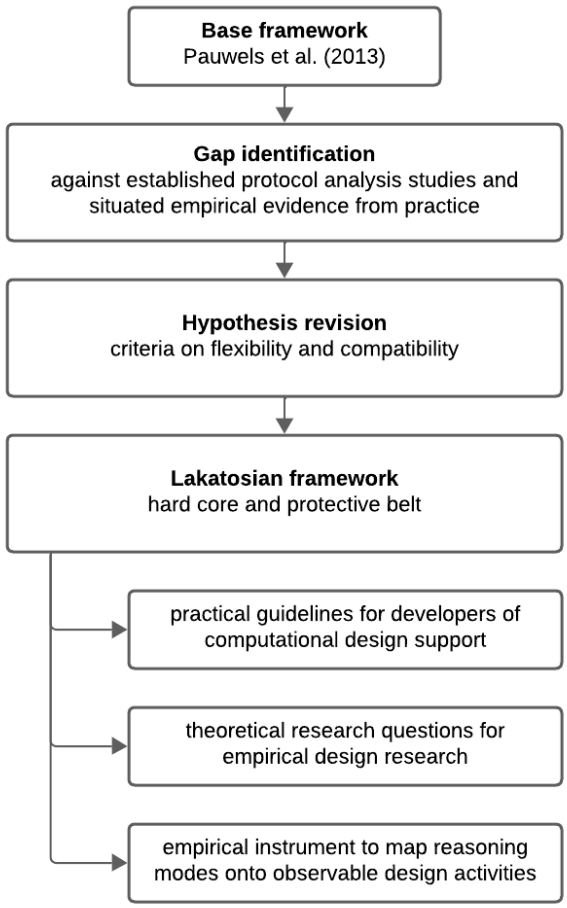

Figure 1: Methodological flowchart

Revised hypothesis on design thinking

The original hypothesis from the base framework states: "Creative designing rests on a cyclic combination of abductive, deductive and inductive reasoning processes." (Pauwels et al., 2013) We support Peirce's reasoning as foundation, because reasoning and decision-making is at the core of designing. However, the original hypothesis leaves no flexibility for varying importance of reasoning modes along a design process.

Protocol analysis and empirical evidence support this: Goldschmidt's (2014) linkography shows fore-linking and back-linking patterns shift measurably. Cramer-Petersen et al. (2019) demonstrate abductive-deductive patterns dominate early ideation. Vissers-Similon et al.'s (2026) living lab provides direct situated evidence: abductive reasoning dominates during presentation sketch creation and manual annotation of generated images; deductive reasoning during cost estimation and mood board assembly; inductive reasoning during 3D modelling and floorplan iteration. Design decisions, the moments that actually advance the project, coincide predominantly with abductive reasoning, conducted through manual annotation and collegial discussion, even when diffusion models are actively adopted.

The living lab thus confirms Schön's (1983) reflecting-in-action with contemporary evidence: generated artefacts from diffusion models succeed 'just as much as traditional artefacts' at 'talking back' to the designer.

We rephrase reasoning modes within the context of design thinking: abduction yields a plausible conclusion based on established design artefacts and background knowledge; deduction deducts a logical conclusion from established artefacts; induction infers a general theory from observations of established artefacts. This leads to an amended hypothesis: "Design thinking rests on a combination of abductive, deductive and inductive reasoning modes. At certain moments during a design process, design thinking adapts so that some reasoning modes are more dominant than others."

Revised hypothesis on tool adoption

The original hypothesis from the base framework states: "Traditional information systems typically target only one of these reasoning processes at a time, which might explain their limited applicability and usefulness." (Pauwels et al., 2013) We question whether targeting a single mode is inherently problematic. What truly matters is understanding which modes are dominant at which stages. The living lab illustrates this: diffusion models function effectively when targeting the right moment, but their outputs require human abductive interpretation to yield design decisions.

The amended hypothesis is thus: "Design support systems typically target only one of the reasoning modes at a time, without understanding which reasoning mode is dominant during the specific design task at hand, which might explain their limited applicability and usefulness."

Guidelines for computational design support

Based on the revised hypotheses, we propose three non-exclusive practical guidelines for developers of computational design support.

Guideline 1: Aides of reasoning modes

Developers should focus on tools that aide reasoning, targeting the right mode for the task at hand. Vissers-Similon et al.'s (2026) living lab shows that during sketch design, when abductive reasoning dominates, designers create hand drawn presentation sketches over printed 3D model views. A mode-aware tool could detect this abductive phase and offer precedent images as prompts, rather than imposing deductive constraint-checking. However, developers should be cautious of the epistemic mismatch in how humans and LLMs produce judgement. (Quattrociocchi et al., 2025)

Guideline 2: Artefacts for experimenting

Developers should focus on tools providing experimental artefacts. The critical question is whether tool outputs function as design artefacts in Schön's (1983) sense: objects provoking reflection-in-action. The living lab provides direct evidence: generated images from diffusion models functioned as effective Schönian artefacts when designers manually annotated them to extract design features (style, colour scheme, materials) and discussed annotations with colleagues. The artefact quality that mattered was *interpretive affordance* - the capacity to provoke functional inference, which Suwa and Tversky (1997) identified as the hallmark of effective design artefacts.

Guideline 3: Collaborative reasoning agents

Developers should focus on collaborative rather than autonomous reasoning agents. Vissers-Similon et al.'s (2026) living lab highlights the necessary collaboration between human designers and diffusion models to make effective design decisions: diffusion models did not generate the project's final façade design, but the human designers did considerably speed up their decision-making process in collaboration with diffusion models.

Empirical research questions

The framework's flexibility depends on empirical evidence to inform the hypotheses. For each guideline, we define one primary research question, which empirical instruments help to answer – and in turn, those new empirical findings might adjust the protective belt's hypotheses. The following empirical design research questions align with the established guidelines:

1. **RQ-E1:** Which reasoning mode is dominant at which moment in the design process?
2. **RQ-E2:** Which types of artefacts facilitate design thinking at which moment in the design process?
3. **RQ-E3:** Which type of interaction facilitates design thinking at which moment in the design process?

Empirical instruments

We propose empirical instruments to help answer the empirical research questions above.

First, a structured coding instrument operating at three levels, which links findings from established protocol-analysis instruments to findings from architectural practice, at each of those three levels. At the micro level, Gero and Kannengiesser's (2014) Function- Behaviour-Structure coding scheme provides the theoretical, ontological base. To map these acts of design, we use "design features". At the meso level, we use abductive coding (Vila-Henninger et al., 2022), to map the "design artefacts" onto their design processes. At the macro level, we relate to Goldschmidt's (2014) linkography method to document how designers think, to map "design thinking". A complete methodology of mapping design features, artefacts and thinking on these three levels is described in Vissers-Similon et al.'s (2026) *Mapping Design Features, Artefacts, and Thinking: Developing a Method for Assessing the Impact of Diffusion Models' Implementation in Interior Design*. By mapping reasoning modes onto observable design activities, we create an empirically grounded instrument for protocol-analysis coding.

Second, for a machine-readable representation, which addresses the fourth and final gap from the "research gaps" section in this paper, we propose an ontology that can be navigated by collaborative reasoning agents. This ontology uses design features, artefacts and thinking as building blocks. The theoretical foundation of such an ontology is described in Vissers-Similon and Dounas' (2026B) *OntoCAAD: an empirically grounded Ontology for Collaborative Agentic Architectural Design*. The OntoCAAD ontology provides the conceptual infrastructure which collaborative reasoning agents could navigate: it formalises design knowledge into classes (Feature, Artefact, Actor, DesignDecision) and formalises design thinking through class interactions (reframe, reason, make, implement) that align with the epistemic pipelines of both human and machine reasoning. (Quattrociocchi et al., 2025) A collaborative reasoning agent built on this ontology could reframe a design problem by identifying relevant features, generate artefacts through artificial intelligence models, and support the designer's reasoning while leaving the actual design decision with the human. The ontology's Actor class distinguishes Person and Agent subclasses, allowing for a precisely calibrated distribution of agency and authorship.

Results: a Lakatosian framework for computational design support

The resulting framework is visualised in Figure 2.

Discussion: empirical research agenda

Regarding RQ-E1, Vissers-Similon et al.'s (2026) living lab provides preliminary answers based on one case study. The empirical mapping instrument can now be applied across additional design processes to test generalisability.

Regarding RQ-E2, Vissers-Similon et al.'s (2026) living lab provides preliminary answers on generated artefacts by diffusion models, which facilitate design thinking through annotation and discussion. OntoCAAD's Artefact class provides the structured vocabulary for further large-scale comparative analysis.

Regarding RQ-E3, Vissers-Similon and Dounas' (2026A) educational experiments show decisions occur at 'moments of interpretation', and OntoCAAD's interact() function and AgentRole enumeration provide categories for evaluating interaction modalities in further large-scale comparative analysis.

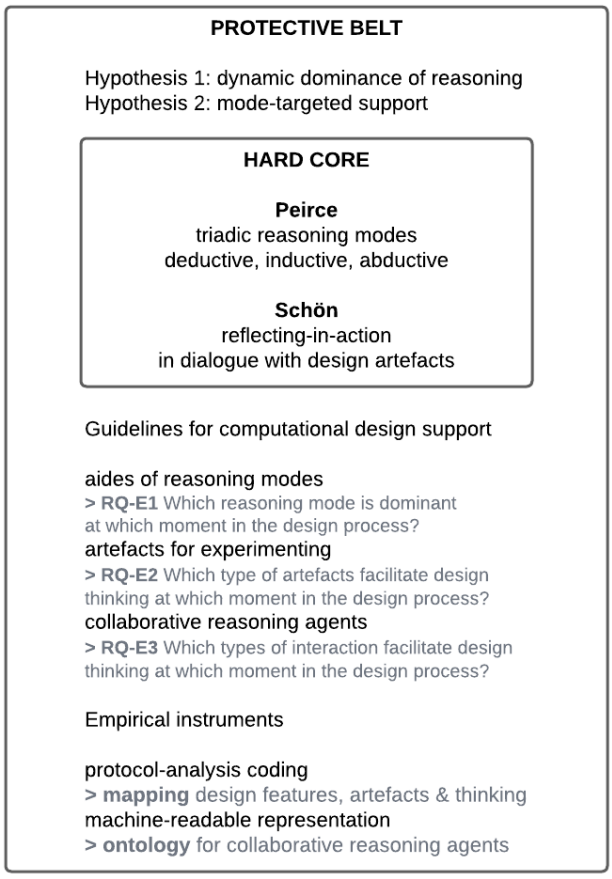

Figure 2: Lakatosian framework for computational design support

Validation roadmap

To provide substantiated answers to the empirical design research questions, and thus to solidify the Lakatosian framework for computational design support, we develop a research programme with the following roadmap.

Phase 1 (completed): establishing the framework. The educational experiments (Vissers-Similon and Dounas, 2026A) and year-long living lab (Vissers-Similon et al., 2026) provided foundational data to establish the Lakatosian framework.

Phase 2 (ongoing): initial calibration of the framework. The empirical mapping instrument as described in Vissers-Similon et al. (2026) will be applied to empirical observations of four additional living lab studies, with small and medium sized architectural firms. The empirical machine-readable instrument, OntoCAAD – as described

in Vissers-Similon and Dounas (2026B), will be built and tested to (i) finetune the ontology and (ii) define potential collaborative reasoning agents.

Phase 3: carrying out the research programme. The OntoCAAD ontology will be integrated in a digital platform, alongside prototypes of useful collaborative reasoning agents. This empirical infrastructure will then be used for testing design sessions across multiple small and medium sized architecture firms to answer RQ-E1, RQ-E2 and RQ-E3 for each collaborative reasoning agent.

Conclusions and contribution

This paper advocates for more empirical architectural design research to bridge the gap between designers and developers of computational design support. We propose a Lakatosian framework based on Peirce's triadic reasoning modes and Schön's reflection-in-action, to substantiate two hypotheses: on dynamic dominance of reasoning modes, and on mode-targeted support.

The framework produces three nonexclusive guidelines for computational design support and two empirical instruments to help achieve these guidelines. The guidelines are computational design support as aides of reasoning modes, artefacts for experimenting and collaborative reasoning agents. The empirical instruments are protocol-analysis coding through mapping, and machine-readable representation through an ontology.

The key contribution lies in recognising that the development of computational design support constitutes applied design research. Each tool instantiates hypotheses about design thinking and creates opportunities for empirical validation, with actual adoption in practice as the end goal. The framework's guidelines provide three primary empirical research questions, which can be answered with the help of two empirical instruments. First, the protocol-analysis coding instrument allows us to map reasoning modes onto observable design activities. Second, the machine-readable representation by the OntoCAAD ontology translates validated findings into structured data, bridging design cognition research and computational agent development.

Limitations

This paper is a conceptual extension grounded in, but not constituting, new empirical data collection. The protocol-analysis instrument is established but not yet calibrated. The ontology instrumented is described but not yet built or calibrated. The empirical findings which serve as the foundation for this research programme are all collected in the Flemish architectural design context; thus, generalisability remains to be demonstrated. The authors bring combined experience in architectural practice, computational design research and empirical design cognition studies, which informed gap identification but may introduce biases toward particular tool typologies.

Acknowledgments

The research on this Lakatosian framework, as well as the completed and ongoing phases of the validation roadmap, was done primarily by Elien Vissers-Similon, under the supervision of Theodoros Dounas. In this paper, Dounas contributed to the state-of-the-art review, research gaps, methodology, discussion and conclusions sections.

SUPPORTING CONSTRUCTION SITE H&S INSPECTIONS WITH COMPUTER VISION: A BPMN PROCESS FORMALISATION

Federica Madaschi[1], Alessandro Bruttini[2], and Marco Lorenzo Trani[1]
[1]Department of Architecture, Built Environment, and Construction Engineering (DABC), Polytechnic of Milan, Milan, Italy
[2]Department of Architecture (DIDA), University of Florence, Florence, Italy

Abstract

Routine construction site Health and Safety (H&S) inspections remain manual, experience-driven, and weakly digitised. While Computer Vision (CV) has advanced construction safety, particularly for real-time monitoring, it has rarely been investigated to support everyday inspection practices. This paper addresses this gap by analysing a routine inspection process and formalising current practice using Business Process Model and Notation (BPMN) 2.0 to make roles, decisions, and information exchanges explicit and expose key limitations. The study then proposes a CV-enabled inspection process that structures the collection and interpretation of visual evidence and suggests compliance-related observations to the H&S Manager, while preserving their assessment responsibility.

Introduction

In recent years, rapid advances in Artificial Intelligence (AI) have accelerated its adoption in the Architecture, Engineering, Construction, and Operations (AECO) sector, with applications demonstrating practical benefits across a wide range of use cases. However, despite the growing availability of mature technologies, their implementation in everyday workflows often remains limited (Abioye et al., 2021; Khan et al., 2024). This is partly due to the construction industry's fragmented nature, which hinders the acquisition and retention of the data required for AI solutions, thereby constraining effective deployment. Furthermore, evidence indicates that adoption among Small and Medium-sized Enterprises (SMEs) remains comparatively limited and slower than in other sectors (Khan et al., 2024; Regona et al., 2022).

This implementation gap is particularly evident during the construction phase in site Health and Safety (H&S) management, where most applications currently focus on hazard detection and real-time monitoring (Pandithawatta et al., 2024), leaving AI's potential to support other routine activities of H&S managers unexploited. In this regard, construction site H&S inspections remain largely manual and weakly digitised, despite their central role in monitoring on-site conditions (Lin et al., 2025; Natasha Mohamad Shubqizam et al., 2025). In practice, effective AI support is constrained by the limited structure and poor quality of available data and the costs of integrating AI tools into established procedures. Among these, Computer Vision (CV) stands out as one of the most mature, accessible, and readily applicable options (Liu et al., 2021). Nonetheless, its adoption in H&S inspection is still hindered by the absence of shared, clearly defined, and actionable processes that translate CV outputs into operational decision support for H&S managers (Daniel et al., 2025), as well as by socio-legal constraints related to liability and on-site data collection and use (Agapiou, 2024). H&S inspections rely on the professional's experience of the individual manager or organisation, with compliance assessment and information management heavily dependent on unintegrated textual documentation (Forteza et al., 2023; Hussamadin et al., 2023). Without a structured understanding of inspection practices, efforts to develop and integrate AI tools into these workflows risk producing solutions that do not address real operational needs. To this end, this study aims to explore and provide a structured basis for the use of innovative CV-based approaches in construction site H&S inspections. Specifically, current inspection processes are analysed and modelled using the Business Process Model and Notation 2.0 (BPMN) to formally represent activities, decisions, and interactions among the involved actors (OMG, 2013). By clarifying how information is currently generated and shared, and by identifying bottlenecks and repetitive manual tasks, the paper discusses where and how CV can be integrated to systematise the collection, interpretation, and management of visual evidence. The proposed perspective is intended to support compliance assessment and reporting activities while accounting for the H&S manager's responsibility. On this basis, the study provides a process-oriented and structured interpretation of H&S inspections to guide the development and adoption of CV-based tools that support H&S managers' everyday operational practice on construction sites.

Background

This study bridges current manual H&S inspection practices and CV-enabled decision support by synthesising inspection limitations, BPMN workflow modelling, and AI/CV applications, moving beyond hazard detection toward process-driven support.

Site H&S inspection: current practice and limitations

Internationally, Health and Safety (H&S) management is increasingly recognised as a cornerstone of sustainable work, with Occupational Health and Safety Management

System (OHSMS) standards such as OHSAS 18001 and ISO 45001:2018 promoting structured cycles of planning, implementation, monitoring, and review to ensure compliance and continuous improvement, particularly in high-risk sectors such as construction (Arévalo Sarrate et al., 2024; Marhavilas et al., 2022). In the European Union, this systemic approach is embedded in a comprehensive regulatory framework centred on the Framework Directive 89/391/EEC and the construction-specific Directive 92/57/EEC for temporary or mobile construction sites, which establish core obligations for risk assessment, prevention, coordination, and the allocation of responsibilities among project actors.

Comparative studies consistently characterise construction as a high-risk industry that requires robust preventive measures, formal H&S planning, and continuous supervision to ensure that dynamic site conditions remain aligned with regulatory requirements (González García et al., 2021). Within this context, the H&S manager assumes a central coordinating role, bearing significant responsibility for organising prevention activities, assessing compliance, and monitoring site conditions through routine inspections. However, these inspections largely rely on manual, experience-based practices: checks are predominantly visual and non-standardised, and observations are often recorded inconsistently across individuals and organisations, reflecting tacit knowledge rather than a structured process logic (Ramos-Hurtado et al., 2022; Saurin, 2016). Fragmented or paper-based data collection further weakens reporting, traceability, and follow-up. At the same time, inspection programmes are frequently irregular and insufficiently risk-based, leading to under-coverage of recurrent high-severity hazards and delayed corrective actions (Rey et al., 2021). Moreover, inspection outputs are rarely leveraged as leading-indicator datasets; reports are commonly archived rather than analysed to identify patterns, systemic weaknesses, or recurring causal mechanisms, limiting their contribution to prevention and continuous improvement (Saurin, 2016).

BPMN for process analysis and improvement

Despite their central role, H&S inspections have so far benefited only marginally from the broader digitalisation efforts underway in the AECO sector, where BIM, digital twins, and AI-based solutions are increasingly adopted to support design coordination, information management, and operational decision-making. Adequate digital support for routine practices, however, requires explicit formalisation of the underlying processes, so that activities, responsibilities, information flows, and decision points are transparent, comparable, and amenable to systematic assessment and continuous improvement (Häußler et al., 2021). This need is particularly acute for H&S inspection workflows, where inconsistent practices and fragmented documentation hinder accountability and limit learning across projects.

Process modelling approaches offer a structured means to capture such workflows and identify opportunities for standardisation and automation. Among these, BPMN provides a widely adopted, domain-agnostic standard for representing processes in a shared and interpretable form (OMG, 2013) and is increasingly supported by executable workflow engines that enable process enactment and monitoring (Geiger et al., 2018). In this sense, BPMN can act as a bridge between manual inspection practices and future digital solutions by supporting both the analysis of current workflows and the design of improved scenarios.

Several studies have applied BPMN to formalise construction inspection workflows, primarily for quality control and information exchange. Tsai and Hsieh (2016) use BPMN in combination with BIM to plan and rehearse inspection tasks in advance, structuring on-site activities and data capture. Similarly, Comai et al. (2022) adopt BPMN to model document- and data-intensive inspection and quality assessment processes, positioning process formalisation as a prerequisite for coherent digital information exchange and workflow execution. Complementarily, Shin and Cha (2023) highlight the lack of actionable process models as a barrier to the adoption of smart inspection technologies and propose a BIM-based quality inspection workflow supported by smart devices. However, these approaches largely focus on quality inspections and do not address routine H&S inspections in a way that clarifies how AI-based solutions can be integrated or how their outputs support H&S managers' decision-making.

AI/CV-based approaches in construction site H&S

In dynamic, visually complex construction site environments, images and videos provide a rich source of safety-relevant evidence that can be automatically analysed, making CV one of the most mature and widely investigated AI-based approaches in this domain (Fang et al., 2020; Guo et al., 2021). As a result, extensive research has focused on the use of CV to enhance situational awareness and automate parts of safety monitoring that are traditionally performed through first-hand visual assessment. Most CV applications address routine tasks such as worker and equipment detection, personal protective equipment (PPE) compliance checking, and recognising unsafe behaviours or hazardous interactions on site (Paneru and Jeelani, 2021; Seo et al., 2015). Recent advances in deep learning have significantly improved detection accuracy, enabling near real-time identification of safety-related conditions even in unstructured construction environments. Accordingly, CV is mainly applied for continuous or real-time safety monitoring via fixed cameras, mobile devices, or surveillance systems, focusing on detecting safety-relevant objects, conditions, and behaviours to improve awareness of on-site risks (Zhang et al., 2020). Although these approaches demonstrate the technical feasibility of CV for construction safety, they largely remain monitoring- and detection-centric, with limited use of CV outputs to support routine inspection workflows. As a result, CV is often deployed as an isolated solution rather than embedded in coherent, process-driven H&S practices, reinforcing the gap between advanced monitoring systems and established inspection routines. In response,

recent research has combined CV with Large Language Models (LLMs) to translate visual evidence more effectively into inspection-ready narratives and decision support. In this regard, Hussain et al. have reported promising results, combining image-based object detection with regulatory rule checking and then feeding the resulting classification and rationale to an LLM for narrative generation and dialogue (Hussain et al., 2026). However, in their approach, safety knowledge is hard-coded as general regulatory rules rather than retrieved from project-specific safety documentation, so inspection outputs are not grounded in the safety requirements defined during project design and planning.

Research Objective & Methodology

Building on the gap identified in the previous section, this study focuses on defining a structured and generalizable representation of routine H&S inspections. Rather than introducing new technologies, the paper aims to organise inspection activities, information flows, and decision logic into a coherent process that makes implicit practices explicit and operationally interpretable. This structured representation is intended to enable a systematic linkage between on-site observations, relevant safety requirements, and subsequent actions, thereby supporting more consistent inspection outcomes and facilitating the integration of digital support mechanisms. Importantly, the proposed approach is conceived as a foundation for the future development of CV-based inspection-support systems, providing a structured reference framework that can be operationalised through different technological implementations.

To achieve this goal, this study adopts a process-modelling methodology grounded in the BPMN standard (OMG, 2013) to make routine H&S inspection work explicit, comparable, and ready for digital support. The modelling effort is informed by a focused review of regulatory requirements, established best practices, and typical inspection deliverables (e.g., reports, issues, and corrective-action records), with primary reference to the Italian construction context while maintaining alignment with internationally recognised H&S management system principles and regulatory frameworks. The resulting workflow is further informed by direct observations conducted at residential and infrastructural construction sites within the broader research framework underpinning this study, providing empirical grounding for the proposed process structure. BPMN is selected not only for its ability to communicate roles, tasks, information exchanges, and decision points in a shared and interpretable form, but also for its suitability as a foundation for implementation. In particular, BPMN models can be operationalised through workflow engines (i.e., process orchestrators) to coordinate activities across heterogeneous tools and information repositories, supporting traceable and consistent execution in fragmented settings such as construction sites (Dumas et al., 2018; van der Aalst, 2013).

The paper proceeds in three steps, following the methodology adopted in the study. First, it models the end-to-end current construction site H&S inspection process, explicitly capturing the involved actors, core activities, exchanged information, and key decision points. Second, it zooms into a recurring inspection task—i.e., the systematic checking of site features of interest such as ongoing activities, workers and equipment, and layout elements—analysing it at a finer level of detail to highlight friction points, bottlenecks, and repetitive manual operations. Third, building on these insights, it proposes an enhanced process model in which CV-enabled capabilities are integrated at well-defined points to support the structured collection and interpretation of visual evidence alongside other H&S information, and to streamline reporting while preserving the H&S manager's central role and responsibility. Together, these three steps provide a process-oriented basis to guide the informed development and adoption of CV-enabled decision support for routine construction site H&S inspections.

Construction site H&S inspection process

This section presents the analysis and BPMN formalisation of a routine construction site H&S inspection process (Figure 1), modelled from the perspective of the H&S manager. The model focuses on the on-site phase of the inspection and considers the two main participants: the H&S manager, acting as the inspector and responsible for safety coordination, verification, and control during the construction phase, and the contractor, representing one or more contracting organisations operating on site. While the model covers only on-site inspection activities, these are situated within the broader construction site H&S management process, which, prior to the start of site operations, includes planning and verification steps involving both participants and the H&S manager's review of the contractor's documentation. To this end, the contractor is required to submit detailed, site-specific documentation, including Safety Operating Procedures (SOPs) for the activities to be performed, records of workers' general and task-specific training, and technical and administrative specifications for equipment and other planned resources. The construction site safety plan, developed by the H&S manager, defines the overarching site organisation and preventive measures. The contractor's documentation is assessed against this plan for compliance, complementarity, and formal validity—particularly with respect to regulatory requirements, safety procedures, and the validity of training and authorisations. Where gaps or inconsistencies are identified, revisions are requested from the contractor; otherwise authorisation to commence works is issued, concluding this preliminary phase.

Although heterogeneous and largely unstructured, the safety plan, together with the contractor's submission, is archived in a local or shared repository and provides the

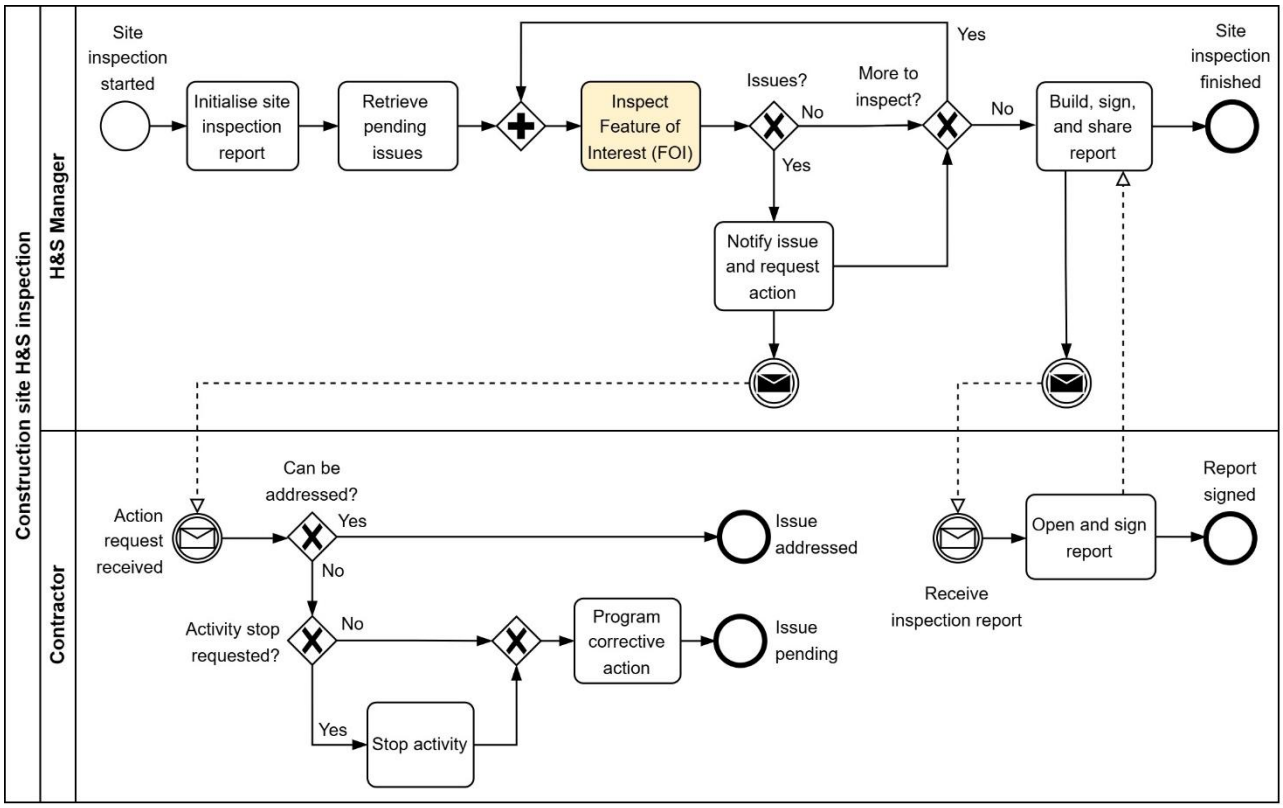

Figure 1: Routine construction site H&S inspection process model (BPMN).

basis for understanding site organisation and involved resources, and for defining the scope of safety inspection activities.

As shown in Figure 1, these are conducted by the H&S Manager as site walkthroughs and begin with creating a new inspection record, including entering site identification information and listing workers and resources (e.g., machinery) present on site. During this formal initialisation, the H&S manager also reviews previously recorded pending issues—especially missing or non-compliant documentation from earlier inspections—to assess corrective actions and identify items that require follow-up during the walkthrough.

Following these preliminary steps, the inspection proceeds to the practical on-site walkthrough, carried out zone by zone across the construction site in accordance with the zonal organisation specified in the construction site safety plan. For each zone, the H&S manager evaluates the compliance of the ongoing activities, relevant site layout elements (e.g., temporary works, access routes, protections, signage), and the workers and equipment present (see Figures 2–3).

These three categories constitute the H&S Features of Interest (FOIs) considered in the process model. For each encountered FOI, the H&S manager directly assesses the observed conditions against the prescribed safety requirements and documents the outcome as a recorded observation, indicating whether they are compliant (e.g., prescribed protections and signage in place), partially non-compliant (e.g., minor deviations from requirements), or critically non-compliant (e.g., severe violations requiring immediate attention). This evaluation and recording represent a core, non-delegable responsibility of the H&S manager, who subsequently manages identified issues by requesting corrective actions from the contractor. Where an observation indicates non-compliance, the process branches to involve the contractor. The contractor is notified of the identified issue and is requested by the H&S manager to implement a corrective action. If the correction is feasible and carried out immediately, the resolution is recorded in the inspection report; otherwise, the contractor programs its implementation, and the issue is registered as a pending item to be verified during subsequent inspections. In cases where the non-compliance is critical—i.e., it constitutes a serious breach of the prescribed safety requirements or poses an immediate risk to workers—the H&S Manager may issue a stop-work order for the affected activity or restrict access to the relevant area until the condition is resolved (e.g., missing mandatory training or authorisation, non-compliant equipment, absence of required permits/ documentation). Once all FOIs within a given area have been assessed, the process iterates to the next zone until the entire construction site has been inspected. The inspection report is drafted and signed by the H&S Manager, then shared with the contractor for acknowledgement and signature. Following this, the on-site inspection concludes. The final report is archived, serving as a formal record of the site's safety at the time and guiding future inspections.

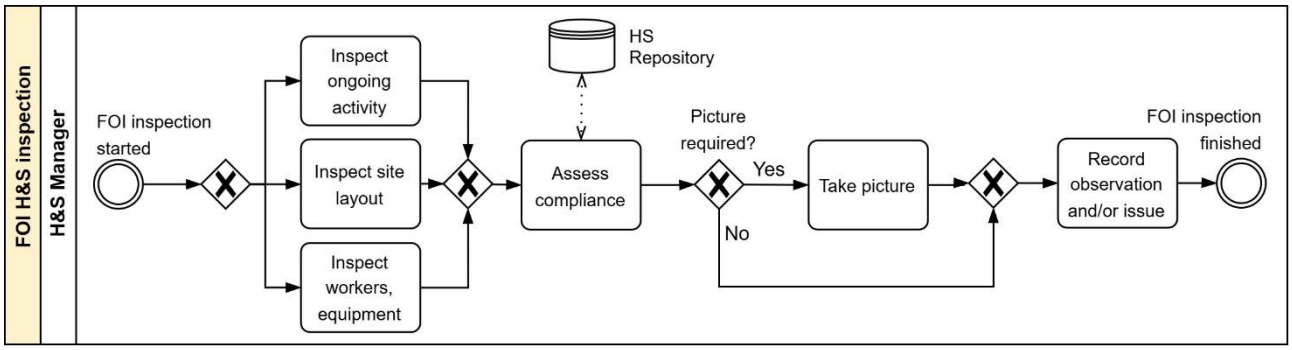

Figure 2: Routine H&S feature of interest inspection sub-process model (BPMN).

Inspection of H&S Features of Interest (FOIs) sub-process

While the overall process includes record initialisation and the management of non-compliances, the most recurrent and information-intensive part of the workflow is the repeated inspection of individual FOIs during the walkthrough. Accordingly, the "Inspect Feature of Interest" sub-process is further detailed and analysed (Figure 2) to clarify current practices and to identify points of friction and opportunities for improvement.

Upon reaching a designated construction site area, the H&S manager assesses compliance with the safety requirements prescribed in the relevant safety documentation by examining FOIs across three complementary categories.

First, ongoing activities are assessed, including the evaluation of operations currently underway in the area and the verification of the authorisations or permits required to perform the specific tasks. Second, the site layout is inspected, focusing on the presence and adequacy of collective protective measures and the implementation of the site organisation and arrangements prescribed in the construction site safety plan and further specified in the contractor's SOP documentation. Third, the workers and equipment present in the area are checked by verifying the validity and completeness of their associated documentation, including workers' general and task-specific training records and machinery inspection and maintenance documentation.

By integrating on-site observations with the relevant safety documentation, the H&S Manager assesses safety compliance for each FOI and, where appropriate, captures photographic evidence to be attached to the recorded observation in support of the inspection outcome. The outcome of the FOI assessment determines the subsequent process flow previously described (Figure 1).

Limitations of current construction site H&S inspection practices

The analysis of the current FOI inspection process highlights several limitations that constrain its efficiency, consistency, and potential for systematic improvement.

Most notably, inspection outcomes remain strongly dependent on the H&S manager's individual practices, expert knowledge, and field experience. While the main tasks and decision points can be identified at the process level, their execution is largely situational and weakly standardised, which reduces replicability and comparability across sites and over time. Supporting the H&S manager in handling this operational complexity motivates the exploration of AI-assisted solutions to structure evidence collection and facilitate timely interpretation and reporting. However, the current process has structural and data-related limitations that complicate this approach, as discussed below. At FOI level, inspections are usually conducted separately: features of interest are evaluated individually without connections to other FOIs or past inspection data, limiting the ability to identify recurring patterns or systemic issues that could guide preventive actions in future inspections or projects. This limitation is reinforced by current recording practices, as FOI assessments are frequently expressed as unstructured natural-language statements, hindering interoperability, structured querying, and integration with other site- and project-related information. Similarly, visual evidence is often collected opportunistically and stored separately, rather than being embedded in a structured workflow and consistently associated with the corresponding observations. Reporting practices represent an additional bottleneck. Inspection reports are typically drafted after the walkthrough through manual consolidation of field notes and documentation, a time-consuming step that can lead to information loss and delayed communication. Reports are commonly archived as PDF documents, which limits their reuse as data sources for analysis and continuous improvement. Finally, documentation management is often fragmented across multiple repositories and formats, further reducing the efficiency and coherence of inspection activities.
Overall, while the inspection process remains central to site safety management, it remains mostly unstructured and poorly suited to systematic data exploitation and AI-assisted support.

Enhanced inspection of H&S Features of Interest (FOIs) with a CV-enabled decision support system

To address these limitations, the enhanced process retains the same underlying inspection workflow while introducing the intervention of a CV-based decision-support system intended to support the user in activities that, in the traditional process, are typically performed manually, interpretatively, and with limited operational structure.

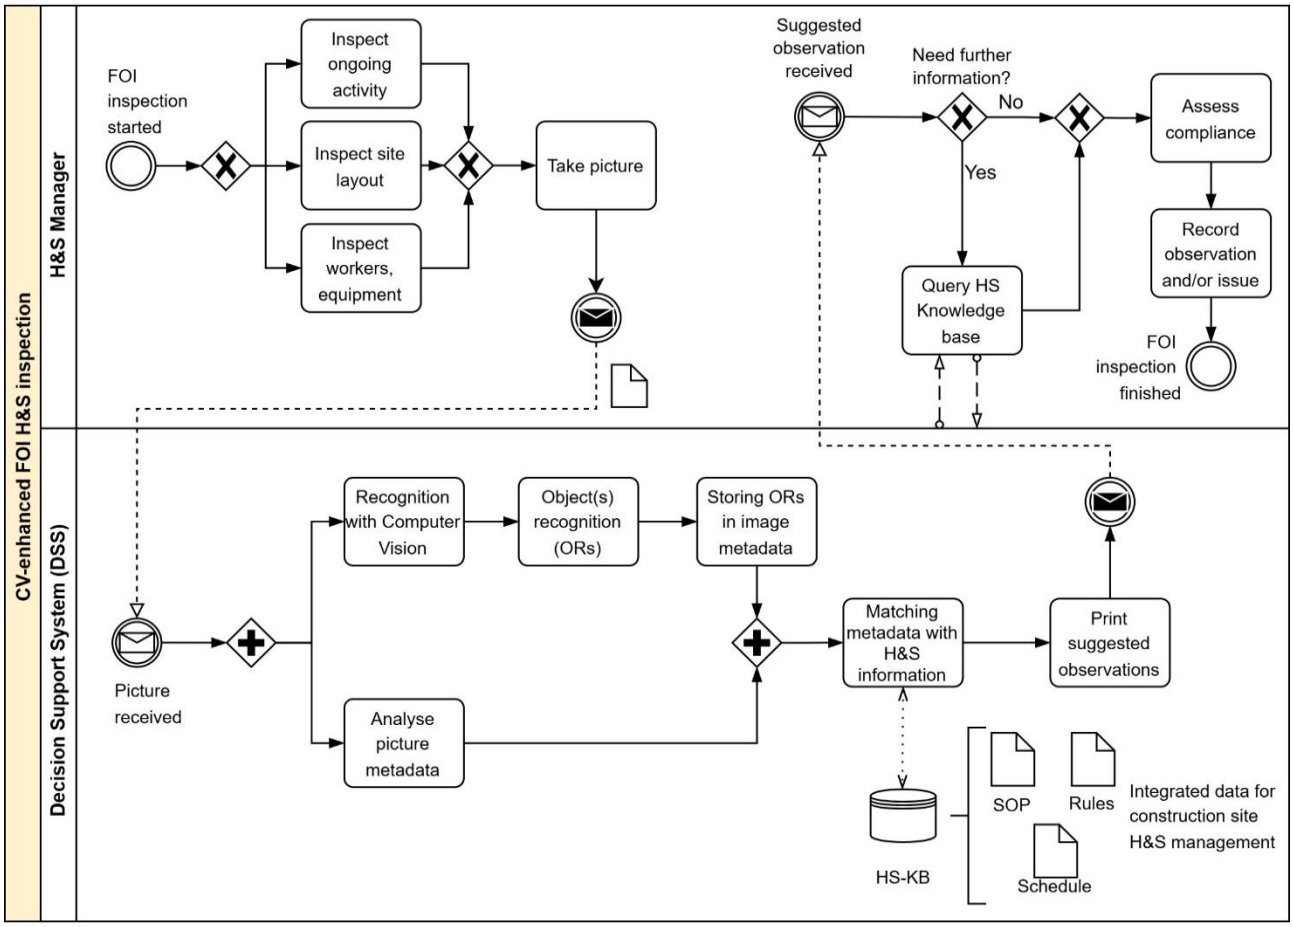

Figure 3: Sub-process model of H&S feature of interest inspection supported by a CV-based Decision Support System (BPMN).

In particular, it enables the real-time validation of on-site observations against project-specific safety requirements, establishing a more direct and actionable link between visual evidence and inspection criteria. Within this perspective, the enhanced workflow is conceived as part of a broader framework connecting inspections with safety planning and knowledge reuse.

As illustrated in Figure 3, the proposed approach intends to leverage existing safety design documents and contractors' safety documentation as primary knowledge sources for inspection planning and on-site control. Since these inputs are predominantly document-based and weakly machine-interpretable, they are first processed to transform H&S-relevant content into structured, queryable data suitable for integration within the proposed decision-support workflow.

The extracted information is stored in a Health and Safety Knowledge Base (HS-KB), integrating safety design requirements, contractors' documentation, inspection observations, and their associated corrective actions. On this basis, a CV-enabled Decision Support System (DSS) is instantiated on demand to cross-reference inspection evidence with applicable safety prescriptions and project-specific requirements. Operationally, the enhanced FOI inspection process embeds this decision-support layer into the routine walkthrough by enabling the H&S Manager to capture photographic evidence via a mobile device and upload it to the DSS. Here, the FOI image is analysed using CV techniques to recognise relevant elements (e.g., guardrails/edge protections), whose labels are stored as photographic metadata together with contextual information such as timestamp and location.

These enriched metadata are used to query the HS-KB and retrieve the corresponding safety prescriptions defined during the design phase, which are then matched with the contractor's SOPs. Based on this matching process, the DSS provides the H&S manager with pre-compiled, context-specific observation suggestions aligned with the applicable safety and project documentation, thereby supporting professional judgement without replacing it. In fact, after receiving the DSS's suggested observations, the final compliance assessment remains entirely under the responsibility of the H&S Manager. The H&S Manager may interrogate the HS-KB in real time to validate the information provided by the system or retrieve additional specifications. FOI-related observations and any encountered issues are then recorded, supporting subsequent communication with the contractor, the request, and the management of corrective actions, as previously shown in Figure 1. Ultimately, this approach enables the production of structured inspection-report data alongside the conventional unstructured document form, supporting not only the H&S Manager's day-to-day inspection activities while enabling systematic reuse of inspection outcomes. The resulting information is stored in the HS-KB, where it can be queried and aggregated

across inspections and construction sites to support cumulative learning and continuous improvement of H&S management practices.

Conclusions and future developments

Despite the growing availability of AI-based technologies, they have not yet been systematically introduced to support routine construction site H&S inspections, which remain weakly structured and largely manual. By adopting a process-modelling approach based on the BPMN 2.0 standard notation, this study formalised current inspection workflows from the H&S Manager's perspective, explicitly capturing roles, activities, decision points, and information flows. The resulting model also highlights key limitations of current practice, including non-standardised observation recording, the need to retrieve relevant H&S information from heterogeneous, fragmented documentation, and the limited reuse of inspection data. Building on this analysis, the paper proposes a structured foundation to guide the development and informed adoption of CV-enabled decision support for routine construction site H&S inspections, integrating a CV-enabled DSS at defined points to support the structured collection and interpretation of visual evidence. Rather than automating compliance assessment, the proposed approach embeds CV within a coherent inspection workflow that preserves the H&S Manager's non-delegable responsibility while improving the consistency and efficiency of inspection activities. From a Human–Data Interaction (HDI) perspective, the proposed approach improves the legibility of inspection processes by structuring the collection and processing of visual evidence within an explicit workflow, supports the H&S Manager's agency by augmenting rather than replacing compliance assessment, and enhances negotiability by allowing system outputs to be interpreted, assessed, and acted upon in light of project-specific requirements and site conditions. These aspects motivate further investigation in future developments.

The process-based approach proposed in this study provides a general foundation for integrating a CV-enabled DSS into routine construction site H&S inspections, but it still requires further specification toward a viable conceptual and technical system architecture, followed by implementation and evaluation.

First, CV algorithms must be further tested and benchmarked in the context of construction site inspections to identify the most suitable approaches.

Future work will examine deep learning models against few-shot and zero-shot approaches, accounting for variability in construction environments, site elements, and routine walkthroughs. Developments will also include structured management of visual evidence and metadata in a HS-KB, such as extracting, storing, and persisting CV outputs and photographic metadata in a machine-interpretable form for integration with other project domains. In this perspective, the system is expected to process visual data potentially including workers present on site, thereby raising issues of data governance, privacy, and responsible data use that future developments will need to address explicitly.

Linking inspection data with safety design documentation, construction planning information, and broader project management data is expected to improve interoperability, support cross-domain reasoning, and promote reuse of inspection knowledge across projects. In this regard, significant challenges remain. A key open issue is defining data structures that align with existing construction and safety documentation practices while interfacing effectively with regulatory requirements.

Addressing these challenges will be essential to ensure that CV-enabled inspection support can be adopted in practice, remain interoperable, and remain aligned with regulatory frameworks and professional responsibilities in construction H&S management.

A DECOUPLED ARCHITECTURE FOR DIGITALLY ACTIONABLE AND TRACEABLE REGULATORY WORKFLOWS IN THE AEC SECTOR

Hans Kristjan Aljas, Ergo Pikas, and Martin Thalfeldt
Tallinn University of Technology, Tallinn, Estonia

Abstract

The Architecture, Engineering, and Construction (AEC) sector faces complex regulatory frameworks like building energy performance certification under the European Energy Performance of Buildings Directive (EPBD). Traditional approaches suffer from fragmented documentation, procedural ambiguities, and poor traceability and auditability, causing outcome inconsistencies and automation challenges. This paper proposes a decoupled conceptual architecture for digitally actionable and traceable regulatory workflows, leveraging compliance modelling, semantic web technologies, and linked data. By separating semantic representation, reasoning, execution, and interaction layers, it improves compliance, interoperability, and adaptability. Demonstrated on Estonian Energy Performance Certificates (EPCs), it addresses key gaps and supports broader application beyond energy efficiency.

Introduction

Regulatory workflows in the AEC sector are characterised by high complexity. They simultaneously involve physical building elements and procedures, formal norms (directives, standards, laws), institutional and professional practices (national methodologies, auditing bodies, firms), and heuristic expert judgment (soft law, socio-cognitive interpretation).

A representative example is the Energy Performance of Buildings Directive (EPBD) and its national transpositions (European Parliament, 2024). Despite a common European framework, these produce poorly comparable Energy Performance Certificates (EPCs) (Jenkins et al., 2024; Sayfikar and Jenkins, 2025) riddled with methodological non-compliance and inconsistencies (Aljas et al., 2025; Carvalho et al., 2024; Schaffer et al., 2026), and create maintenance burdens for public authorities responsible for custom software pipelines (buildingSMART International, 2023). These phenomena reveal a fundamental tension between:

(1) the hybrid socio-technical nature of regulatory norms and
(2) the current paradigms used to digitise and automate them.

Importantly, this tension cannot be resolved through comprehensive standardisation or exhaustive semantic formalisation alone. Regulatory methodologies are shaped by institutional, geographical, and methodological heterogeneity, alongside practical and organisational constraints that limit the feasibility of total harmonisation (Jenkins et al., 2024; Sayfikar and Jenkins, 2025). As a result, regulatory workflows must remain operable under conditions of partial standardisation, evolving methodologies, and uneven digital maturity.

Existing approaches treat regulations either as static rules to be checked post-hoc aka “Compliance by Detection” or as logic to be programmed into custom software aka “Compliance by Design” (Casanovas, 2017). Both paradigms inevitably produce tightly coupled, brittle systems that struggle to evolve harmoniously with the norm, the context, or the technology. Furthermore, (Feng and Wang, 2025) note that overlapping stakeholder pressures in complex construction workflows expose the limitations of post-hoc compliance mechanisms.

This work advances Compliance through Design (CtD) — the governance-oriented, interpretive paradigm introduced by (Casanovas, 2017)—by providing a systematic operational framework for digitally actionable and traceable regulatory workflows.

The core artefact is a decoupled conceptual architecture with four layers (Semantic Workflow Model, Reasoning and State Engine, Execution and Orchestration Layer, Interaction Layer). The artefact functions as a knowledge-modelling framework that treats regulatory workflows as evolvable, linked-democratic ecosystems rather than monolithic code bases or conventional data pipelines. In practice, such an approach aims to reduce data and logic fragmentation, allowing stakeholders to focus on their core responsibilities or interests by minimising routine administrative tasks and extraneous cognitive load, and thereby reducing the potential for errors.

Taxonomy of compliance

In regulatory contexts, compliance encompasses adherence to laws and standards while extending to ethical and societal norms (Governatori, 2018; Hashmi et al., 2018). Compliance paradigms form a progression of increasing proactivity, addressing the limitations of reactive methods in complex environments.

Compliance by Detection operates reactively, identifying non-conformity during or after execution, which often necessitates costly redesign. Conversely, Compliance by Design shifts to prevention, incorporating rules into the design stage to ensure conformity in advance (Casanovas, 2017; Governatori, 2018). Legal Compliance by Design further refines this by addressing value-based requirements and the legality of the entire process rather than simple formal rules (Hashmi et al., 2018).

Compliance through Design (CtD) constitutes the most holistic evolution; it moves beyond rule-embedding to encompass the systemic interoperability required to model affordances—the action possibilities enabled by a system—alongside broader socio-legal conditions (Poblet et al., 2019). The paradigm acknowledges that compliance is not merely a technical constraint but a social process involving legal interpretation, institutional coordination, and the relationships between regulated entities, citizens, and the law (Casanovas, 2017; Hashmi et al., 2018). From this viewpoint, regulatory requirements operate within an ecosystem of practices and responsibilities, rather than being fully reducible to technical checks.

The shift toward greater proactivity is technically enabled by declarative paradigms. Unlike imperative approaches that specify rigid, step-by-step procedures, declarative modelling focuses on what must occur by defining relationships, preconditions, and effects (Governatori, 2018). This allows regulatory requirements to be expressed without prematurely committing to a fixed resolution strategy or technical details.

Linked Data ecosystems complement this approach by supporting norm sharing and knowledge aggregation across institutional boundaries, enabling compliance mechanisms to remain interpretable, adaptable, and aligned with broader governance structures (Poblet et al., 2019).

Structural mismatches in regulatory automation

Despite increasing digitalisation, regulatory workflows in the AEC sector remain difficult to automate in a traceable and sustainable manner. This is not primarily a data availability problem but a structural mismatch between regulatory intent, information representation, and technical execution.

Regulatory intent is expressed through natural-language instruments designed to establish legal authority and support professional interpretation. In technical domains, this intent is commonly conveyed through condensed, presentation-oriented formats—such as tables, annexes, and figures—that facilitate communication while remaining aligned with legal drafting practices. Empirical evidence highlights the limits of treating these representations as directly formalisable: (Hettiarachchi et al., 2025) show that, from an initial set of 20 674 sentences in English and Finnish building regulations, only 6% could be annotated as self-contained rules suitable for machine-readable formalisation. This observation is consistent with legal informatics research, which distinguishes between sources of authority and documentary resources, noting that regulatory meaning is not fully embedded in such artefacts and must be reconstructed through interpretive knowledge-acquisition processes (Casanovas, 2017).

Empirical analysis of design-stage EPCs in Estonia shows how this complex interpretation process propagates into methodological inconsistencies and mismatches between declared design solutions, assumed input parameters, and practical outcomes (Aljas et al., 2025).

EPBD provides an example of how fixed technical thresholds are combined with heuristic judgement, spanning multiple knowledge domains:

"Where technically and economically feasible, non-residential buildings with an effective rated output for heating systems, air-conditioning systems, systems for combined space heating and ventilation, or systems for combined air conditioning and ventilation of over 290 kW, must be equipped with building automation and control systems." - (European Parliament, 2024).

This hybrid formulation leaves essential aspects of compliance underspecified, including actor responsibilities, data sources, and the sequencing of decisions and practical actions.

Current digital tools primarily focus on operationalising these static methodologies by automating calculations, enforcing parameter constraints, and guiding data entry and reporting. While this improves usability and administrative efficiency, it also embeds a single, implicit interpretation of the regulation within individual software systems, resulting in tightly coupled implementations with limited transparency, adaptability, and traceability (buildingSMART International, 2023; Sayfikar and Jenkins, 2025).

Semantic approaches, including Linked Building Data, Building Information Graphs, regulatory-focused initiatives such as Regulatory Information Requirements, and building permitting-oriented ontologies such as OBPA or AEC3PO, contribute valuable partial formalisations of regulatory-relevant data, structures, and artefacts (buildingSMART International, 2023; Dridi et al., 2024; Hagedorn et al., 2025; Lygerakis et al., 2022; Wang and Sacks, 2025). However, these approaches do not explicitly model the procedural aspect that translates regulatory intent into executable workflows. As a result, compliance logic is either applied post-hoc through validators (Compliance by Detection) or embedded imperatively into software (rigid Legal Compliance by Design), which are commonly implemented across fragmented or siloed toolchains, with associated maintenance and coordination costs reported in the literature (buildingSMART International, 2023; Governatori, 2018).

At the workflow level, these fragmented implementations produce overlapping responsibilities and disconnected steps, imposing manual coordination and repeated data entry on users, while obliging software developers to replicate procedural logic and manage fragile integrations across tools. Such challenges persist even where extensive standardisation or semantic modelling is applied, reflecting well-documented institutional, societal, and

technological heterogeneity in regulatory practice (Carvalho et al., 2024; Jenkins et al., 2024).

Taken together, these observations reveal a procedural blind spot: the absence of an explicit, declarative representation of how regulatory intent is translated into executable workflows. Addressing this gap requires an architectural separation that preserves interpretive logic, supports traceability across abstraction levels, and enables adaptable automation.

The decoupled, goal-driven architecture

To address the procedural blind spot identified in regulatory automation, this work proposes a decoupled conceptual architecture that restructures regulatory workflows around explicit procedural representation. The architecture separates regulatory intent, logical reasoning, technical execution, and agentic interaction into distinct but linked layers, as shown in Figure 1.

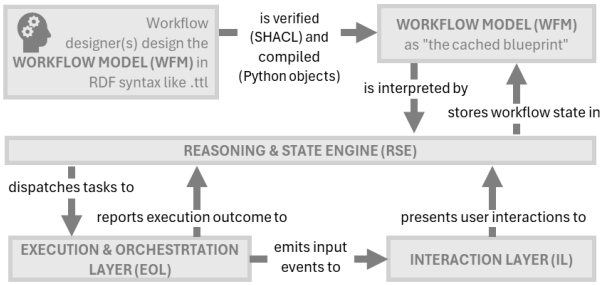

Figure 1: The 4-layer decoupled architecture

The workflow model: a design-time semantic blueprint

At the core of the architecture is a semantic Workflow Model (WFM) that serves as a design-time blueprint defining how regulatory completion can be achieved. The model is goal-driven: it defines the space of possible pathways through which explicit completion goals can be satisfied. Rather than prescribing a fixed execution sequence, the model specifies the set of steps, logic, and information dependencies that lead to these goals.

These elements are modelled as Resource Descriptive Framework (RDF) objects in a knowledge graph, making execution-relevant structure and meaning explicit through the use of two fundamental abstractions – Activities and Entities (*core layer* in Figure 2). Entities represent planned data items, which Activities can declare as inputs or outputs, forming a directed dependency structure that guides the execution, as exemplified in Figure 3. We modeled this core using a domain-independent semantic layer based primarily on the P-PLAN ontology.

The core model is complemented by our custom lightweight control vocabulary (*control layer* in Figure 2), which allows completion criteria and other regulatory logic to be explicitly represented within the Workflow Model as first-class, i.e., regulatory constraints and decision points are subclasses of as Activities and Entities.

Where beneficial, the core model can be extended with domain-specific knowledge graphs, such as Linked Building Data (LBD) vocabularies or local regulatory reference data. The semantic depth and operational specificity (as noted in Figure 2) of the WFM is thus configurable: different deployments can provide only the level of detail that execution handlers and users can interpret. Increased semantic depth enables tighter alignment between domain data and regulatory logic, allowing constraints and dependencies to be expressed explicitly where needed, but without requiring uniform detail across all deployments.

Scope of activities and hybrid control

The notion of an Activity is intentionally broad, reflecting the hybrid socio-technical nature of regulatory workflows. Operationally, Activities may be fully digital—such as automated data acquisition from APIs, parameterised calculations, consistency checks (e.g. BIM/LBD-aligned post-hoc conformity checks), logic resolution—or physical–digital, where a physical activity or professional judgment is acknowledged and documented through the system. Examples include confirmation of an on-site inspection, upload of supporting documents, or an explicit declaration that a regulatory requirement has been satisfied or acknowledged. Activities also distinguish between steps that can be executed automatically and those that require agentic input, while modeled uniformly within the same dependency structure.

Decoupled architectural layers

The architecture operationalises the WFM through four coordinated layers, following annotations in Figure 1.

The workflow model (WFM), as discussed, provides the design-time blueprint by encoding Activities, Entities, including goals and control points as a declarative semantic knowledge graph. At runtime startup, these semantic definitions are loaded, enriched with lightweight reasoning, and validated against design-time constraints (via Shapes Constraint Language aka SHACL) to ensure model conformity; they are then compiled into cached blueprint structures in two steps (the following terminology is aligned with Figure 2): first, the foundational workflow meta-model is superimposed on the project-layer blueprint instances to generate an in-memory workflow graph—i.e., cached Activity/Entity records with a compiled dependency map. Second, the *design & specialisation vocabulary* is retained as lightweight annotations (semantic types and dispatch configuration) that enable generic routing to execution and interaction handlers. However, *domain vocabulary* and *executable bindings* from the *project layer* are not required for the generic reasoning and orchestration mechanisms, but can be leveraged to implement custom functionalities (e.g., domain-specific functions, queries, or service adapters). In this way, the WFM functions as the authoritative specification of the workflow's structure and meaning, while remaining decoupled from the concrete mechanisms that execute steps, solicit inputs, and perform external tasks.

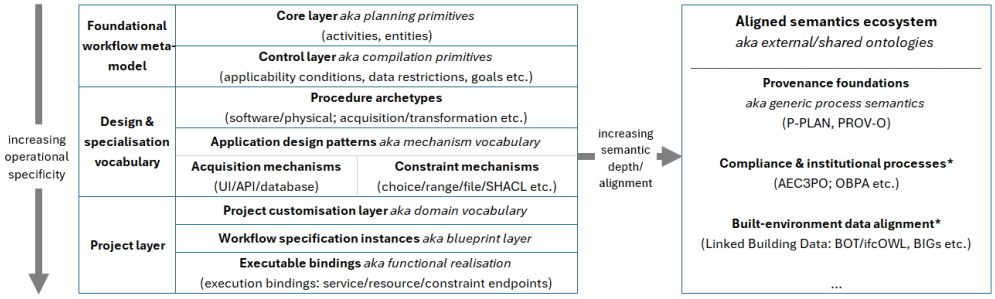

Figure 2: The Workflow model's semantic decomposition. (*) marks frameworks not implemented in the current instantiation.

The reasoning & state engine (RSE) represents the stateful operational structure of a workflow run. It operates over a directed dependency model whose first-class elements are Activities and Entities of the WFM. During execution, the RSE may further extend this structure by materialising latent semantic conditions—such as unresolved alternative production paths or exceptional situations—into explicit control-point Activities (e.g. *:MultipleProducerChoice* on Figure 3) whose outcomes gate subsequent progression. Therefore, all state transitions are exposed as structured events and can be synchronised to provenance records, enabling traceable reconstruction of how outcomes were produced and which decisions governed the execution path.

The execution & orchestration layer (EOL) carries out the Activities that the RSE has determined to be ready for execution. It receives an Activity together with its corresponding semantic type(s) and configuration, routes it to an appropriate execution mechanism via pluggable handlers, and either executes the Activity and commits its outcomes back into the runtime state, or emits an explicit interaction request and transitions the Activity into a waiting state until the Interaction Layer fulfills it. By standardising execution behind handler contracts, the EOL provides a stable execution interface that accommodates both internal functions and external services, while preserving decoupling between workflow semantics and execution mechanisms.

The interaction layer (IL) functions as the unified presentation boundary for the system. It consumes execution-state and interaction events forwarded by the EOL, and renders them through interaction primitives—such as data entry requests, explicit pathway choices, and progress events—so the interface adapts to different workflow configurations. For human experts, the IL can procedurally generate appropriate UI elements like fields, dropdowns, choice dialogs and file uploads. Alternatively, for machine agents, these primitives can be exposed through structured interfaces for programmatic consumption (e.g., an API or an MCP-style server), enabling artificial agents to consume required input/choice requests and submit decisions against the same underlying workflow logic.

Instantiation of the architecture: Estonian EPC workflow

This section presents a proof-of-concept instantiation of the proposed architecture using the Estonian Energy Performance Certificate (EPC) methodology for new buildings, grounded in the EPBD framework and ISO 52000-series standards (Minister of Economic Affairs and Infrastructure of Estonia, 2023; Dijk and Hogeling, 2019). The methodology requires prediction of primary energy use based on typical building energy modelling components such as envelope characteristics, HVAC systems, ventilation rates, infiltration rate, component efficiencies, lighting, renewable energy contributions etc. It allows using defaults from national tables or documented values from design/measurements, with professional validation or additional proof required where substitutions occur.

The implementation focuses on modelling local regulatory *domain vocabulary*, procedural dependencies, and decision logic, rather than on full numerical coverage or exhaustive system integrations. In particular, the current scope emphasises conditioning of calculations, alternative compliance pathways, and explicit control points that govern how EPC calculations may be completed at building design stage.

While the implementation covers all four layers of the architecture, the WFM's *operational specificity* (vertical arrow on Figure 2) is currently limited to non-functional placeholders for integrable data sources (e.g. *:GetBimModelFromBuildingRegistry* on Figure 3) such as the Estonian National Building Registry (later potentially via the E-ehituse OpenAPI services), or for Semantic BIM pipelines (Land and Spatial Development Board of Estonia, 2026; Pauwels and Terkaj, 2016; Wang and Sacks, 2025), with parallel options to explicitly re-declare such data entities (e.g. *:UploadBimModel*). The result is a dynamically conditioned, form-like execution environment composed of dropdowns, numerical inputs, checkboxes, acknowledgements, and calculation steps.

At runtime, available fields, selectable options, and required acknowledgements are progressively introduced or constrained as upstream Entities become resolved. Early building-level declarations—such as building category, size class, and primary construction type—function as conditioning inputs that determine which regulatory requirements apply, which calculation methods are admissible, and which exceptions or simplifications may be used. For example, small buildings may qualify for simplified calculation procedures, certain building categories apply adjusted EPC thresholds (e.g. multiplicative factors for specific construction types), and building type selections govern lookup strategies for default parameters such as ventilation rates.

This conditioning is reflected directly in the user interface. Selections made at higher levels constrain which subsequent inputs are exposed and which options are selectable, ensuring that only methodologically admissible choices are presented. Data restrictions—such as expected data type, allowed value lists, or numeric ranges—are materialised in the front-end as input field configurations (e.g. dropdown enumerations, bounded numerical fields, or categorical selectors).

At points where the Estonian methodology permits alternative means of satisfying a requirement, the workflow introduces explicit procedural choices (*:MultipleProducerChoice*) that resolve how an Entity is grounded. A common pattern is the substitution between normative defaults and documented values. Selecting a default immediately resolves the Entity using standard tables (*:LookupInfiltrationCoeff*), while inputting a custom value (*:InputInfiltrationCoeff)* may introduce additional dependent steps, such as acknowledgements or the provision of supporting material (*:InfiltrationTest-Report*). The method by which the value was obtained is preserved in Entity state and provenance records, allowing downstream logic to access previous compliance-relevant decisions.

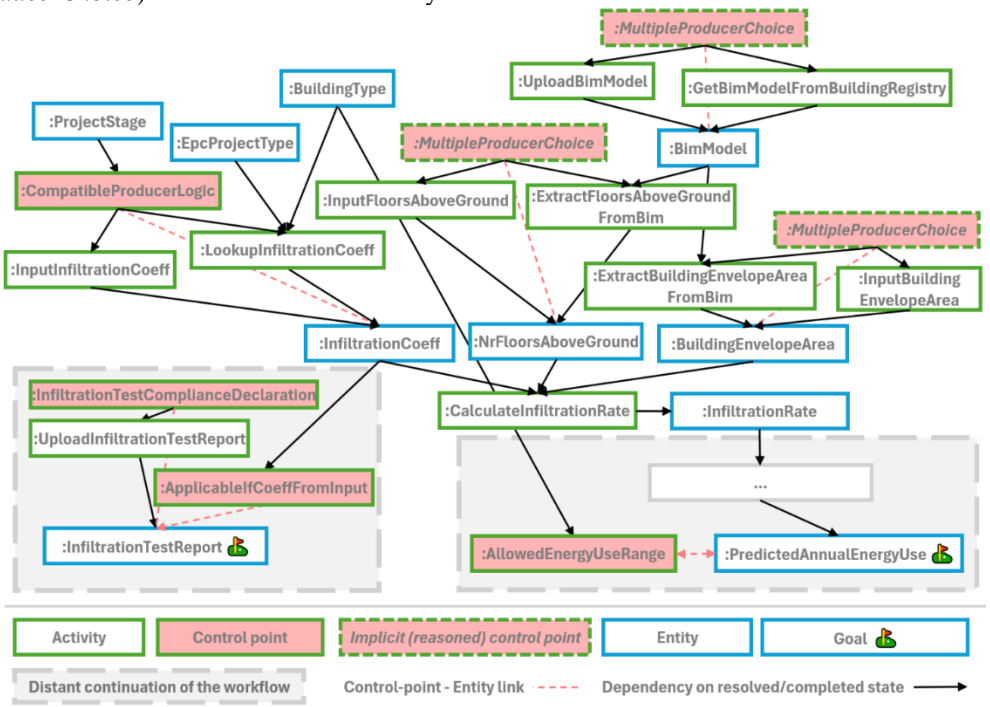

Figure 3: Simplified excerpt of the Estonian EPC Workflow Model showing main structural elements and their relations.

Not all regulatory requirements are digitally verifiable within the current scope. Where compliance depends on professional judgement, certification, or conformance to external standards that cannot be computationally assessed, explicit acknowledgement events are modelled in the Workflow Model and instantiated by the RSE as first-class Activities (*:InfiltrationTestComplianceDecla-ration)*. Although their outcomes are not derived numerically, they are committed to the runtime state and exposed through the Interaction Layer as explicit confirmations, preventing implicit assumptions and preserving traceability of regulatory decisions.

The implementation further addresses regulatory logic that applies across multiple instances of similar elements, such as technical systems or energy carriers. Their compatibility and co-dependence rules are expressed as aggregate conditions over sets of Entity instances in the Workflow Model. This constrains available options consistently across the workflow, preventing incompatible configurations at the point of selection. If upstream conditions change, previously valid choices are invalidated and surfaced through the Interaction Layer with clear visual feedback.

As the graphical interface is not the only possible data entry surface, the same restrictions are also enforced through implicit validation Activities attached directly to data Entities. Values are checked against their declared constraints regardless of how they are introduced, allowing inconsistencies to be detected even when upstream changes invalidate previously accepted inputs. This dual use of semantically declared data rules establishes a single source of truth, while supporting both immediate user-facing guidance and backend consistency validation at different stages of execution.

Where calculations are delegated to external procedures, such as *:CalculateInfiltrationRate*, these are represented as pluggable Activities bound to execution handlers in the EOL. Each such Activity consumes shared input Entities—such as building type (*:BuildingType*) or HVAC parameters—and produces a single declared output Entity, preserving the one-activity–one-output constraint of the Workflow Model. This keeps the dependency graph explicit for the RSE, while allowing external implementations to be introduced or replaced without affecting surrounding procedural logic or interaction behaviour. Figure 4 shows illustrative sections

from the Estonian EPC workflow expert system's UI in its present form (in development).

Discussion

This work frames regulatory automation as a problem of procedural articulation rather than document processing or isolated rule extraction. From this view, the central challenge is not digitising regulatory content, but coordinating intent, interpretation, and execution as workflows evolve, branch, and interact with external actors and systems. The proposed framework tackles this coordination structurally, though it cannot resolve every tension in regulatory and AEC digitalisation.

A recurring challenge is deciding how much formal structure is practical and desirable. Many regulatory steps involve physical actions, professional judgement, or context that resist full specification. The framework deliberately leaves such elements underspecified, treating them as obligations to acknowledge rather than compute, which prompts the question: how much structure supports traceability and coordination without over-constraining practice? Thus, workflow design remains an agent-guided task, with models reflecting institutional choices on where precision matters and where judgement should stay flexible.

Questions of maintenance and evolution follow naturally. Regulations change, interpretations shift, and data infrastructures mature unevenly. The Workflow Model does not erase these realities; it offers a stable reference point for managing them. Changes still demand agentic oversight and governance, but their effects become more localised and visible—underscoring that long-term viability depends as much on organisational processes and knowledge transfer as on technical design.

The framework delivers greatest value in workflows with strong interdependencies, sophisticated logic, and interaction with semantic or non-tabular data—the complex, evolving processes typical of energy performance certification or building permitting. In contrast, for workflows dominated by independent steps with minimal downstream impact—such as uploading parallel documents, running a fixed linear data pipeline, or handling predominantly physical sequences with little digital conditioning—the semantic modelling effort may yield limited incremental gains. Yet truly dependency-free cases are uncommon in regulated domains, where even seemingly separate or physical actions often carry traceability requirements, conditional applicability, or audit consequences that justify structured coordination.

The framework also highlights the limits of specialised, handcrafted solutions. Richard Sutton's "bitter lesson" from 70 years of AI research offers a useful lens: systems built around general, scalable structures or „meta-methods" ultimately outperform finely tuned domain heuristics, as the „contents of minds are tremendously, irredeemably complex" (Sutton, 2019). In regulatory automation, this suggests that durable progress more likely comes from simple, composable procedural primitives rather than from bespoke software. Early results with our framework—effective despite modest semantic depth—reinforce this view and motivate continued emphasis on foundational abstractions over narrowly optimised implementations.

The design remains intentionally open-ended, prescribing no single execution environment, interaction style, or data standard. This flexibility accommodates diverse implementations but raises challenges in interoperability, semantic alignment, and trust. Our semantic modelling (built on P-PLAN, PROV-O, a custom control vocabulary, and preliminary design & specialisation elements, as outlined in Figure 2) is still evolving; more sophisticated ontology alignment and refinement will appear in forthcoming work. Establishing and functionalising shared conventions through ontologies and data dictionaries remains an active area of research (buildingSMART International, 2023; Hjelseth et al., 2025; Utkucu and Sacks, 2025; Wang and Sacks, 2025). While the architecture supports incremental semantic enrichment, determining when and how to invest in deeper alignment is as much a policy decision as a technical one.

We see many directions demanding further exploration: real-world testing of long-running workflows to refine error handling and richer user-facing elements; semantic integration of permitting/compliance ontologies, including overlap resolution and cross-system

governance; and direct RDF graph interaction (designing/querying workflows) via natural-language and augmented retrieval tools (e.g., GraphRAG) to reduce technical overhead for non-experts. Future work is also expected to provide insights into the dilemma of deeper semantic standardisation vs reliance on self-contained tools or services, and explore semantic modelling strategies beyond the core layer that can most optimally cater for practical needs across the 4-layer architecture.

Ultimately, the framework is best viewed as scaffolding for ongoing exploration rather than a packaged product. By making procedural structure explicit, shareable, and inspectable while preserving institutional flexibility and technological diversity, it addresses—rather than ignores—the fragmented, dynamic, digital-physical realities of regulatory contexts. In such environments, this openness is likely essential for automation that proves meaningful and sustainable.

Conclusion

This paper addressed a persistent gap in the digitalisation of regulatory workflows: the absence of a stable structure for coordinating intent, interpretation, and execution across diverse actors, tools, and lifecycle stages. In fields like AEC, where compliance involves conditional procedures, partial automation, and professional judgement, existing approaches often fragment regulatory logic across documents, custom software, and informal practices—undermining traceability, adaptability, and sustainability.

To tackle this, the work introduced a declarative workflow model that reframes compliance as a procedural knowledge problem rather than a document- or rule-processing task. By encoding activities, entities, dependencies, and control points as semantic structures, the model defines what must be achieved and under what conditions—without dictating how steps are executed. This explicit, inspectable representation preserves regulatory meaning while keeping execution, interaction, and domain implementations flexible.

The four-layer architecture operationalises this model by decoupling semantic specification, state reasoning, execution orchestration, and interaction. The separation is practical: regulatory interpretation can evolve independently of software, execution mechanisms can change without rewriting semantics, and agentic judgement can be acknowledged as a first-class element rather than hidden or flattened into technical artefacts. The framework does not demand full formalisation—ambiguity, physical actions, and discretion are treated as legitimate procedural features, not automation failures.

Taken together, the contribution is not a finished system but a conceptual backbone for curating complex compliance processes. It enables incremental semantic enrichment, cross-domain coordination, and clearer accountability while remaining open to institutional practices and technological evolution. By prioritising simple, composable procedural abstractions over bespoke solutions, the work aligns with a broader shift toward scalable, general-purpose digital structures—offering a foundation for future research at the intersection of regulation, semantic technologies, and human–AI collaboration, where meaningful progress depends on making interpretation explicit, governable, and traceable rather than treating it as isolated engineering problems.

Acknowledgements

The authors acknowledge the use of large language models—including Grok 4.1 (Fast, Expert, Thinking modes), ChatGPT 5.1 & 5.2, and Google Gemini 3 (Pro & Flash)—used independently, and also within the Cursor software environment. These tools assisted in synthesising and communicating authors' original ideas and notes, referenced literature, codebase, and drafts.

All ideas, arguments, and conclusions remain the original work of the named authors. The text underwent rigorous manual review and iterative rewriting to ensure precise alignment with the authors' intent, cited sources, and scholarly standards, leaving no sloppy logic, over-interpretations or hallucinations. The models served only as aids for expression and refinement; full responsibility for content rests with the authors.

OPERATIONALISING HEALTH AND SAFETY REGULATIONS THROUGH DESIGN SCIENCE RESEARCH

Nicholas Nisbet and Zijing Zhang
University College London, London, UK,

Abstract

Investigations into compliance checking have paid little attention to how process-oriented regulations can be made accessible and operable. This paper explores ways that these expectations can be met. The study considers the macro level requirements enforced by a government agency, as exemplified by the UK Construction (Design and Management) Regulations (CDM 2015) which assigns responsibilities and duties clients, designers, and contractors, many of whom lack confidence in fulfilling these obligations or in evidencing their discharge. The findings highlight an opportunity for guidance that is firmly grounded in regulatory requirements yet tailored to the distinct roles of industry participants.

Introduction

Compliance checking has usually been associated with the systematic comparison of regulations against a building proposal, typically structured building models (BIM) (Eastman et al., 2009; Nawari, 2012). Previous work has shown how the semantic mark-up of Requirements, Applicability, Selection and Exceptions (RASE) can support compliance checking, whether applied to design models (BIM) (Nisbet et al., 2023) or to site monitoring information (Nisbet et al., 2024). However, regulatory obligations that prescribe required behaviours, rather than physical or spatial performance, are qualitatively different. While the built-environment literature has devoted substantial attention to product-based regulation, far less attention has been paid to the regulation of processes, even though process-based duties are often invoked when product information is incomplete or unavailable. Health and safety regulation exemplifies this challenge: although trailing indicators such as incidents and near-misses are well understood, there are few leading indicators that can be assessed in advance (Zhang et al., 2024a). This paper therefore examines a situation in which evidence of compliance is unlikely to exist in either structured or unstructured form, and where the discharge of continuing obligations depends on duty holders who are often uncertain about what those obligations entail.

Highlighting the logical semantics of a regulation (its hierarchy of objectives, associated duties and specific metrics) offers a way to investigate the structures and behavioural patterns implied by the text (Nisbet et al., 2023). By systematically seeking hypernyms for the objects and properties named in the regulation, patterns of expected behaviour emerge, illuminating the intent and making the structures in the regulation explicit. These insights extend beyond checklists or decision trees and point toward the possibility of generating interactive teaching and learning materials that help embed compliant behaviour. In the current example, the outcome of the systematic analysis can be compared to the informal 'manage, maintain and improve, document' model used by UK Health and Safety Exective (HSE) HSE Inspectors.

Context and literature review

Regulatory context and application of CDM 2015

The Construction (Design and Management) Regulations 2015 (CDM 2015) represent the third iteration of the UK's CDM regulations (HSE, 2015a), introduced to align with the EU Directive on Temporary or Mobile Construction Sites (EU, 1992). Although construction fatalities have decreased since the first CDM regulations were introduced, the construction sector continues to experience the highest number of work-related deaths (HSE, 2025). These persistent health and safety (H&S) challenges prompted the revisions of the CDM regulations in 2007 and 2015, aiming to address shortcomings in coordination, clarity of duties, with the intention of improving H&S outcomes.

CDM 2015 places strong emphasis on accountability. The regulations are structured around five key duty holders: client, principal designer (PD), principal contractor (PC), designer and contractor. A key idea of the 2015 revision was to highlight the influence of design decisions on construction H&S, placing greater responsibility on designers and PDs to identify and manage risks early in the project lifecycle. This reflects a broader shift toward improving H&S performance through more effective design risk management, also referred to as Construction Hazards prevention through design (CHPtD) (Toole & Gambatese, 2008). However, despite this improved clarity of responsibility, the CDM 2015 regulations remain process focused and outcome oriented, offering limited detail on the specific procedures required to achieve compliance (Zhang et al., 2024a). As a result, practitioners often struggle to interpret what compliance looks like in practice, particularly during the design stage.

To address these gaps, significant effort has been made to interpret and operationalise CDM 2015. The HSE's official guidance (L153) provides definitions, clarifications and examples of what constitutes compliance, including expectations for key documents such as the health and safety file and the construction phase plan (HSE, 2015b). The HSE has also been delivering the "Discovering Safety" programme, which includes a range of projects focused on improving health and safety in construction. This has involved several 'SafetyTech' regulatory sandbox initiatives that bring in industry start-ups to trial innovative solutions and develop case studies supporting CDM compliance and enhanced H&S outcomes and construction risk library which mapped out risk scenarios and mitigation measures.

A range of industry and standards bodies have also produced supplementary guidance to support practitioners. For example, the Institution of Civil Engineers (ICE) has published guidance on Design Risk Management (DRM), a core requirement under the CDM regulations (ICE, 2020). The document provides clear explanations of risk concepts, the fundamentals of DRM, and the respective responsibilities of different stakeholders throughout the process. The Construction Industry Training Board (CITB) has published six guides, five for duty holders and one for workers. The duty-holder guides outline the key tasks, the information required or to be provided, practical suggestions of how responsibilities can be carried out, and guidance on applying these duties when working with domestic clients. The worker guide explains what the regulations mean on site, emphasises consultation and communication, sets out the information workers should give and receive, highlights the need for cooperation and coordination, clarifies expectations around competence and training, and illustrates what good health and safety practice looks like in construction. Despite the comprehensive list of actions, the guides do not always distinguish between what is essential and what is desirable; applying CDM requires judging what is reasonably practicable in context, and not all of the listed measures are proportionate or necessary on every project. In addition, without some example case studies from real life projects, the list can feel theoretical. In addition, national and international standards such as BSI PAS 1192-6 (BSI, 2018) and ISO 19650-6 (ISO, 2025)focus specifically on health and safety information management, offering guidance on how hazard and risk information can be structured, shared, and maintained throughout a project. Both standards promote treating risk information and mitigation measures as shared project resources that can later be generalised into organisational learning. These two standards have inspired the development of a Construction Risk Library (CRL) (Osorio-Sandoval et al, 2023), as an open resource to guide the identification of design risks and the selection of appropriate treatments.

Along from these general guidelines, there are also efforts to clarify key concepts such as "so far as is reasonably practicable" (SFARP). The ICE published a commentary for SFARP, which outlines the legal summary and guidance and a compliant design approach (ICE, 2010). However, it lacks concrete examples and only touched on high-level evidence for a compliant design approach. In addition, the Construction Industry Research and Information Association (CIRIA) attempted to unpack SFARP for designers by explaining how to balance risk, proportionality and practicability in design decisions, emphasising cautious, team-based judgement and the need to eliminate or reduce foreseeable risks through the design process (CIRIA, 2015).

CDM in practice

More recent research has moved beyond interpreting the CDM regulations themselves to examining how they shape practice. Mzyece et al. (2019) approached CDM regulatory compliance from a BIM-integrated perspective, proposing a BIM–CDM interoperability framework to support the discharge of CDM duties. Their framework focused on three key CDM documents (pre-construction information, construction phase plan and H&S file) and explored how BIM and common data environment could support managing these documents. An ICE review conducted three years after the regulations came into force found that, although the industry had broadly adapted to the new framework, many practitioners continued to struggle with ambiguous clauses and terminology (ICE, 2019). The report highlighted persistent uncertainty around how to interpret certain duties, particularly at the design stage. This is where misunderstanding is most evident: many designers still under apply design risk management principles, especially the requirement to eliminate, reduce and control risks through design. Responding to the outcome-oriented nature of CDM 2015, Zhang et al. (2024b) developed a process map of the H&S by design process based on interview results with practitioners, providing a practical and detailed workflow to support designers and PD to fulfil their duties. Also focusing on the design stage, Hare et al. (2020) developed a multimedia digital tool to help designers identify and mitigate common design-related hazards, offering practical support for design-stage CDM compliance. Adaku et al. (2021) focused on clients, identifying seven key practices they use to achieve CDM compliance. The findings highlighted that some these practices depend on the PD's arrangements, underscoring the importance of understanding the PD's role in coordinating pre-construction H&S. Shifting the focus to the construction stage, Nisbet et al. (2024) used a semantic annotation approach (RASE mark-ups) to support live CDM compliance checking on construction sites, integrating site diary entries and site-monitoring data to evaluate compliance in real time.

Industry working groups have also played a significant role in supporting CDM compliance on projects through collective knowledge sharing. Workshops that bring multiple duty holders (e.g., clients, PDs) were organised and lessons learned documents and best practice guidance were published addressing specific aspects of CDM

compliance. Notable examples include the BIM for Health and Safety (BIM 4 H&S) group, chaired by the HSE, and the Highways Safety Hub, underpinned by the National Highways' Principal Designer Working Group (Highways Safety Hub, 2023). Together, these initiatives provide a forum for cross-organisational learning and help translate regulatory requirements into practical approaches for improving design risk management.

The principal designer role

The studies above highlight both the importance of the Principal Designer role and the persistent uncertainty surrounding its practical interpretation. Introduced in CDM 2015 to replace the CDM Coordinator, the PD was intended to lead and coordinate pre-construction H&S matters. This shift reflected the HSE's aim to embed H&S considerations at the centre of the design process by placing responsibility with the lead designer rather than peripheral H&S consultants (Jolly, 2023). However, architects and lead designers have often been reluctant to take on the PD role, with findings indicating that many still view H&S as a contractor responsibility, resulting in the role being frequently undertaken by H&S consultants, client advisors and project managers (MPW R&R Ltd, 2023).

In addition, a key requirement of CDM 2015 is that PDs must be competent, yet the regulations offer little clarity on what this competence entails in practice. Addressing this gap, Adaku et al. (2022) developed conceptual models for assessing PDs' skills, knowledge and experience, expanding CDM competence across multiple levels, such as occupational and task-specific dimensions. Ndekugri et al. (2022) investigated the coordination role of the PD during the pre-construction stage. They found that while CDM 2015 has improved early PD appointment, significant challenges remain around assessing PD competence, ensuring adequate resourcing, and overcoming barriers such as limited awareness, misunderstandings of duties and intentional non-compliance. These issues have direct implications for how design risks are identified, coordinated and managed, which is the focus of the next section.

Design risk management

Design risk management is a core process undertaken by designers and the PD. It is an iterative process focused on identifying and managing risks during the design stage and forms an integral component of both overall project risk management and routine design practice (ICE, 2020). The central principle is that an inherently healthier and safer design can improve H&S performance across the entire project lifecycle, benefiting both construction workers and end users. Design risk management is guided by the principles of prevention, most commonly expressed through the "ERIC" hierarchy: eliminate, reduce, inform and control (HSE, 2015b). This hierarchy prioritises eliminating risks through design or design changes wherever reasonably practicable, with control measures such as reliance on personal protective equipment (e.g., using earplugs or protective gloves) considered only as a last resort. Although construction projects may involve hundreds or even thousands of potential hazards and risks, design risk management puts more emphasis on a smaller subset of significant, unusual or difficult-to-manage risks (CIRIA, 2015; ICE, 2019). This focus highlights the need for designers to address these risks proactively and early in the design process to achieve effective H&S outcomes. Design risk management, despite its focus on the design stage, also emphasises the need for residual risks to be appropriately managed and handed over to those who will control the subsequent stages of the project, typically the PC (or the contractor where no PC is appointed) (ICE, 2019).

However, despite the aspirations set out in CDM 2015, studies consistently show that designers and PDs often struggle to apply these principles consistently in practice, particularly when interpreting what constitutes a 'significant' risk or determining how far mitigations are reasonably practicable (ICE, 2019). This persistent challenge reflects a broader pattern identified across the literature, where understanding and operationalising CDM duties remains inconsistent, especially during the design stage.

Research gap

Despite extensive guidance and a decade of implementation, the literature consistently shows the varied levels of understanding and ongoing challenges in fulfilling CDM duties, particularly in relation to design risk management. Practitioners in industry still lack operable, practice-ready knowledge on how to fulfil CDM duties at the design stage. In particular, the PD role and design risk management processes remain poorly understood. This requires an iterative investigation framed to answer whether the absence of an operable target (analogous to BIM or site logs) invalidates the use of semantic annotation and whether gap between legislative text and operable knowledge can be closed by other means.

This paper addresses this gap by using semantic annotation (mark-up) to expose the logical intent of the clauses relating to the PD and then classifying those actions by examining the operative verbs. This ensures that the outcome of four classes of action is learnable and teachable whilst remaining evidently grounded in the legislation.

Research methodology

This paper is presenting a case study based on the existing UK regulations around health and safety, examined from the point of view of one of the nominated 'duty holders', namely the 'Principal Designer' (PD). Design Science Research (DSR) (Hevner et al., 2004; Peffers et al., 2007) allows a progressive sequence of iterative steps to be taken to move from the regulation to a concise summary of the duties, meeting the criteria of arriving at a learnable and teachable understanding. Figure 1 shows a DSR dashboard based on Takeda et al (1990). The knowledge base is UK legislation and regulations, and the practice context is the uncertainty around CDM 2015 duties. The problem is to produce accessible guidance with quality

around learnability and teachability, as a grounded presentation of CDM 2015. The iterative research process needs to test for clarity and simplicity.

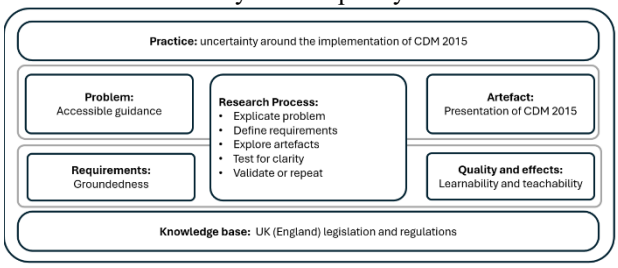

Figure 1: DSR approach (based on Takeda et al 1990)

Investigation

The investigation began with applying the RASE annotation (mark-up) methodology to the regulation. This involves identifying the hierarchy of objectives as boxing which in this case is mostly identical with the sectional hierarchy of clauses and sub-clauses. In one case a clause '8(1)' acts as a sub-clause of another '8(2)'. Mark-up is also applied to the terms that identify any testable proposition, such as the 'role' being taken, using underlining. These metrics can be annotated with their implied property and target. Some propositions may require further discussion such as 'reasonably practical' but in principle these can be answered. All the objectives and metrics are then assigned a logical role, chosen from 'Requirement' (blue), 'Application' (green), 'Selection' (purple) or 'Exception' (orange), indicating how they contribute to the evaluation of their immediate containing section. This mark-up is sufficient to make the document machine operable. For example, by specifying that the actor of interest for this case study is the 'Principal Designer', the document is immediately shortened to reflect only the clauses that refer to that actor. Figure 2 shows the mark-up following this choice.

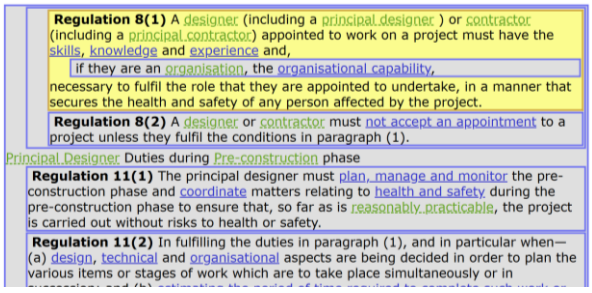

Figure 2: CDM 2015 with RASE mark-up (extract)

However, this still contained a wide variety of tests. Whilst these can be answered individually, given our aim of making the regulation more comprehensible, we can apply a systematic approach to identify not just the test such as '(has) skills' but to group this test with others such as '(has) knowledge' and '(has relevant) experience'. By consulting an online dictionary service (such as Wordnet or WordHippo) and or informally, the concept of 'skill' can be found to have the hypernym 'capability'. Capability is also a good hypernym for 'knowledge' and 'experience'. The metric '(has relevant) skills' can be revised to be 'property=capability comparator=includes target=skills'. Table 1 shows five examples.

Table 1: Regulation terms and hypernyms (extract)

Terms	Hypernym
accept, manage, monitor, coordinate	consider
plan, comply	specify
inform, liaise, ensure, cooperate, assist, provide to	communicate with
report, review	share
reasonably practical, relevant, foreseeable, appropriate	scoping

Having performed this substitution, the number of different properties mentioned in the metrics is considerably reduced. Some comments relating to their evidencing in practice are given in Table 2.

Table 2: Hypernyms with possible evidence (extract)

Hypernym	Possible evidence
consider	memos, design file notes or other records
specify	changes affecting the design and specification of the works
communicate with	confirmation of both sending and receipt.
share	information exchange records

The selection of hypernyms allows us to see a pattern in the kinds of properties involved in the metrics present in the text. Some properties remain categoric, such as whether the PD is an organization (as opposed to an individual). Functional properties tend to be numerical, but there are none in the current example. Lastly, many properties are tests for membership of classes and sets, which may require background knowledge of any hierarchy and synonyms.

Having created a rationalised mark-up for the regulation, a number of presentations can be generated automatically. For example, a conceptual graph can represent the logical operability of the Regulation. Other decision-based presentations are possible including decision trees and flow diagrams. However, these are not shown here because the regulations are not applied at a single point but are intended to be applied continuously.

A presentation derived from the marked-up regulation (Figure 3) summarizes the selected hypernyms as a form allowing the input of values for the properties involved. The text of the regulation is repeated below offering the alternative of the input of values in context. Where the range of possible answers is known, the form offers a drop-down selection. Selecting or providing a value fills in all synonymous slots.

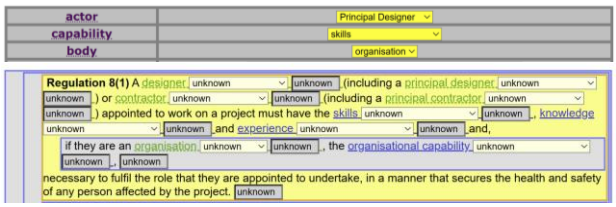

Figure 3: CDM 2015 as linked form and text (extract)

Results

An alternative presentation offers a matrix of the clauses (vertically) and the property hypernyms (horizontally), with each cell including all the target values. Figure 4 shows selected cells from the matrix. This simplifies the PD duties once appointed into a set of four manageable activities: consider/specify/communicate-with/share.

clause	consider	specify	communicate with	share	measure
R11-01	• health and safety	• plan, manage and monitor • coordinate			• reasonably practicable
R11-02	• general principles of prevention • construction phase plan • health and safety file	• design • technical • organisational • estimating the period of time required to complete such work or work stages			• relevant
R11-03	• carrying out or liable to be affected by construction work • maintaining or cleaning a structure • using a structure designed as a workplace	• risks to the health or safety			• reasonably practicable • foreseeable
R11-04	• duties in regulation 9		• designers		
R11-05		• cooperate	• client • each other		
R11-06a			• assist the client	• pre-construction information	
R11-06b			• every designer and contractor appointed, or being considered for appointment	• pre-construction information	• control
R11-07			• liaise with the principal contractor	• planning, management and monitoring of the construction phase • coordination of health and safety matters during the construction phase	

Figure 4: CDM 2015 as a matrix (extract)

This allows us to highlight the lists of key targets the PD has duties around (see Table 3). Under the duty to 'consider', we can note the inclusion of 'health and safety' and the risk register. The PD is required to 'communicate with' all of the other roles identified in the regulation. The PD is required to 'specify' (by affecting the drawings, specifications and risk registers) design, technical and organizational matters. 'Sharing' of the risk register(s) in the form of the 'pre-construction information', 'construction phase plan' and the 'health and safety file' is required.

Table 3: Hypernyms with topics (extract)

Hypernym	Topics
consider	Health and safety
	General principles of prevention
	Construction phase plan
	Health and safety file
specify	Planning
	Coordination
	Design
	Technical (matters)
	Organizational (matters)
	Time for work (estimate)
	Risks to health and safety
	Cooperation
communicate with	Designers
	Client
	Principal contractor
	All
share	Pre-construction information
	Construction phase plan
	Health and safety file
scoping	Reasonably practical
	Relevant
	Appropriate
	Foreseeable

Since these duties are open-ended in terms of their scope and in terms of their duration, it is important to note the qualifications offered for several of these duties. Table 3 summarizes some scoping filters applied to these duties. These apparently ambiguous filters are the subject of specific legal and regulatory guidance. Phrases such as 'reasonably practical' have specific meanings. These frame compliance in terms of normal practice, best practice and other considerations of proportionality. The recently developed Uniclass 'RK' risk classification table (NBS, 2026) and the publication of a 'Construction Risk Library' (CRL) may inform this judgement. The Uniclass table creates a reference list of many types of risk with RK_40 focused on risks to health and safety. This CRL library provides lists of common construction risks and possible treatments and mitigations. These two resources may help judge relevance and appropriateness. The publication of BSI PAS1192 Part 6 and its subsequent development into ISO 19650-6 has explored how the risk register can be treated as a single shared resource, through all three versions in the UK regulations 'Pre-construction information', Construction Phase Plan' and 'Health and safety file' (in-use). The forthcoming guidance to Part 6 in the Information Management Initiative (IMI, 2026) will suggest the filters (views) applicable to a risk register to obtain each of these documents.

Discussion

Regulatory compliance can be effected through changes to the physical and spatial aspects of the built environment

or through governance over the actors and information involved. Regulating actors can focus on requiring levels of competence including skill, knowledge, and experience. Alternatively it can prescribe programmes of actions that must be carried out. In either case there is unlikely to be direct evidence that can be checked systematically in real time. Instead, it becomes important that the expectations are embedded in the level of understanding of the actors so as to inform their behaviour continuously. A simple but justifiable model can be trained and learnt. The technique will be presented to a focus group later this year which may lead to the deployment of the learning/teaching materials. This should produce the evidence to support the validation of the approach.

UK CDM regulations are an example of secondary legislation that imposes expectations on process, not product, in the expectation that the desired outcomes will be achieved. The requirements are open-ended in the sense of not specify the timing of actions and in the sense of no limitation to the amount of effort and output required but for the limiting phrases. This makes the legislation daunting for practitioners and hard for third parties such as insurers to evaluate.

RASE mark-up has been used to expose the objectives and metrics used in defining one actors duties. A repeatable process has then been used to extract the verb-noun predicates. The verbs have been rationalised through the use of hypernyms and the nouns (and scoping adverbs) have been rationalised by reference to emerging classification and information management principles. The same process can be applied to any regulatory document in any language. Exceptionally, if no dictionary of hypernyms is available for a particular language, then manual intervention will be required. Filtering for any particular role, stage or duty or any other attribute is non-specific and is a feature of the generic generation of the presentations.

Conclusion and future work

This paper illustrates that benefits from RASE mark-up can exist even when there is not likely to be a target database for systematic compliance checking. It has addressed a knowledge gap by using RASE mark-up to expose the logical intent of the clauses relating to the PD and then classifying those actions by examining the operative verbs to generate a concise conceptual model of the duties imposed by the regulation. This conceptual model can inform teaching and learning material and act as a simple tacit framework to guide practitioners in their work, without having to refer to the legislation repeatedly and without the potential for scope creep induced by anxiety about under-performing the satisfaction of the obligations. This is significant for bringing 'process' based regulations into the realm of operable knowledge.

Future work can look at how online dictionaries and Natural Language Processing (NLP) tools can support Large Language Models (LLM) in automating the addition of RASE mark-up. With this in place learning/teaching material could be rapidly generated from source documents.

A SEMI-AUTOMATED BIM-TO-VR WORKFLOW FOR TEACHING: ROBUST MODEL REVIEW IN CAVE AND HMD ENVIRONMENTS

Hu Hanwen, Emara Merna, and Menzel Karsten
Technical University Dresden, Germany

Abstract

Current BIM-to-VR approaches enable immersive visualization of buildings but often require extensive manual preprocessing and rely on rigid modeling conventions, limiting scalability and reuse. This paper presents a semi-automated BIM-to-VR workflow that enables immersive interaction with building data derived from Autodesk Revit in a VR environment implemented in Unity. The method automatically parses model hierarchies, derives building-level and component groupings, assigns colliders, and enables group-based visibility control and navigation without additional preprocessing. The workflow is demonstrated in both room-scale VR and head-mounted display setups and validated in teaching scenarios, showing reduced preparation effort and robust reuse across VR platforms.

Introduction

The architecture, engineering, and construction (AEC) industry has undergone a gradual transition from two-dimensional drafting toward three-dimensional digital modeling, with Building Information Modeling (BIM) becoming a core method for representing geometry and technical information across the building lifecycle (Sacks et al., 2018). However, interacting with complex BIM data through conventional desktop-based tools can be cognitively demanding, often limiting spatial understanding and collaborative discussion at building scale (Whyte, 2003). Immersive Virtual Reality (VR) has therefore gained attention as a complementary medium that enables intuitive exploration of BIM models, enhancing spatial cognition and improving the comprehension of architectural spaces compared to traditional visualization approaches (Samarasinghe et al., 2019).

In addition to improved visualization, VR systems support real-time interaction with building models. This capability helps designers and stakeholders identify design issues, respond to feedback, and refine solutions at early stages, thereby reducing the risk of costly changes later in the project lifecycle (Kamari et al., 2021). Due to these advantages, VR has been increasingly applied across different stages of the building lifecycle to enhance collaboration, decision-making, and design communication. Several studies have demonstrated the value of VR in stakeholder-driven sustainable design decision-making. For example, Atwa et al. (2019) used VR to collect feedback from users and experts during the development of sustainable landscape design principles for green business parks, enabling more informed and inclusive decision-making processes. Similarly, Tseng and Giau (2022) applied VR as an assessment tool for elderly housing, suggesting that immersive VR experiences offer a more realistic sense of presence and improved spatial understanding prior to occupancy.

In parallel with professional practice, significant efforts have been made to integrate BIM into AEC education curricula worldwide (Arundhati et al., 2013; Sacks and Pikas, 2013). BIM-based models and associated databases offer an enhanced educational platform by presenting complex construction information in a visual and accessible format (Clevenger et al., 2012). In particular, BIM's 4D capabilities enable students to better understand construction sequencing and assembly processes through animated simulations (Gledson and Dawson, 2017). In parallel, immersive technologies such as VR have been increasingly adopted in education, including gamification, game-enhanced learning, and experiential learning environments (Shavinina, 2013). Research on VR in education has increased substantially over the past two decades, with studies consistently reporting improved student understanding through direct interaction within realistic environments (Blazauskas et al., 2017).

Nevertheless, prior research emphasizes that VR applications must be grounded in appropriate pedagogical frameworks and learning theories to ensure alignment with educational objectives (Liu et al., 2017). This aligns with core Human-Data Interaction (HDI) principles, which suggest that for building data to be effectively utilized, the workflow must ensure legibility—making complex data understandable to the human observer—and provide the user with sufficient agency to control and customize the review process (Davila-Delgado et al., 2024; Kassem and Kifokeris, 2025).

Recent studies have specifically explored the integration of BIM and VR for AEC education. Elgewely et al. (2021) developed a BIM-integrated VR platform for construction detailing education and demonstrated that immersive, collaborative interaction with BIM models significantly improved students' engagement, motivation, and learning outcomes compared to traditional paper-based study. Similarly, Sanchez et al. (2021) reported on an intuitive and accessible BIM–VR educational framework

embedded within an AEC course curriculum. Their work illustrated how BIM–VR can be leveraged as a data-rich learning infrastructure to support complex design understanding, teamwork, remote collaboration, and client-oriented project presentation, reinforcing the value of BIM–VR as an effective educational medium in higher education.

Despite these promising results, Radianti et al. (2020), in a systematic mapping study of immersive VR applications in higher education, concluded that many VR-based educational systems remain experimental, lack grounding in learning theories, and focus primarily on usability rather than learning outcomes. Nevertheless, their findings confirm the strong potential of immersive VR as an effective and affordable pedagogical tool in university-level education.

In response to the limitations identified in existing BIM–VR applications, this paper presents a semi-automated BIM-to-VR workflow that enables immersive interaction with building data while minimizing manual preprocessing and avoiding reliance on proprietary VR middleware. The approach relies on hierarchy-based parsing of BIM-derived models after export, without requiring additional naming conventions or model-specific preparation. Building structures and component groupings are derived automatically from the existing model hierarchy, with interaction logic applied at the group level rather than per object. The workflow supports group-based visibility control, access to material information, automatic collider assignment, and navigation, and is robust to variations in model quality.

System Capabilities

The proposed workflow enables the immersive exploration of BIM data in VR environments, focusing on minimal manual preprocessing and broad accessibility. The system operates independently of proprietary VR middleware and requires only a standard export in the FBX format—the primary geometry exchange format utilized by Unity—from BIM authoring tools such as Autodesk Revit. Supporting both room-scale immersive

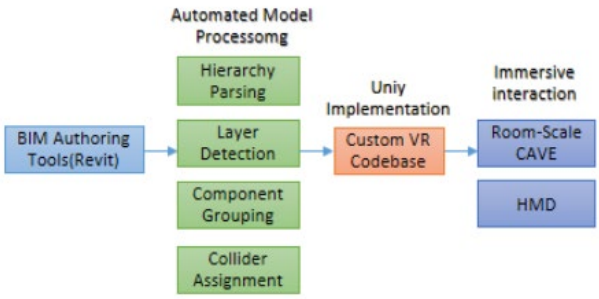

Figure 1: BIM-to-VR workflow

CAVE systems and personal head-mounted displays (HMDs), the implementation ensures a consistent user experience across varied hardware configurations. Figure 1 provides an overview of the processing stages, illustrating how the workflow enhances the legibility of complex building data—a core HDI principle—by ensuring that model hierarchies are automatically structured into a format that is understandable to non-expert users.

Upon importing a BIM-derived model, the system performs several automated operations to prepare it for interaction. Hierarchy parsing traverses the FBX structure to identify structural groupings and assemblies, detecting vertical levels and horizontal component clusters based on geometry distribution and node organization. Layer detection then infers building levels using geometry-aware height clustering, producing an ordered sequence of floors without relying on manual naming conventions or semantic annotations. Component grouping organizes subcomponents within each layer according to their hierarchical position, typically corresponding to major systems such as walls, slabs, or equipment assemblies, while collider assignment automatically equips mesh components with physics colliders to enable navigation without manual setup.

Building on this automated structuring, the interaction logic supports intuitive exploration, preserving spatial continuity through continuous, grounded movement. To ensure the system remains accessible to novice users,

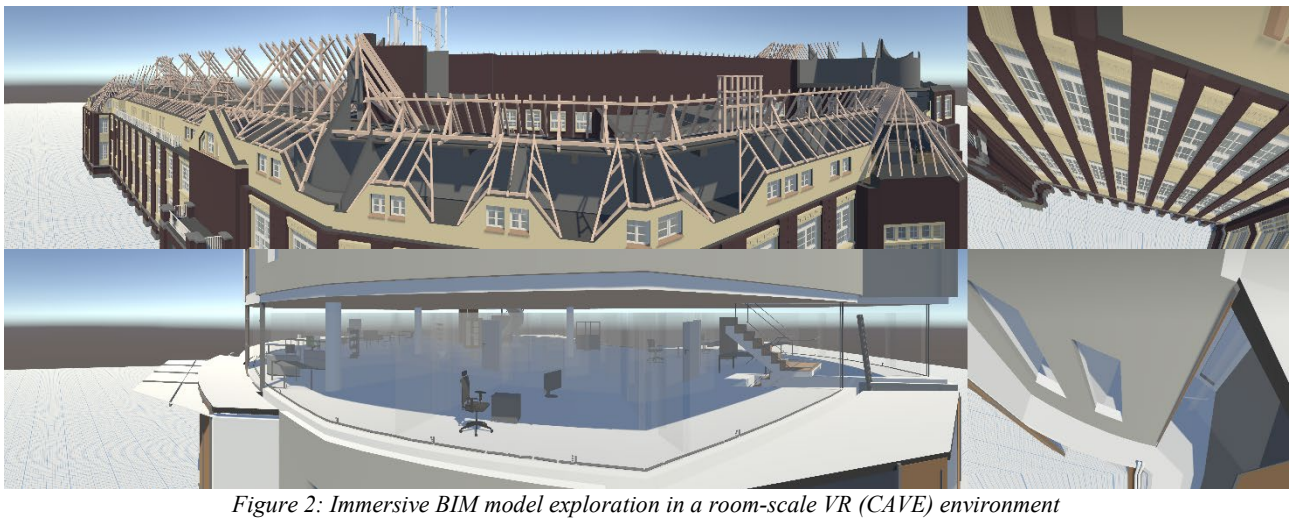

Figure 2: Immersive BIM model exploration in a room-scale VR (CAVE) environment

Table 1: Comparison of BIM-to-VR workflows for educational and exploratory use

	Proposed Workflow	Unity Reflect	Twinmotion
Required Export	fbx	Direct link	Datasmith exporter
Group/Layer Automation	yes	limited	limited
Interaction flexibility	high	low	moderate
CAVE support	yes	limited	limited
Primary use	Education&discussion	presentation	visualization

navigation is mapped to a standard Xbox controller. This choice of input device provides a familiar interface for students, allowing them to move through the building model with minimal technical training. The system's unified interaction logic ensures that the controller functions identically across both the room-scale CAVE and HMD-based setups, providing a consistent sense of agency as users choose their own paths through the digital environment.

To contextualize the proposed approach within the broader landscape of BIM-to-VR solutions, Table 1 compares the workflow with commonly used commercial and engine-based pipelines from the perspective of educational deployment. The comparison highlights differences in required preprocessing effort, dependence on proprietary middleware, and interaction flexibility.

Methodology

This study adopted an experimental research methodology conducted through a field-based teaching deployment to evaluate the real-world utility of the semi-automated BIM-to-VR workflow. The research was designed as a single-cohort study without a control group, focusing on the use of BIM models authored by participants in Autodesk Revit to isolate the specific impact of the automated processing from the general cognitive benefits of VR visualization. The deployment involved 40 students from architecture and engineering programs, organized into 11 groups of 5–6 participants. To facilitate the technical onboarding and ensure consistent system usage, the students were guided by one expert facilitator.

The VR application was deployed exclusively in a room-scale, multi-wall CAVE system to support shared immersive experiences. To facilitate navigation within this space, each student group utilized an Xbox controller as their primary interaction tool. During the standardized 30–45 minute introductory session, the expert facilitator trained the 40 students on how to use the controller to traverse the model, toggle layer visibility, and perform "peeling" interactions. By using a familiar consumer-grade controller, the study aimed to reduce the cognitive load on participants, allowing them to focus on the architectural review tasks rather than the mechanics of navigation.

The study is grounded in Human-Data Interaction (HDI) principles, specifically focusing on how the workflow enhances the legibility of complex building data and provides users with the agency to control and customize their review process. To emphasize educational application rather than tool demonstration, the VR sessions were structured as model-based review tasks aligned with established BIM learning objectives:

- **Spatial understanding and scale:** Participants explored their own partial BIM models at a 1:1 scale to assess proportions, spatial relationships, sightlines, and potential bottlenecks. This task leveraged VR's documented strengths in conveying scale and spatial detail, which are often lost on 2D screens.
- **Structural and system understanding:** Layer- and group-based visibility controls, including the progressive "peeling" interaction, were used to analyze complex relationships between internal building systems, such as the coordination between structural slabs and MEP equipment.
- **Data reflection and model quality:** Students performed material plausibility checks and metadata inspections to identify inconsistencies, such as missing or implausible material assignments. This process was designed to foster trust in the digital model by allowing students to verify informational accuracy directly within the 3D environment.
- **Collaboration:** Teams engaged in group-based discussion and joint critique of model segments directly within the immersive environment. This supported collective reasoning and peer-based feedback, as the shared viewpoint in the CAVE enabled members to ground their dialogue in the same visual evidence.

To reduce entry barriers and ensure consistent use across the 11 groups, a standardized training procedure was implemented. At the beginning of the study, participants attended an introductory session lasting approximately **30–45 minutes**, covering essential aspects of VR usage, including safety considerations, navigation principles, group-based visibility controls, and the use of material plausibility checks. Following this introduction, student groups were granted repeated, independent access to the CAVE system over a period of **2–3 weeks**. During this deployment phase, participants independently imported their own BIM models, performed the assigned review tasks, and documented their observations and discussion outcomes.

Data collection followed a mixed-methods approach, utilizing a structured questionnaire (n=40) and short reflective interviews to capture both measurable perceptions and contextualized user experiences. Quantitative data from Likert-scale and categorical items were analyzed using descriptive statistics, including

frequencies and percentages, to measure system usability and spatial comprehension. Qualitative data from open-ended questions were analyzed using thematic analysis following Braun and Clarke's inductive approach to identify recurring themes in the users' experiences. This rigorous approach allowed the study to distinguish between the inherent effectiveness of VR and the specific performance of the automated BIM-to-VR pipeline.

Discussion and Result Analysis

The evaluation of the system, based on 40 completed questionnaires, indicates high usability and effective pedagogical support despite the participants' limited technical background. As illustrated in Figure 3, which summarizes participants' prior experience with BIM tools, game engines, and VR, the study sample predominantly consisted of novice users. Specifically, nearly half of the participants (47.5%) reported no prior experience with Autodesk Revit, while 95% had no prior exposure to Unity and 87.2% had never used VR before. Despite this limited background, quantitative results indicate overall positive system usability, with 65% of participants expressing a desire to use the system frequently and 56.4% reporting confidence in its operation. While some participants initially faced a learning curve, qualitative feedback suggested these challenges diminished quickly with the guidance of the single expert facilitator who supported the 40 students during their initial onboarding. This suggests that the usability challenges were primarily related to first-time navigation rather than the fundamental design of the automated workflow.

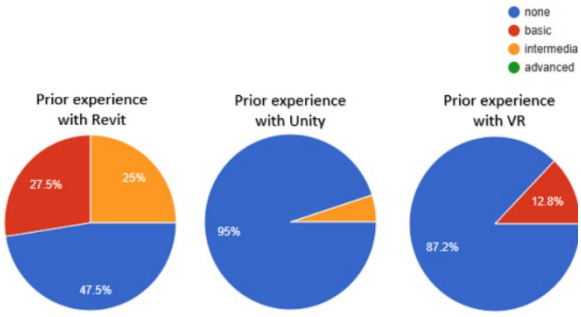

Figure 3: Prior Experience with BIM tools and VR

To address the distinction between general VR effectiveness and the proposed BIM-to-VR workflow, it is important to note that while VR inherently aids spatial reasoning, the automated hierarchy parsing was the specific factor that enabled these results for novice users. Without the semi-automated assignment of colliders and grouping, students would have spent the majority of their time on technical model preparation rather than analytical review. Spatial understanding represented the strongest observed effect, with 74.2% of participants reporting a better grasp of proportions and 61.3% finding spatial problem detection easier in VR than in desktop BIM tools. As illustrated in Figure 4, which displays the quantitative responses to spatial understanding and learning-related items, the results are strongly skewed toward agreement. By reducing technical friction, the workflow allowed participants to focus on high-level cognitive tasks, such as system-level reasoning and collaborative critique, which are often hindered in manual or proprietary pipelines.

From a Human-Data Interaction (HDI) perspective, the use of the Xbox controller was a key factor in promoting user agency and reducing the initial learning curve. Quantitative data showed that 56.4% of participants felt confident using the system, a result that qualitative feedback linked to the familiarity of the controller interface. While 20% of participants initially found navigation challenging, the "game-like" nature of the input device allowed them to overcome these hurdles quickly with the help of the expert guide. This choice of hardware, combined with the automated model preparation, effectively bridged the gap between complex architectural data and the user, ensuring that the legibility of the BIM model was matched by an intuitive means of exploration.

Following this intuitive navigation, the role of the workflow is further reflected in how participants interacted with structured building information. Quantitative results show that 50% of participants found layer and group visibility controls essential for understanding building organization, while 57.5% reported benefits from metadata inspection. The "peeling" interaction provided users with the agency to isolate specific systems, making sense of internal relationships that are typically obscured. Furthermore, the inclusion of material checks fostered a sense of trust, as participants could verify the accuracy of their models in real-time, identifying inconsistencies that were previously invisible in the desktop view.

Ultimately, 75% of participants agreed that the VR experience enhanced their learning compared to traditional methods. By removing the need for manual preparation and empowering students to manipulate data directly, the semi-automated workflow successfully bridged the gap between complex digital twins and human understanding. In addition to individual interaction, collaborative use emerged as a vital dimension, with 70.0% of participants perceiving improved team performance. These results suggest that the workflow is a robust tool for educational deployment, fostering improved individual and team performance while upholding the core HDI principles of empowerment and data transparency.

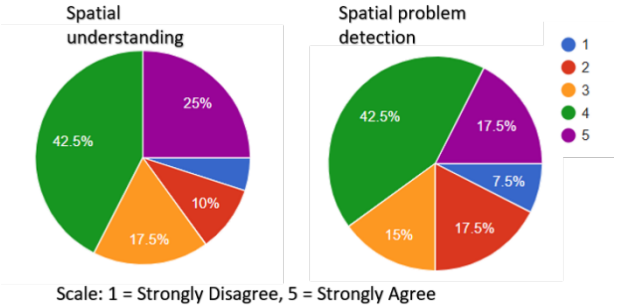

Figure 4: Spatial understanding in VR

Conclusion & Limitations

This research has presented and evaluated a semi-automated BIM-to-VR workflow specifically engineered to bridge the technical gap between complex architectural data and immersive educational review. By implementing an automated pipeline for hierarchy parsing, layer detection, and collider assignment using the FBX format within the Unity engine, the system successfully democratizes access to Virtual Reality for users without game-engine expertise. The field-based deployment, involving 40 students and guided by a single expert facilitator, demonstrates that the workflow is not merely a visualization tool but a functional interface for architectural analysis. A critical finding of this study is the distinction between the inherent cognitive affordances of VR—such as 1:1 scale perception and spatial reasoning—and the operational accessibility provided by the workflow. While the virtual medium provides the "where" for spatial understanding, it is the automated processing of the BIM data that provides the "how," allowing novice users to transition from desktop authoring to immersive critique without the burden of manual model conditioning.

From a theoretical standpoint, this study offers a significant contribution to the framework of Human-Data Interaction (HDI) in the built environment. By structuring interaction at the level of building systems and assemblies rather than granular geometric nodes, the workflow fundamentally enhances the legibility of complex BIM data. This structural clarity allows students to perceive a building not as a collection of meshes, but as a coherent system of floors, walls, and equipment. Furthermore, the provision of visibility controls and the progressive "peeling" interaction grants users a high degree of agency, empowering them to manipulate the digital environment to suit specific analytical tasks. This sense of control is essential for deep learning, as it moves the user from a passive observer to an active investigator of the building's internal logic. Additionally, the integration of material plausibility checks and metadata inspection fosters a vital sense of trust, ensuring that the immersive experience remains a high-fidelity reflection of the underlying engineering data.

The results from the room-scale CAVE deployment underscore the workflow's efficacy in fostering collaborative learning and peer-based critique. With 70% of participants reporting improved team performance and 75% noting an enhanced learning experience, the system proves to be a robust pedagogical aid. While the study identified certain limitations—specifically regarding the initial onboarding curve and the requirement for specialized CAVE infrastructure—the overall success of the deployment suggests that semi-automated BIM-to-VR transitions are a scalable solution for the AEC industry. Future research will focus on extending the system's capabilities to include bi-directional data synchronization, allowing users to annotate and modify BIM data directly within the VR environment. By continuing to refine the interface through the lens of HDI, this work aims to further empower the next generation of AEC professionals to interact with, understand, and trust the increasingly complex digital twins of our built environment.

DEVELOPMENT OF AN IFC-BASED CONVERTER FOR BIM INTEGRATION INTO AUGMENTED REALITY APPLICATIONS FOR BUILDING CONSTRUCTION TRADES

Christian Annen, Hendrik Morgenstern, and Katharina Klemt-Albert
RWTH Aachen University, Aachen, Germany

Abstract

To address the shortage of skilled labor in the construction industry, the application of augmented reality on construction sites offers substantial potential to enhance coordination and communication among different trades, thereby reducing labor-intensive processes. This requires the reliable transfer of geometric and semantic information from Building Information Models, including all data relevant to construction execution, through suitable data exchange formats. This paper defines information requirements for the IFC schema for the BIM-to-field use case in the construction trades, discusses appropriate exchange formats for geometric and semantic data, and presents the development of an IFC-to-Unity converter.

Introduction

A key challenge currently facing the construction industry is the shortage of skilled labor. Numerous studies (Klaus *et al.*, 2025; PwC, 2025; Emanuel *et al.*, 2023) indicate that this shortage is particularly pronounced in construction and craft-related occupations.

The implementation of digital technologies can enhance process efficiency in the construction sector (PwC, 2025), thereby contributing to the alleviation of skilled labor shortages.

At the same time, the gap between digitalization potential and actual digital capabilities in the construction industry continues to widen (PwC, 2025).

According to Klaus *et al.* (Klaus *et al.*, 2025) the gap between digitalization potential and actual capabilities is especially pronounced in the areas of simulation and visualization, cloud technologies and platforms, and Internet of Things solutions.

When the potential of digital solutions is examined across different user groups in the construction sector, it becomes evident that construction trades, particularly construction workers, play a central role.

According to the Bitkom study *Digitalization in Skilled Trades* (Geffert, 2026), only 18% of the surveyed construction and finishing trades currently use BIM. At the same time, 76% of all surveyed skilled trade companies report that their employees require stronger digital skills (Geffert, 2026). These findings point to limited BIM adoption and a continued need for workforce-oriented digital support.

In this context, the BIM-to-field concept offers a promising approach. Its objective is to make BIM-based information accessible and usable on construction sites by delivering execution-related information in a user-centered and role-specific manner. Augmented reality (AR) represents a particularly suitable interface for transferring such information from the BIM model to the site in a form tailored to the specific requirements of different user groups and supportive of their on-site activities.

Against this background, the BIM-to-field concept offers considerable potential to improve on-site coordination, support craft workers during execution, and help mitigate the shortage of skilled labor.

Correspondingly, previous studies have shown that the use of AR on construction sites can accelerate on-site decision-making (Marinho *et al.*, 2026), improve collaboration, and enhance overall project performance (Alizadehsalehi *et al.*, 2020).

The BIM-to-field concept enables the positioning of building information models from the planning phase directly on the construction site using AR, allowing relevant information to be visualized via a device such as a smartphone, tablet or AR headset. The workflow from the building information model to the construction site is illustrated in Figure 1. In particular, the underlying data and its preparation represent a major challenge.

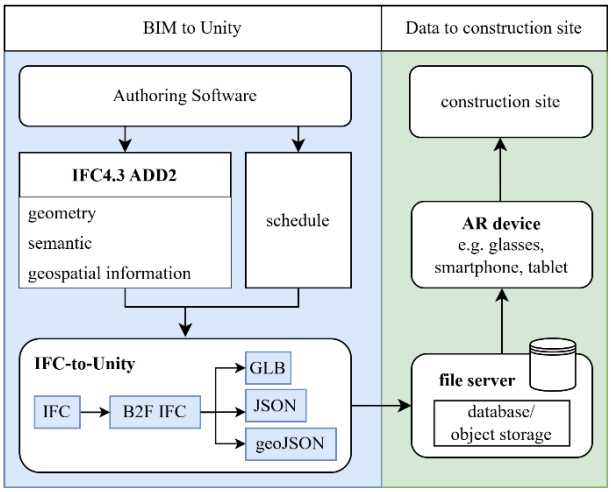

Figure 1: BIM-to-field concept within this research

Research Gap

Several AR applications already exist for both research and professional practice. These applications describe the BIM-to-field process in detail or provide functional solutions for a specific use case. However, most existing AR applications are based on the principle that information from the Building Information Model is used primarily for inspection and verification purposes. Consequently, these systems are not yet suitable for providing complex, role-specific action instructions for the various trades involved in construction execution. To sum up, most current AR applications are designed to support supervisory and managerial roles on construction sites, rather than operative roles within the construction trades.

At the same time, it is necessary to address how the different BIM standards adopted by various companies can be handled consistently. In this context, the varying information requirements and divergent coordinate reference systems (CRS) used during the planning phase must be considered. In OpenBIM, Industry Foundation Classes (IFC) is used as an open standard for exchanging model information. For this reason, the focus of this research is placed on the IFC-to-Unity process illustrated in Figure 1.

This paper describes how planning information for on-site execution can be systematically extended within an IFC model and defines the basic information requirements necessary to enable actionable, role-specific guidance for construction trades in an AR environment. Rather than extracting model data in isolation, the approach focuses on IFC-standard-compliant enrichment of existing model information, ensuring semantic consistency and interoperability.

In addition, the paper demonstrates how schedule-related information can be integrated into the IFC data structure in order to explicitly address individual trades as well as distinct role profiles within each trade. This enables the derivation of task-oriented, temporally structured instructions suitable for execution-level workflows on construction sites.

Furthermore, approaches are presented to address challenges arising from heterogeneously georeferenced IFC files and from common modelling inconsistencies and errors. Together, these measures ensure a robust, reliable and standards-based BIM-to-Unity data integration pipeline that supports construction workers beyond purely supervisory use cases.

Methodology

This study presents a structured approach to defining information requirements, analyzing the IFC schema and developing a converter for the BIM-to-field use case. The aim is to integrate BIM-to-field-specific information into the IFC schema to enable context-sensitive, AR-based work instructions for craft workers on construction sites.

The process begins with defining the problem and delimiting the research scope, driven by the absence of interoperable, IFC-compliant representations of the information required for field-oriented BIM applications.

To identify relevant concepts, existing approaches, and technical implementation strategies, an exploratory, non-systematic literature search was conducted using backward and forward snowballing, following Wohlin (Wohlin, 2014).

The literature search started from an initial set of key publications on construction scheduling, construction-specific information requirements, approaches for integrating such information into the IFC schema, georeferencing in IFC, digital data exchange and AR-supported construction workflows. It was iteratively expanded by reviewing the reference lists of relevant papers and identifying citing publications, thereby capturing relevant concepts, existing approaches and technical implementation strategies that informed the subsequent methodological steps.

On this basis, the study addresses four interrelated objectives:

- to define core information requirements for representing the BIM-to-field use case in IFC
- to examine how use-case-specific information, including schedule-related information, can be integrated into the IFC schema
- to implement these requirements in a technically robust and IFC-compliant manner
- to optimize the IFC-to-Unity information flow for downstream visualization and AR-based task guidance

These objectives are addressed through a detailed analysis of the IFC schema based on the IFC4X3_ADD2 documentation (buildingSMART International, 2026). The analysis focuses on the entities, attributes, and semantic relationships required to represent, link, and transfer the relevant information.

The resulting requirements are then translated into the development of a Python-based converter, including the selection of suitable Python packages for IFC processing, data handling, and workflow implementation.

Information Requirements

In current practice, information on building elements is commonly embedded directly within the IFC model, whereas scheduling information is usually generated in a separate planning environment and only subsequently linked to the building information model. Nevertheless, IFC provides several mechanisms for incorporating such information and representing schedule structures.

In addition to model information and schedules, supplementary information is sometimes also required. For example, tradespeople need access to assembly instructions for different products.

Therefore, an AR application for use in different construction trades must be able to interpret information from both the building model and the schedule. It must also be able to supplement information that is not part of the building information model, if necessary.

To support this objective, the following section presents a concept that defines the minimum structural requirements of an IFC model for consolidating the essential information in a single IFC file.

In line with the taxonomy proposed by Liu (Liu, 2021), which distinguishes the main categories of *product*, *organization*, *process* and *external factors* for construction workers, the discussion focuses primarily on what is being built and who is responsible for carrying out the work at a given time and place.

IFC Structure requirements

This section defines the minimum IFC data structure requirements for building construction that are necessary to support the coordination of complex trade structures and interdisciplinary interfaces through an AR-based application. The information requirements and relationship definitions developed in this work are based on the IFC4X3_ADD2 standard (DIN Deutsches Institut für Normung e. V., 2024). Additionally, this section illustrates the foundational concepts of the IFC schema that facilitates the integration of 4D information and responsibility assignments into the IFC data structure.

To ensure interoperability across different BIM software environments, the proposed extensions are realized through an entity-based modelling approach that is fully aligned with the IFC schema. Rather than introducing proprietary data structures, this approach uses existing IFC entities and standardized relationships. This preserves schema conformity and enables consistent interpretation across different BIM authoring and analysis tools.

Consequently, no new attributes are introduced in the form of *IfcPropertySingleValue* unless they are explicitly required as an extension. In this paper, existing IFC entities are systematically reused. These entities are interconnected via *IfcRelationship* instances. These relationships are defined according to the mapping shown in Figure 3.

This establishes a semantically consistent link between structures and responsible actors within the AR application. In this context, *IfcCrewResource* is used to represent a specific construction trade, to which different IfcLaborResources are assigned.

These *IfcLaborResources* are specified by an *IfcActor* which is defined by *IfcOrganization* (organization name) and *IfcPerson* (first name, last name).

Huymajer et al. (Huymajer *et al.*, 2024) present a similar approach. However, their work focuses on construction scheduling in tunnel engineering. Applications in building construction, as well as interfaces to augmented reality systems, are not addressed. Nevertheless, *IfcTask*, *IfcLaborResource* and *IfcPerson* are also used to represent IFC-based construction processes.

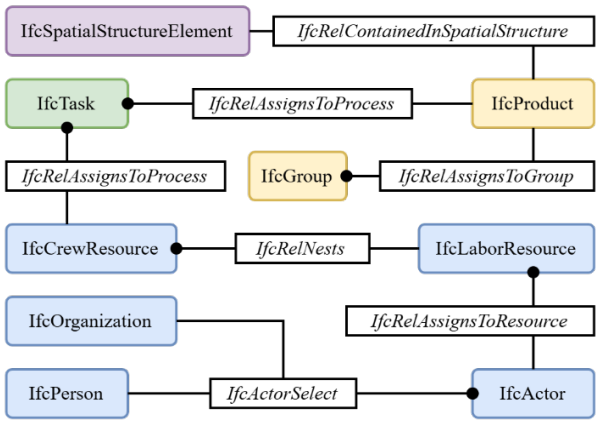

Figure 3: Entities and Relationships used in IFC

The construction trade (*IfcCrewResource*) can be associated with *IfcTask* entities, which represent construction activities. These tasks are, in turn, linked to *IfcBuiltElement* instances, which constitute a subtype of *IfcProduct* and describe the physical building elements involved in the execution of the tasks. *IfcMaterial* is used to describe the material characteristics, while *IfcPhysicalSimpleQuantity* entities are used to specify geometric properties, such as volume.

An *IfcBuiltElement* can be spatially located through its assignment to an *IfcSpatialStructureElement*. For instance, *IfcBuildingStorey* defines the corresponding floor level, whereas *IfcSpace* specifies the room or functional area in which the element is situated.

The defined entities are illustrated in Figure 2. In the figure, the information associated with the masonry trade and a sand-lime brick wall is highlighted in green for illustrative purposes.

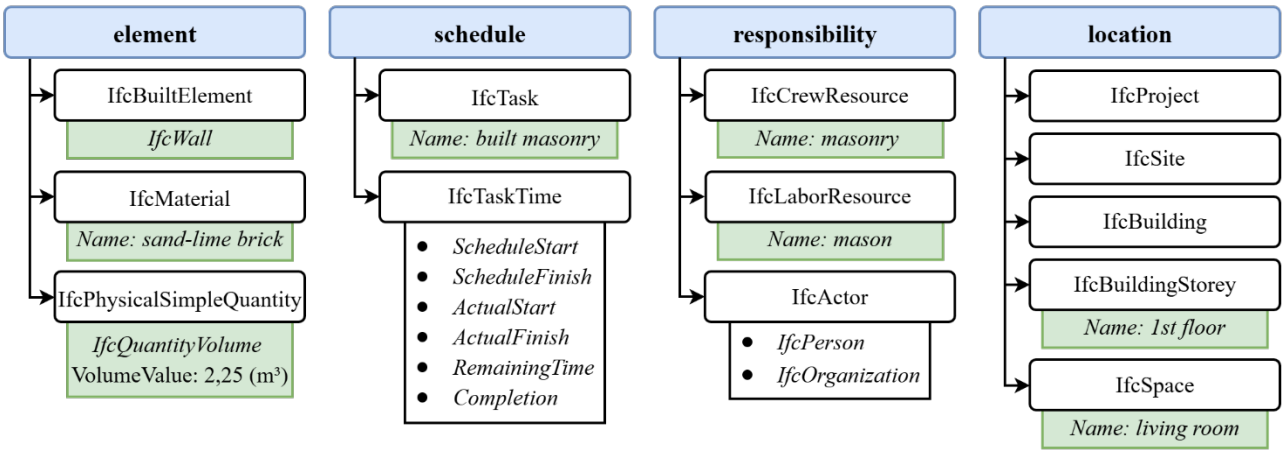

Figure 2: IFC entities for coordinating construction trades in building construction - exemplified by the trade masonry

In addition to *IfcTask*, scheduling information is enriched using selected *IfcTaskTime* attributes (Figure 2), which capture planned durations derived from the BIM model, as well as on-site execution states. Schedule deviations are documented using the *ActualStart* and *ActualFinish* attributes, the *RemainingTime* attribute shows the remaining time, and the Completion attribute indicates task completion, encoded as an *IfcPositiveRatioMeasure* (0.0-1.0).

Geometric and spatial reference Information

In addition to the semantic requirements imposed on an IFC file, particular attention must also be paid to the geometric modelling with respect to the heterogeneous BIM standards applied by industry practitioners. For the concept presented in the previous section to function as intended, building components must be modelled as instances of *IfcElement*.

With regard to georeferencing, it must be considered that different coordinate reference systems are commonly used in practice. This heterogeneity poses challenges for data integration in Unity, as models must be correctly aligned in a common coordinate reference system while simultaneously ensuring that their spatial extent remains sufficiently close to the origin. The latter is essential due to performance constraints and spatial jitter caused by floating-point precision limitations due to the large distance of the objects from the world origin (Thome, 2005).

The problem can be mitigated by positioning the model coordinates close to the origin. If necessary, they can be converted to a global CRS using the transformation parameters defined in *IfcMapConversion*.

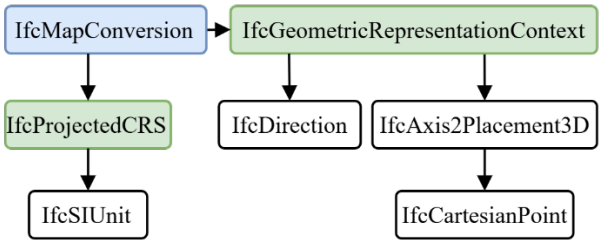

Figure 4: IFC entities linked to IfcMapConversion

IfcMapConversion stores the transformation parameters of the 2D Helmert transformation (buildingSMART International, 2020) and references *IfcProjectedCRS*, which defines the target CRS, as well as the applied length unit (*IfcSIUnit*). All entities associated with *IfcMapConversion* are illustrated in Figure 4.

To improve the interoperability of geospatial data and allow it to be integrated into Geographic Information Systems (GIS), the origin of the Cartesian model is converted into geodetic coordinates using the 2D Helmert transformation.

To preserve the associated geospatial information, these data are stored separately in a GeoJSON file. As GeoJSON relies on the World Geodetic System 1984 (WGS84) datum as its underlying CRS (Butler et al., 2016), the developed converter evaluates the EPSG code specified within *IfcProjectedCRS* to identify the coordinate reference system in which the IFC model is defined and to ensure a consistent transformation into the global reference frame. The coordinate transformation workflow is illustrated in Figure 5.

Development of an IFC-to-Unity Converter

During the development of the converter, the focus is placed on transmitting the previously defined semantic, 4D and geospatial information requirements for the BIM-to-field use case to the construction site.

Additionally, as the AR application runs natively on AR-capable end devices and is Unity-based, the building information model must be converted into Unity-compatible formats.

To validate the converter's functionality during development, two different IFC files are used as input datasets. Table 1 summarizes the key characteristics of these files.

Table 1: IFC Test Files used for Development

Test IFC	1	2
Size	80217 KB	286 KB
Nr. of Objects	1591	15
Source	Revit 2025	(buildingSMART, 2026)
Length Unit	m	mm
EPSG-Code	EPSG:25832	EPSG:32760
File Schema	IFC4X3_ADD2	

An AI assistant was used to support parts of the programming work (code suggestions and refactoring). All methodological decisions, result validation and final implementation approval were performed manually.

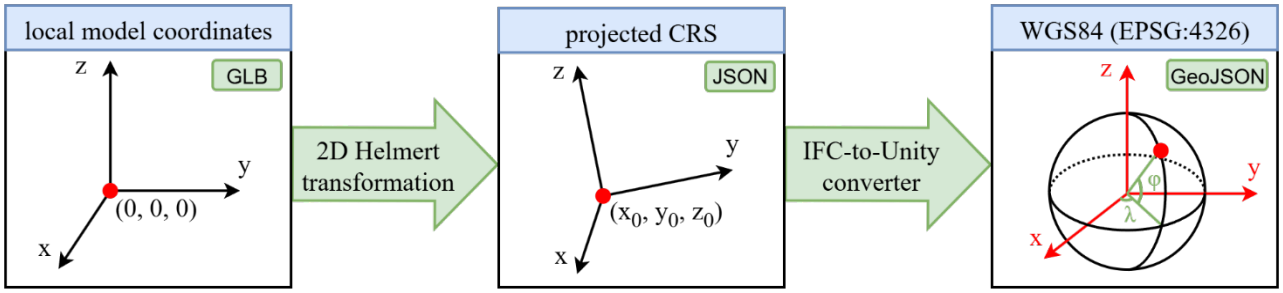

Figure 5: workflow for coordinate transformation to increase interoperability

Transmission of Geometric Information

As Unity cannot read the IFC schema, an appropriate 3D file format is selected to minimize data volume and loading times. Lee et al. (Lee *et al.*, 2019) compare the performance characteristics of commonly used 3D file formats, such as OBJ, STL, FBX, glTF and GLB. The analysis shows that glTF and GLB exhibit the highest rendering efficiency based on measured loading times within a web application.

A glTF asset is represented by a JSON-formatted (.gltf) file that contains a complete scene description, accompanied by separate binary files that store geometry data and image files that contain textures. If all this information is encapsulated within a single container file, the format is referred to as GLB. (Khronos Group, 2021)

To minimize loading times in the AR application while reducing the number of files to be managed, GLB is selected as the export format.

To transform the data from IFC to GLB, Python is used in combination with the *ifcopenshell* package (*IfcOpenShell*, 2024). The *ifcopenshell.geom* extension is used to control the geometric properties.

Since length units may be defined differently in different IFC files (see Table 1), the converter verifies whether the coordinates are defined in the length unit metre. If this is not the case, the coordinates are converted to metres before the transformation is applied.

Test IFC 1 (see Table 1) contains building openings that are modeled using void elements (*IfcOpeningElement*). To prevent these void elements from being exported as visible 3D objects into the GLB file, an auxiliary function is implemented within the codebase that collects the IDs of all objects of the type *IfcOpeningElement* and enforces the creation of openings in the GLB file by explicitly enabling opening subtractions. For this purpose, the software package *ifcopenshell* (*IfcOpenShell*, 2024) is utilized. During the export process, the filtered void elements are excluded.

Transmission of Semantic and 4D Information

The GLB format is geometry- and material-centric and does not provide a standardized way to natively represent IFC semantic information such as entity types, property sets or relational structures.

Various file formats are used in the literature to store semantic data for AR applications. Common options include CSV (Arvikar *et al.*, 2025), XML (Rehman *et al.*, 2025) and JSON (Lieblich & Weise, 2013). As XML (Extensible Markup Language) and JSON (JavaScript Object Notation) are both object-based, they can represent hierarchies and relationships derived from the IFC structure. This makes them particularly well-suited to the BIM-to-field use case.

As buildingSMART provides a dedicated ifcXML standard (Lieblich & Weise, 2013), XML is the preferred choice for representing the pure IFC structure. However, the performance of the AR application on the construction site poses a significant challenge within the BIM-to-field context. In this regard, the JSON format offers a significant advantage as it can be parsed more efficiently (Afsari *et al.*, 2017), resulting in improved runtime performance. Consequently, JSON is used as exchange format.

Before the properties are written to the JSON file, the converter first enriches a duplicated IFC model (B2F IFC) with the required entities.

At this stage, supplementary information – specifically scheduling and responsibility data (see Figure 2) – is extracted from a construction schedule. For validation purposes, a simplified schedule in JSON format is used, incorporating information on *IfcTask*, *ScheduleStart*, *ScheduleFinish*, *IfcCrewResource*, *IfcLaborResources*, *IfcActor*, *IfcPerson and IfcOrganization.*

Once the properties have been added to the B2F IFC, the BIM-to-field–relevant information is stored in an object-based manner in JSON format using Python. The exported properties are mapped to the corresponding 3D object using the GUID as the linking key.

Transmission of Geospatial Information

Geospatial information is stored in accordance with the workflow illustrated in Figure 5. Local model coordinates are stored in the GLB file to improve rendering performance and avoid visual artefacts. The projected coordinate reference system used during the planning phase is stored as an object in a JSON file. This enables spatially consistent, project-specific alignment and assembly of multiple models.

To further enhance interoperability, particularly with GIS applications, the coordinates of the projected coordinate reference system are also transformed into the WGS84 reference system and stored in GeoJSON format.

The converter uses the Python package *pyproj* (*pyproj*, 2026) to transform the coordinates into the target system (WGS84; EPSG:4326). As illustrated in Figure 5, the local model coordinates are transformed into global coordinates, and the EPSG code defined in IfcProjectedCRS is used to determine the source CRS for transforming the model origin into WGS84.

The geospatial coordinates stored within the IFC model itself remain unchanged.

Graphical User Interface

Figure 6 illustrates the graphical user interface (GUI) of the developed IFC-to-Unity Converter. To provide planning data for use in a BIM-to-field application in the most accessible and flexible way possible, the GUI has been designed so that the core functionalities can be controlled via the GUI. Accordingly, the converter functions described in the preceding sections can be selectively enabled via the GUI. The default configuration is shown in Figure 6.

Geometry-related functions are not selected by default in the GUI as these operations are only required when the underlying IFC file does not conform to the modelling standard. In such cases, in addition to the geometry functions already described, the GUI provides further options to rotate the model around the Z-axis and redefine

the Z-axis (force Z-axis), should the coordinate system be misinterpreted.

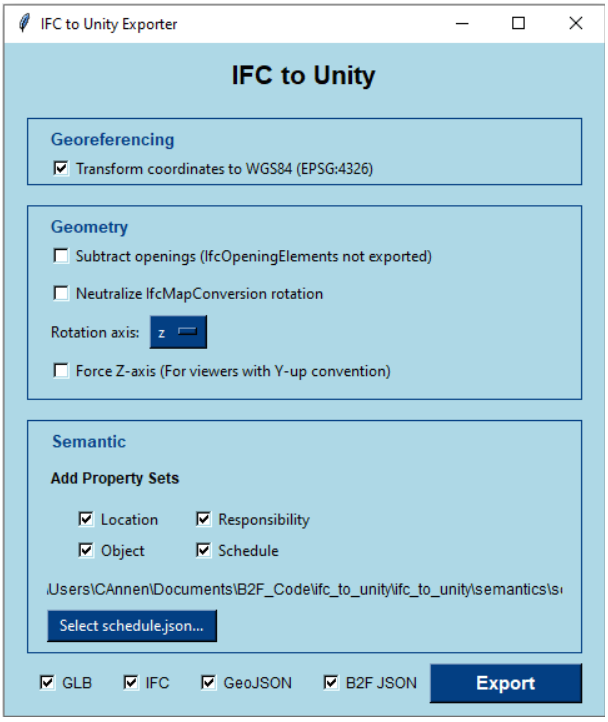

Figure 6: Graphical User Interface of the Converter

Validation

The validation of the IFC-to-Unity converter was carried out in two phases:

(1) preparation of the input data and
(2) execution of the validation.

Twelve IFC models were used as input data. Additional model information is summarized in Table 2. As no construction schedules were available for these models, model-specific schedule files were generated automatically from the IFC data. For this purpose, a Python-based schedule generator was developed to identify *IfcProduct* entities with geometric representations, group them by building storey and element category, and assign them to the trade groups structural works, finishing works, building services and other works. Based on this, deterministic synthetic actors and sequential task schedules were created.

The implementation was carried out in Python using *IfcOpenShell* for IFC parsing and geometry-related model queries. Standard Python libraries were employed for grouping, identifier generation, schedule logic and serialization. The objective was not to create technically realistic construction schedules, but to provide formally complete schedule data in JSON format, containing all input parameters required by the converter and thereby covering the previously defined minimum information requirements.

After a suitable schedule had been generated for each IFC file listed in Table 2, the resulting IFC-schedule pairs were processed by the IFC-to-Unity converter and transformed into the target formats GLB, IFC, GeoJSON, and B2FJSON. All input files were successfully transformed and thus formed the basis for the subsequent validation phase.

Table 2: IFC Files used for Validation

File	Model	Nr. of Objects	Size
1.1	structural	693	73058 KB
1.2	architectural	380	912 KB
2.1	structural	1138	49974 KB
2.2	architectural	469	922 KB
3.1	structural	435	79480 KB
3.2	architectural	322	1044 KB
4.1	structural	1016	80595 KB
4.2	architectural	639	1840 KB
5.1	structural	778	77369 KB
5.2	architectural	698	1897 KB
6.1	structural	890	17205 KB
6.2	architectural	383	972 KB

During validation, particular attention must be paid to the quality of the input data. The converter fully populates the entities assigned to the categories *Schedule* and *Responsibility* shown in Fig. 2, whereas those assigned to *Element* and *Location* depend on the completeness of the information contained in the input data. For example, if no material is assigned to an element, the exporter cannot infer the missing information automatically.

Accordingly, the validation is performed as follows. The properties assigned to the categories *Element* and *Location* are checked by means of scripts such that missing properties are reported only as warnings during export. By contrast, the properties assigned to *Schedule* and *Responsibility* must be transferred completely and correctly. Any deviation detected in these categories is therefore reported as an error during export. The whole validation process is shown in Figure 7.

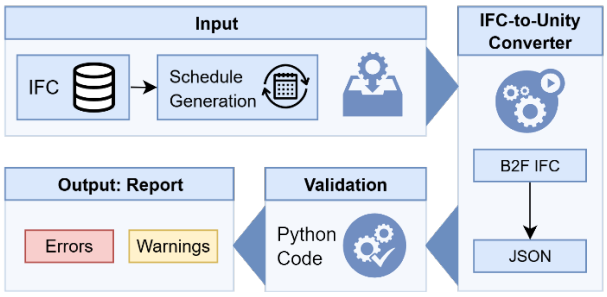

Figure 7: Validation Workflow

The validation is considered successful if the reports for the IFC files listed in Table 2 contain no errors and if all warnings can be logically explained.

The validation is performed on the exported JSON file, as this file is generated at the final stage of the IFC-to-Unity workflow. If a given piece of information is present in the JSON file, it can be assumed that it has also been successfully transferred to the B2F IFC.

The results of the validation are shown in Table 3.

Table 3: Validation Results

File	Attributes Checked	Errors	Warnings	Warning Ratio
1.1	8494	0	638	7.5%
1.2	15882	0	1526	9.6%
2.1	10601	0	654	6.2%
2.2	26916	0	2484	9.2%
3.1	7094	0	627	8.8%
3.2	9507	0	935	9.8%
4.1	14584	0	1132	7.8%
4.2	23968	0	2302	9.6%
5.1	15758	0	1374	8.7%
5.2	17377	0	1667	9.6%
6.1	8650	0	632	7.3%
6.2	21086	0	2072	9.8%
Total	**179917**	**0**	**16043**	**8.7%**

The warnings can be attributed to the following issues:

(1) the IFC source data do not provide values for either *Name* or *LongName* of *IfcBuilding* and
(2) some objects within the spatial IFC structure are not assigned to an *IfcBuildingStorey*.

As both warning types result from inconsistent input data, they are considered acceptable within the scope of the pipeline validation. Since the cross-model verification reveals no errors, the validation of the IFC-to-Unity converter is therefore considered successful.

Conclusions

Within the scope of this paper, various approaches are investigated to transform information from a building information model into a format readable by a game engine (Unity). It is demonstrated how both geometric data and semantic information can be transferred in a structured and interoperable manner. In accordance with the principles of OpenBIM, IFC version 4.3 ADD2 is employed as the source format for data transformation.

This paper formulates semantic requirements for building information models and the underlying IFC schema in order to enable the BIM-to-field use case for trades and construction workers in the construction industry. A set of relevant entities is defined based on IFC4X3_ADD2 to support targeted coordination among different trades. This includes information on building element properties, responsibilities, construction schedules and spatial location on the construction site. By relying on standardized IFC entities, interoperability between heterogeneous BIM authoring tools is ensured, while simultaneously establishing a foundation for enriching IFC models with additional information acquired during construction in future developments.

For geometric representation, GLB is identified as a suitable target format, while JSON is proposed for the transmission of semantic information. With regard to the export of 3D data, particular attention is given to the handling of IFC models that have already been georeferenced during the planning phase using *IfcMapConversion*.

While Unity operates using local model coordinates, BIM-based building planning typically relies on cartesian CRS. In contrast, data integration into GIS environments requires the use of global coordinate reference systems. To enhance interoperability in the context of data exchange, a workflow for handling these differing geospatial requirements is presented.

Furthermore, strategies are presented to prevent the export of non-essential 3D objects (e.g., *IfcOpeningElement*) by selectively filtering them out of the resulting GLB file.

Based on these findings, an IFC-to-Unity converter was developed and successfully validated.

In the context of further research, the defined information requirements will be refined and extended with trade-specific attributes. In addition, an interface for integrating construction scheduling data will be developed. This includes the specification of a linkage to scheduling tools commonly used during the planning phase, enabling the consideration of complex temporal dependencies within a BIM-to-field application. Moreover, future work will investigate methods for integrating newly acquired on-site information into the planning model. Within the field-to-BIM approach, particular emphasis will be placed on integrating schedule updates and construction progress data into the BIM environment.

BIM–AR INTEGRATION IN PRACTICE: OPPORTUNITIES, CHALLENGES, AND TRADE-OFFS FROM A LIVE CONSTRUCTION CASE STUDY

Avar Almukhtar, Muhammad Shahzad, Marri Deepak Kumar, Joseph H.M Tah
Oxford Brookes University, Oxford, United Kingdom

Abstract

Building Information Modelling (BIM) and Augmented Reality (AR) integration has been widely proposed to improve construction coordination, yet evidence from live site deployments remains limited. This paper presents a qualitative case study of BIM–AR use with Gamma AR on an active university accommodation project in the UK. Site observations and interviews were used to examine workflow integration, benefits, and challenges. The findings indicate that BIM–AR enhances visualisation, coordination, and early error detection when applied selectively, but is constrained by alignment reliability, site conditions, and adoption factors. The study contributes practical deployment insights for BIM–AR implementation in construction.

Introduction

The Architecture, Engineering and Construction (AEC) industry continues to face persistent inefficiencies arising from fragmented information flows, bespoke project delivery practices, and limited integration between design intent and site execution (Wuni et al., 2024; Mujahed et al., 2025; Farea et al., 2026). Building Information Modelling (BIM) has emerged as a central response to these challenges by enabling shared digital representations of built assets and supporting coordination across disciplines and project lifecycle stages (Waqar et al., 2023; Rezgui et al., 2025). Through standardised data structures and interoperable formats such as Industry Foundation Classes (IFC), BIM provides a common information backbone that improves data consistency and cross-disciplinary communication (Gerbino et al., 2021; Lee et al., 2021; Chatsuwan et al., 2025).

In parallel, Augmented Reality (AR) has gained increasing attention as a means of improving how digital construction information is accessed and interpreted on site. By overlaying virtual content onto the physical environment via mobile or head-mounted devices, AR enables more intuitive, spatially contextualised interaction with BIM data compared to conventional screen-based tools (Alizadehsalehi et al., 2020; Sidani et al., 2021; Chen and Xue, 2022). Prior research reports that AR can enhance spatial understanding, support design review and progress monitoring, and facilitate early detection of discrepancies between planned and as-built conditions (Amin et al., 2023; Girgin et al., 2023; Tan et al., 2024; Pan and Isnaeni, 2024). AR-based visualisation has also been associated with improved task accuracy and reduced error rates through just-in-time guidance and in-situ verification (Dallasega et al., 2023; Marino et al., 2024; Chaudhari et al., 2025).

The integration of BIM and AR therefore holds promise for narrowing the long-recognised gap between digital project models and physical site realities. Empirical and review studies have demonstrated potential productivity and accuracy gains from BIM–AR integration across activities such as design review, assembly, discrepancy checking, and hazard identification (Fazel and Adel, 2024; Tan et al., 2024; Arvikar et al., 2025). However, despite these reported benefits, adoption of BIM–AR on live construction projects remains limited. Prior work consistently highlights challenges related to model preparation and interoperability, alignment and tracking accuracy, hardware constraints, environmental interference, and the need for user training and workflow adaptation (Schiavi et al., 2022; Kolaei et al., 2022; Amin et al., 2023; Jin et al., 2026). Importantly, these challenges are increasingly recognised as socio-technical in nature, with organisational readiness, staff capability, and compatibility with existing information management practices playing a decisive role in determining whether AR solutions deliver value in practice (El Asmar et al., 2021; Wang et al., 2024).

A key limitation in the current body of knowledge is the scarcity of detailed, in-situ evidence documenting how BIM–AR integration is deployed on active construction sites using commercial platforms, and how such deployments interact with established project workflows. Much of the existing literature focuses on prototype systems, controlled experiments, or performance metrics such as alignment accuracy, offering limited insight into real-world deployment conditions, calibration practices, issue-management integration, and day-to-day usability trade-offs faced by site teams (Cheng et al., 2020; Girgin et al., 2023; Bhatarai et al., 2025). This gap constrains both practitioner decision-making and the translation of research outcomes into scalable industry practice.

This paper addresses this gap through a qualitative case study of BIM–AR integration using Gamma AR, a commercial AR platform deployed on a major construction project in Oxford, UK. The study examines

how Gamma AR was configured to access BIM models hosted on Autodesk Construction Cloud (BIM 360), how AR visualisation was used on site via handheld devices, and how issues identified in AR were linked back to established digital coordination workflows. Drawing on site observations and semi-structured interviews with project staff, the research investigates both the opportunities created by BIM–AR integration, such as enhanced visualisation, improved coordination, and early error detection, and the challenges encountered during live deployment, including alignment reliability, environmental and hardware limitations, data-update frictions, and user adoption barriers. Some of these barriers, particularly around usability, trust, and model interaction, can also be interpreted through the lens of Human–Data Interaction (HDI), where constraints in *legibility*, *agency*, and *negotiability* (Mortier et al., 2014) may help explain the limited mainstream adoption of BIM–AR technologies in construction settings.

The contribution of this paper is threefold. First, it provides an empirically grounded account of an end-to-end BIM–AR deployment using a commercial toolchain under live construction conditions. Second, it synthesises practitioner experiences into a structured analysis of observed benefits and challenges, complementing prototype-focused research with deployment-level evidence. Third, it derives practical implications for both construction teams considering AR adoption and developers seeking to reduce friction in BIM–AR integration, particularly in relation to workflow fit, usability, and calibration robustness.

The remainder of the paper is structured as follows: the next section presents the research methodology and case study context; this is followed by results and discussion; and the paper concludes with key findings and implications for future research and practice.

Methodology

This research adopted a qualitative case study approach to investigate the deployment of a BIM-integrated Augmented Reality (AR) solution on an active construction site. A case study method was selected as it is well suited to investigating emerging digital technologies in real-world contexts, where implementation conditions, workflows, and user interactions cannot be meaningfully isolated or controlled. Rather than seeking to quantify performance metrics, the study focuses on understanding how BIM–AR integration is configured, used, and experienced in practice.

Case Study Context

The case study was conducted on the Clive Booth Student Village redevelopment project at Oxford Brookes University, UK; a large-scale student accommodation development delivered by a major UK contractor. The project employed a coordinated BIM model hosted on Autodesk Construction Cloud (BIM 360) to support design coordination and construction management. Gamma AR, a commercial AR application designed for construction use, was introduced on the project to enable on-site visualisation of BIM models and support spatially contextualised issue identification.

Gamma AR was used via handheld tablet devices to overlay BIM content onto the physical construction environment in real time as shown in Figure 1. The application was configured to access the latest project models from BIM 360 and to synchronise AR-based issues capture back into the project's established digital coordination workflows. The deployment therefore represented a realistic, industry-facing implementation rather than a prototype or experimental system.

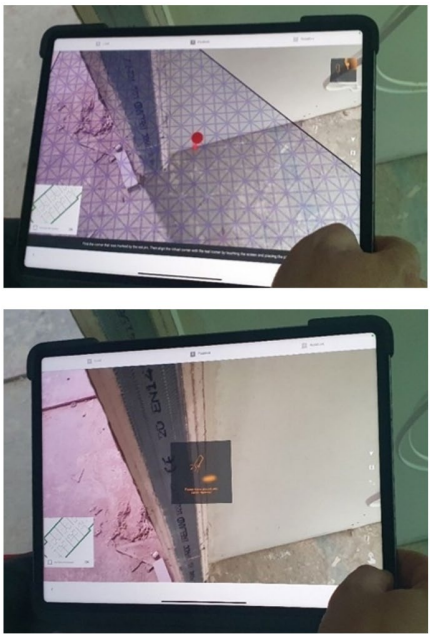

Figure 1: Identifying the purple mesh on a flat surface before restarting the Gamma Application

BIM-AR Workflow Configuration

To enable AR visualisation, the project's BIM model authored in Autodesk Revit, was exported in formats compatible with Gamma AR (including RVT, IFC, and NWC) and made available through the cloud-based BIM collaboration platform. On site, users selected relevant floors or zones within the Gamma AR application and aligned the virtual model to the physical environment using identifiable reference features such as structural gridlines and slab edges. Once aligned, the application maintained model registration using marker-less tracking based on the tablet's onboard sensors and camera.

A key aspect of the workflow was the integration of AR-based issue identification with the project's existing issue management processes. Discrepancies observed through the AR overlay could be logged directly within Gamma AR, including descriptive text and images, and synchronised back to BIM 360. This enabled issue identified in the field to be reviewed and addressed by the wider project team using familiar coordination tools. Figure 2 illustrates this BIM–AR workflow, from BIM

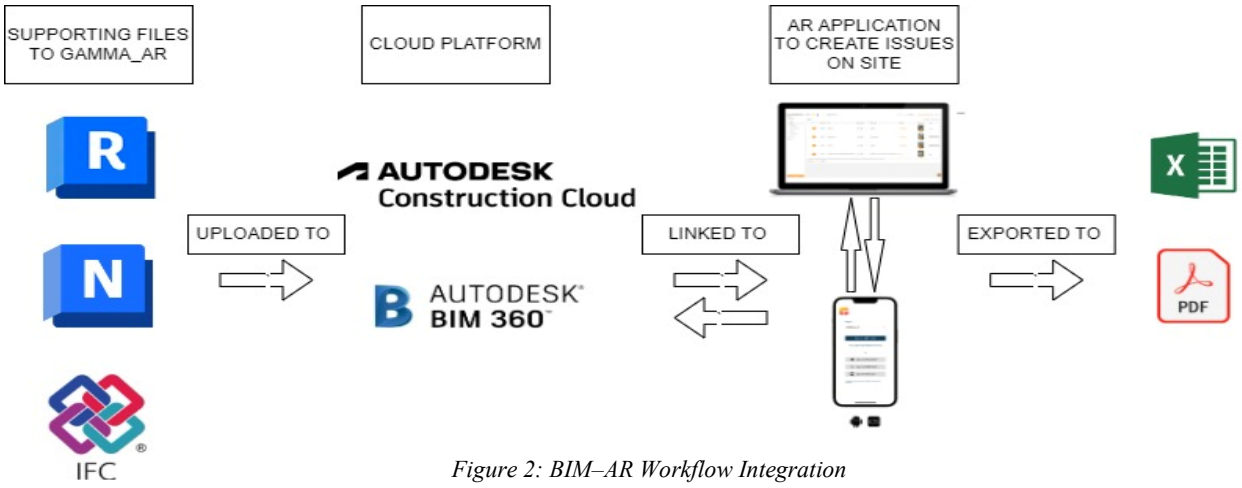

Figure 2: BIM–AR Workflow Integration

authoring and cloud-based model management to on-site AR visualisation and issue synchronisation.

Data Collection

Data collection combined direct site observations with semi-structured interviews involving members of the project team who actively used Gamma AR. Multiple site visits were conducted during which the researcher observed how site engineers and managers used the AR application for tasks such as installation verification, coordination discussions, and progress checks. Observational notes focused on alignment procedures, usage patterns, perceived benefits, and practical difficulties encountered during use.

Semi-structured interviews were conducted with six construction professionals involved in the project, including the site manager, BIM coordinator, a digital construction advisor, and site engineers. Participants were selected based on direct involvement with the Gamma AR deployment and their varied roles in on-site decision-making and BIM coordination. Interview questions explored participants' experiences with the AR tool, perceived value for construction coordination, challenges related to accuracy, usability, and workflow integration, and views on adoption and training requirements. A short questionnaire with 10 site-based staff members who had trialed the AR tool was used to supplement interview data and capture recurring themes across participants.

Data Analysis

The collected qualitative data were analysed using a thematic approach. Observation notes and interview transcripts were coded to identify recurring patterns related to (i) opportunities created by BIM–AR integration, such as enhanced visualisation, coordination, and error detection, and (ii) challenges encountered during deployment, including technical limitations, environmental constraints, and user adoption issues. The analysis focused on identifying practical trade-offs and deployment considerations rather than measuring system performance quantitatively. The overall data collection and analysis process adopted in this study is summarised in Figure 3.

Figure 3: Data collection and thematic analysis process adopted in the Gamma AR case study

Scope and Limitations

The study is based on a single case study and is not intended to provide statistically generalisable results. Instead, it offers empirically grounded insights into BIM–AR deployment under real construction conditions. The findings should therefore be interpreted as illustrative of practical opportunities and challenges, rather than definitive performance evaluations of AR technology.

Results and Discussion

The deployment of Gamma AR on the Clive Booth Student Village project provided insight into how BIM–AR integration functions under real construction conditions. The findings are organised around three themes: (i) opportunities observed during on-site use, (ii) challenges encountered during deployment, and (iii) practical trade-offs that shaped how the technology was ultimately used in practice.

Opportunities of BIM-AR Integration

The Gamma AR deployment revealed several opportunities where BIM–AR integration added value to construction coordination and decision-making. Importantly, these opportunities emerged not from automation or measurement precision, but from enhanced contextual access to BIM information within the physical site environment. One site engineer remarked, *"It's easier to understand what you're building when the model is literally on the slab. It helps reduce confusion from the drawings."* Similarly, the BIM coordinator observed, *"Having the model in the space gave the client a clearer picture — they could point out issues straight away."*

Enhanced visualisation of design intent in context

The most consistently reported opportunity was improved spatial understanding of design intent on site. By overlaying BIM models directly onto partially constructed spaces, Gamma AR enabled site personnel to visualise upcoming works in context, particularly during early fit-out stages where two-dimensional drawings were difficult to interpret. AR was frequently used to preview partition layouts, service routes, and spatial clearances prior to installation, supporting more intuitive comprehension of scope and sequence. From a Human–Data Interaction (HDI) perspective, this enhanced the *legibility* of BIM data by making abstract digital information more comprehensible in its physical context, particularly for those without prior technical training.

This finding aligns with prior research showing that AR enhances spatial cognition and design comprehension by reducing the mental effort required to translate abstract representations into physical form (Sidani et al., 2021; Chen and Xue, 2022). However, the case study suggests that these benefits are most pronounced when AR is used selectively for spatially complex tasks, rather than as a general-purpose visualisation tool. In this sense, AR acted as a cognitive aid, supporting shared understanding rather than replacing conventional drawings.

Improved coordination and communication workflows

BIM–AR integration supported stronger on-site coordination by enabling discrepancies between the BIM model and site conditions to be identified and discussed directly within the physical environment. In several observed instances, AR overlays revealed potential clashes, such as conflicts between services and structural elements that had not been immediately apparent in drawings or model reviews conducted off-site.

The ability to capture issues directly from the AR interface and synchronise them with BIM 360 shortened feedback loops between site and design teams, reducing reliance on post-hoc interpretation of photographs or annotated drawings. This supports findings from prior studies reporting that BIM–AR integration can improve coordination efficiency by anchoring discussions around a shared, spatially contextualised representation (Garbett et al., 2021; Girgin et al., 2023). Notably, the effectiveness of this workflow depended on tight integration with existing issue-management processes; AR added value by augmenting, rather than bypassing, established coordination practices.

Error reduction and quality assurance support

AR functioned as a practical quality assurance aid by enabling rapid "overlay checks" between planned and installed elements. In one example, a minor misalignment in pipework was detected when the virtual model did not align with the physical installation, prompting immediate correction. While AR was not treated as a precision measurement tool, it provided a fast and visually intuitive means of identifying potential issues early, reducing the likelihood of downstream rework.

This use of AR as a screening mechanism rather than a substitute for formal inspection or surveying was viewed positively by site staff and is consistent with prior experimental findings that AR can reduce human error in construction tasks by improving perceptual alignment between design intent and execution (Fazel and Adel, 2024; Surri and Kuncoro, 2025). The case study reinforces that AR's value in quality assurance lies in early detection and visual confirmation, rather than in guaranteeing geometric accuracy.

Time savings in issue identification and resolution

Although time savings were not formally quantified, interviewees consistently reported that AR-based issue identification reduced time spent interpreting drawings and clarifying spatial problems. The integration of issue capture within the AR environment allowed problems to be communicated with fewer clarification cycles, particularly for spatially complex issues.

Site managers estimated that certain issues were resolved in approximately half the time compared to conventional workflows, largely due to improved shared understanding rather than process automation. This aligns with findings by Wang et al. (2024), who reported that AR-supported workflows reduced selected process durations by up to 50% in comparable construction contexts. However, the case study suggests that such time savings are highly task-dependent and should be interpreted as indicative rather than guaranteed performance gains.

Stakeholder engagement and confidence

An indirect but notable opportunity was improved engagement with clients and non-technical stakeholders. During site visits, AR visualisations helped communicate layouts, progress, and design intent more effectively than drawings or screen-based models, increasing stakeholder confidence in coordination decisions. This immersive mode of communication reduced misunderstandings and supported more informed discussions around design changes.

While difficult to quantify, these effects echo prior research suggesting that AR's experiential "walkthrough" capability can enhance stakeholder engagement and support transparency in construction projects (Mutis and Ambekar, 2020; Wang et al., 2013). In the present case, AR also contributed to a perception of innovation among site staff, supporting openness to digital tools. However, such engagement benefits were contingent on usability and reliability; technical friction quickly diminished perceived value.

Challenges in BIM-AR Deployment

While the Gamma AR trial demonstrated clear value, it also revealed a range of challenges that reflect the current limitations of BIM–AR integration under live construction conditions. These challenges are discussed below, drawing on both empirical observations from the case study and findings reported in recent literature.

Model alignment and registration reliability

Achieving and maintaining reliable alignment between the BIM model and the physical environment was one of the most persistent technical challenges as shown in Figure 4. Users reported occasional drift or offset in the AR overlay, typically attributable to imprecise initial calibration, cumulative tracking error, or changes in the surrounding environment. Similar alignment instability has been widely reported in prior studies, particularly in markerless AR systems deployed on construction sites (Surri and Kuncoro, 2025; Schiavi et al., 2022).

To mitigate this issue, site staff relied on known reference features (e.g., slab edges, gridlines) and periodically rechecked alignment during use. While these workarounds were effective in maintaining acceptable visual correspondence, they introduced additional setup effort and reduced confidence in using AR for fine-grained verification tasks. Minor alignment errors also risked false interpretations, such as suggesting an installation was incorrect when the overlay itself was inaccurate, highlighting the need for more robust and transparent registration mechanisms. This reinforces findings by Cheng et al. (2020) and Girgin et al. (2023), who emphasis that registration reliability remains a critical barrier to dependable AR deployment in construction.

Figure 4: Aligning the level manually

Environmental and site condition constraints

Construction site conditions introduced several practical limitations for AR use. Bright daylight caused screen glare that reduced visibility on tablet displays, while cluttered or visually homogeneous environments occasionally disrupted feature detection and tracking stability. Unlike controlled indoor settings, lighting and surface conditions on site cannot be regulated, constraining when and where AR can be used reliably.

These challenges align with previous research noting that environmental variability significantly affects AR performance in construction contexts (Machado and Vilela, 2020; Kolaei et al., 2022). In practice, AR use was often restricted to shaded areas, interior spaces, or specific times of day to ensure acceptable visibility. This highlights the importance of hardware and visualisation modes optimised for outdoor use, as well as tracking algorithms resilient to changing lighting and surface conditions.

Hardware and usability limitations

The choice of hardware strongly shaped the AR experience. Using tablets provided accessibility and a low barrier to entry, consistent with industry preferences for familiar devices. However, prolonged use resulted in rapid battery drain and user fatigue from holding the device for extended periods. While head-mounted displays were discussed, they were considered impractical for routine site work due to known limitations such as restricted field of view, added weight, and user discomfort.

These observations are consistent with recent studies reporting that extended AR use, particularly with head-mounted devices, can cause physical discomfort and reduced situational awareness, potentially increasing safety risks on construction sites (Chen et al., 2024; Sidani et al., 2021). Although Gamma AR's compatibility with standard mobile devices is a strength, effective deployment still depends on access to relatively recent hardware with sufficient processing power and battery capacity, which introduces procurement and cost considerations.

Data management and integration frictions

Maintaining smooth BIM–AR data flow presented additional challenges. Large or highly detailed BIM models required simplification to ensure acceptable performance on mobile devices, necessitating deliberate model optimisation strategies. Furthermore, model updates introduced workflow friction: exporting and reloading revised models into Gamma AR took time and depended on reliable site connectivity.

On one occasion, limited Wi-Fi connectivity delayed synchronisation of newly logged issues with BIM 360, echoing findings from prior studies that highlight connectivity and data transfer as persistent constraints for BIM-based AR in construction environments (Cheng et al., 2020; Bhatarai et al., 2025). While Gamma AR's integration with BIM 360 was broadly effective, not all metadata were consistently accessible through the AR interface, limiting the depth of information available in the field. These findings underscore the dependence of BIM–AR workflows on robust digital infrastructure and carefully planned update strategies, including offline or pre-download options where network coverage is unreliable.

User adoption and learning curve

Beyond technical constraints, human factors emerged as a significant barrier to adoption. User acceptance varied across roles and experience levels, with initial scepticism particularly evident among staff accustomed to traditional drawings and paper-based workflows. Survey and interview feedback highlighted limited awareness of AR

capabilities, resistance to changing established practices, and concerns about implementation cost and learning effort.

Adoption improved when the technology was actively championed by site leadership and supported by hands-on demonstrations and vendor assistance. However, participants consistently noted that effective use "takes time to learn," reinforcing findings from Wang et al. (2024) and El Asmar et al. (2021) that training, managerial commitment, and usability strongly shape AR uptake in construction. These observations indicate that ease of use, intuitive interfaces, and minimal interaction overhead are critical for sustaining long-term adoption on site.

Table 1 summarises the key opportunities and challenges observed during the Gamma AR deployment, providing an overview of the empirical findings discussed in this section.

Table 1: Summary of key opportunities and challenges observed during the Gamma AR case study.

Opportunities (Benefits Observed)	Challenges (Issues Encountered)
Enhanced visualisation of design intent in real spatial context, improving comprehension of complex layouts.	Alignment and registration issues - occasional model drift requiring manual recalibration and confidence checks
Improved coordination and communication through shared AR views and faster on-site issues identification	Lighting and environment interference - screen glare and tracking instability under bright or cluttered site conditions.
Error reduction and quality assurance support by identifying discrepancies early and reducing downstream rework	Hardware limitations - battery drain, device fatigue, and dependence on relatively recent mobile hardware
Time savings in issue verification and resolution through streamlined AR-based logging and visual explanation	Data integration frictions - model preparation effort, update delays, and reliance on reliable site connectivity
Stakeholder engagement via intuitive 3D visualisation that improved confidence during site discussions	User adoption barriers - learning curve, resistance to change, and need for training and managerial support

Trade-offs and Practical Implications

The Gamma AR case study highlights several trade-offs inherent in BIM–AR deployment on live construction projects. While AR improved visualisation, coordination, and issue communication, these benefits were accompanied by additional effort related to model preparation, alignment, device management, and user training. Understanding these trade-offs is critical for determining when and how AR should be deployed to deliver net value in practice.

A central trade-off observed was productivity versus preparation. AR supported faster inspections, coordination discussions, and issue resolution once operational; however, achieving this reliability required upfront investment in model optimisation, calibration, and troubleshooting. For brief or low-complexity tasks, this overhead could outweigh the immediate benefits. In contrast, for projects characterised by spatial complexity and repeated coordination demands, the investment was more likely to pay off. A practical implication is that AR should be targeted at high-value use cases, such as scheduled coordination walks, stakeholder reviews, or verification of critical installations rather than applied indiscriminately across all site activities.

A second trade-off concerned immersion versus practicality. Although head-mounted AR systems can offer hands-free and immersive experiences, the project team preferred tablet-based AR due to comfort, familiarity, and ease of integration into everyday site routines. This suggests that the most effective AR solutions for construction are not necessarily the most immersive, but those that fit seamlessly into existing workflows. From a design perspective, construction-oriented AR tools should prioritise usability, rapid set-up, outdoor-readable displays, and one-handed operation over advanced visual realism.

The study also revealed a trade-off between accuracy and effort. High-precision alignment typically demands additional setup steps, such as multiple calibration points or physical markers, whereas faster registration can reduce confidence in positional accuracy. In this case, AR was used pragmatically as a screening and communication tool, with apparent discrepancies verified using conventional methods such as laser measurement. This approach helped maintain trust in technology while avoiding over-reliance. Design implications include the need for clearer uncertainty cues, faster recalibration mechanisms, and training that reinforces AR as a decision-support aid rather than an infallible measurement system. From a Human–Data Interaction (HDI) perspective, Gamma AR supported *agency* by enabling users to interrogate and act on real-time overlays. *Negotiability* was evident in on-site discussions where planned elements were confirmed or challenged in context. However, these affordances also raised *privacy* concerns around the passive capture of site conditions and worker activity, pointing to the need for ethical data handling and user awareness.

From an organisational perspective, the trade-off between innovation and disruption was evident. Introducing AR altered established routines for issue reporting and coordination, requiring staff to adapt to new information flows. Adoption improved when AR use was visibly supported by site leadership and introduced incrementally with clear purpose. This reinforces prior findings that managerial commitment, training, and structured protocols are decisive factors in successful AR deployment in construction (Wang et al., 2024). Without

attention to these human factors, even technically robust AR solutions risk limited uptake.

Several broader design implications emerge from the case. First, tight integration with existing common data environments is essential; AR tools should operate as extensions of established platforms rather than standalone systems. Second, interface simplicity and low interaction overhead are critical, as on-site users have limited tolerance for complex configuration. Third, future AR platforms could further extend value through real-time collaboration features, such as multi-user sessions or remote expert support, which were not available in this deployment but were strongly desired by participants.

Overall, the findings point to a pragmatic principle for BIM–AR deployment: flexibility over prescription. Gamma AR was most effective when treated as an optional support tool rather than a mandated process. Site teams used AR when it added clear value and reverted to conventional methods when these were faster or more reliable. This coexistence suggests that AR does not need to replace established practices to be useful; instead, it can enhance them when deployed selectively and thoughtfully.

Conclusion

This paper investigated the deployment of a BIM-integrated Augmented Reality (AR) solution on an active construction site through a qualitative case study of Gamma AR on a large-scale university accommodation project in the UK. By focusing on real-world use rather than controlled experimentation, the study provides empirical insight into how BIM–AR integration operates in practice and interacts with established construction workflows.

The findings demonstrate that BIM–AR integration can deliver tangible benefits when applied selectively to coordination, visualisation, and quality assurance tasks. AR-supported overlays improved spatial understanding of design intent, facilitated clearer communication between site and office teams, and enabled earlier identification of discrepancies between planned and as-built conditions. These benefits were driven not by automation or precision measurement, but by enhanced shared understanding and contextualised access to BIM information. When integrated with existing issue-management workflows, AR reduced interpretation effort and shortened feedback loops.

At the same time, the study highlights practical constraints on BIM–AR deployment, including alignment reliability, environmental conditions, hardware limitations, model maintenance effort, and user adoption factors. The findings indicate that AR is most effective when treated as a complementary tool rather than a replacement for established practices, supporting early detection and discussion while relying on conventional methods for precise verification.

The contribution of this paper lies in documenting an end-to-end BIM–AR deployment using a commercial platform under live construction conditions and articulating the trade-offs that shape practical use. While limited to a single case study and handheld AR configuration, the findings provide deployment-level evidence that can inform both practitioners considering AR adoption and developers seeking to improve BIM–AR integration. Overall, the study reinforces that realising the potential of BIM–AR depends less on technological sophistication than on alignment with site realities, user practices, and existing digital workflows.

SPACE-DRIVEN KNOWLEDGE: A TOPOLOGICAL FRAMEWORK FOR SEMANTIC INFERENCE IN BUILDINGS

Isabelle Fitkau, Max Hammer, and Maximilian Sternal
Technische Universität Berlin, Germany

Abstract

Current building modeling approaches treat geometry as primary and semantics as secondary, limiting knowledge-integrated building design where spatial reasoning informs iterative design decisions. This paper presents a space-driven knowledge framework that integrates topological space partitioning with semantic triple generation, enabling immediate inference over spatial relationships. The workflow progresses through iterative stages of partitioning, algorithmic triple generation from topological queries and quantity calculations, axiomatic reasoning, and rule-based inference for requirements. A proof of concept demonstrates how storey classification, spatial adjacency, and fire safety requirements can be inferred during the modeling process using the BOT ontology extended with fire safety concepts from FiSa.

Introduction

Building design is inherently iterative (Pauwels and Bod, 2014). Regulatory requirements arise from building-level classifications to component-level specifications, depending on geometric and functional properties that emerge during design. However, current workflows separate modeling from compliance checking, meaning designers receive feedback on regulatory implications only after committing to spatial configurations.

This paper argues for a different approach in which semantic knowledge is assigned simultaneously with geometric modeling, allowing immediate reasoning about classifications and requirements. Rather than treating semantics as metadata attached after modeling geometry, we propose treating every modeling operation also as a knowledge-modeling event. When a designer partitions a building envelope into storeys, this operation should not only create geometric objects, but also instantiate semantic resources, compute quantities, and trigger inference rules that classify those objects.

The technical foundation combines two domains. Topology-aware modeling kernels, such as Topologic (Jabi and Chatzivasileiadi, 2021) and the Partition Platform (Sternal et al., 2025; Sternal, 2025; Huhnt et al., 2023), provide space partitioning operations that inherently compute spatial relationships. Semantic web technologies such as triple stores, ontologies, SPARQL, and rules provide mechanisms for representing, querying, and reasoning over knowledge. This paper presents a framework coupling these into a ”space-driven knowledge” workflow: a topology-aware kernel performing space partitioning, a triple store persisting semantic knowledge using BOT (Rasmussen et al., 2017) and FiSa (Fitkau and Hartmann, 2024), and an inference engine deriving new knowledge. The workflow proceeds through iterative cycles of **model**, **assign**, **compute**, and **infer**. Triples are generated algorithmically from topological queries, axiomatically through OWL reasoning, or through custom rules.

With spatial relationships and derived classifications explicitly represented in real-time throughout the architectural design process, changes to geometry automatically derive to updated inferences, enabling exploration of alternatives, e.g., with awareness of their regulatory consequences. Recent frameworks for the evaluation of early-phase design variants integrate spatial, structural, and environmental feedback in iterative design loops (Napps et al., 2026). Our work complements such approaches by providing the topological and semantic basis from which variant-specific classifications and requirements can be derived continuously during modeling. This paper makes two contributions: (1) a framework coupling geometric and topological modeling with semantic inference, and (2) a proof of concept demonstrating storey classification and fire safety requirement inference. We focus on the building scale while indicating how the approach extends to multi-scale contexts.

Background

First, a theoretical background introduces the main concepts of the proposed design workflow.

Design as an Iterative Process

Current CAD and BIM tools support geometric iteration and semantic attribute management, but evaluative knowledge remains disconnected from the modeling process. Requirements checking typically occurs after design decisions are made (Eastman et al., 2009; Pauwels et al., 2011), despite design being an inherently iterative, model-based reasoning process (Pauwels and Bod, 2014).

Coupling semantic inference with geometric modeling allows designers to observe how spatial configurations affect classifications and requirements during iteration (Pauwels et al., 2024). This requires information systems in which

spatial operations produce both geometric objects and semantic assertions.

Space Partitioning

Traditional geometric modeling represents shapes through boundary representations (B-rep) or constructive solid geometry (CSG), focusing on the geometry itself rather than its spatial relationships. Topology-aware modeling approaches instead emphasize the relational structure of space through the use of topologically connected data structures, creating a consistent hierarchical partition of space through subdivision (Huhnt et al., 2023). Therefore, such data structures offer direct topological queries without geometric computations (Massafra et al., 2024). However, these relationships typically remain within the geometric representation rather than being exposed as querable semantic triples (Donkers and Petrova, 2025). It should be noted that the modeling operations employed in topology-aware kernels, e.g., extrusion, slicing, and placement of primitives, are not fundamentally different from the established parametric design gestures in current CAD and BIM tools (Sternal et al., 2025).

The key distinction is not in the operators themselves but in the underlying paradigm. Many tools follow an object-centric approach, constructing components individually and validating consistency post-hoc. Space partitioning follows a space-centric approach in which the entirety of Euclidean space is subdivided into non-overlapping domains with inherently consistent topology. This guaranties manifold consistency by construction and provides a reliable geometric model for the semantic enrichment proposed in this paper.

The idea of a space-centric approach dates back to the 1970s, when soap-bubble and grid-bubble space management systems were explored (Eastman, 1999), yet adoption declined in favor of component-based tools that prioritize individual building elements over spatial coherence. Our framework addresses this gap by synchronizing topological computations with semantic knowledge graphs, going beyond what both early space management systems and current component-based tools offer.

Knowledge Management in Building Modeling

Building information workflows typically separate geometric modeling from semantic enrichment. This separation means that feedback on regulatory implications or other design related decision support arrives after spatial configurations are already established (Pauwels et al., 2024). Industry Foundation Classes (IFC) provide a unified data model that integrates geometry and semantics. However, file-based exchange treats semantic assignment as a pre-export step rather than a part of the modeling process itself. Authoring tools default to generic element types, and adding semantic knowledge requires effort disconnected from geometric manipulation (Beetz et al., 2009).

Semantic web technologies enable multiple domain-specific descriptions to coexist within a linked web of data, motivating coupling between modeling environments and semantic representations (Pauwels et al., 2012). Linked Building Data approaches represent building information as semantic graphs using the Resource Description Framework (RDF), which allows SPARQL queries and reasoning (Pauwels et al., 2011). Lightweight domain ontologies, such as the Building Topology Ontology (BOT) (Rasmussen et al., 2017), provide vocabularies for spatial structures corresponding to how designers progressively subdivide space. These representations can participate in design iterations when coupled with modeling environments.

Triple stores persist RDF data and support SPARQL queries. The deployment ranges from embedded libraries (RDFLib, RDF4J, Apache Jena) as shown by Elshani et al. (2026), to server-based endpoints (Fuseki, GraphDB) and federated architectures that distribute data between stakeholders (Werbrouck et al., 2024). Embedded approaches reduce latency for design-time integration, while federated architectures support collaboration but introduce consistency challenges during iteration.

Whereas some CAD tools are limited by restricted programmatic access to geometric and topological data through proprietary APIs, custom topology-aware kernels compute adjacency, containment, and connectivity as by-products of partitioning. When a horizontal plane subdivides a building volume into storeys, the kernel reports the resulting zones and which zones share faces or contain others. These facts map directly to BOT relationships (`bot:adjacentZone`, `bot:containsZone`), enabling triple generation from geometric operations. This provides a foundation for inference-guided design: the topology-aware kernel produces spatial relationships, the semantic model assigns and persists triples, and the inference engine derives classifications and properties. Computed quantities and extracted relationships feed classification rules that derive regulatory implications while geometry remains open to change. At the same time, data remain in their originating source.

Ontologies and Inference

Ontologies formalize domain knowledge as concept hierarchies and relationships interpretable by machines (Gruber, 1993). RDF represents knowledge as graphs of subject-predicate-object statements. OWL extends RDF with description logic semantics (Pauwels et al., 2011), which supports automated reasoning. Class membership can be inferred from property values, and property characteristics (transitivity, symmetry, inverse) derive knowledge through the graph. However, using OWL does not require utilizing its reasoning capabilities. Leveraging inference requires triggering a reasoner (Pellet, HermiT) that evaluates axioms against asserted facts. When reasoning is active, two mechanisms derive knowledge:

Axiomatic reasoning derives class memberships through necessary and sufficient conditions. OWL provides restrictions that constrain what holds for instances of a class.

Reasoners evaluate these definitions and automatically assign instances to their respective classes. This suits classifications derivable from properties, such as storey type from height and containment from transitivity. The same restrictions that enable classification also support consistency checking: a reasoner can detect when asserted facts contradict class definitions.

Rule-based inference handles conditions beyond OWL's expressivity, particularly arithmetic comparisons and conditions spanning multiple objects and properties. Custom rules can be written in rule languages, such as SWRL (Horrocks et al., 2004), Jena's rule syntax, Prolog, or native code. The mechanism often matters more than the syntax. When antecedent conditions match, consequent triples are asserted. Work on automated code checking (Eastman et al., 2009; Pauwels et al., 2011) demonstrated that regulatory logic can be encoded as executable rules in various formalisms.

We want to incorporate semantic inferences directly into the design process. We are not arguing against the continued use of rule-based applications for automatic compliance checking. However, an important distinction concerns missing information. OWL operates under the Open World Assumption (OWA), where absent statements are unknown, not false. Rather than lacking a fire stair, a building without an asserted fire stair might simply lack that information. OWL restrictions enable classification and consistency checking but cannot verify completeness. Constraint languages like SHACL operate under the Closed World Assumption (CWA), where absent information indicates a violation. Shapes verify that required properties exist and satisfy cardinality or value constraints, similar to OWL restrictions, but with different semantics suited for validation rather than classification. For iterative design, the OWA inference derives classifications and requirements from available information without treating incompleteness as an error. CWA validation fits later stages when completeness is expected before submission and permitting processes.

Our proposed framework uses OWL axioms and restrictions for classification and consistency, as well as custom rules for requirement property inference.

Method

The framework couples three components (Figure 1): a topology-aware modeling kernel, an RDF triple store, and an inference engine. Each component has distinct responsibilities and user inputs in the triple generation process.

Topology-Aware Modeling Kernel

The modeling kernel handles geometric operations: space partitioning through parametric design operations (extrude, slice, subdivide) and geometric checks. It maintains topological relationships between cells, including which faces are shared, which cells are adjacent, and which cells contain others.

The kernel exposes these relationships through a query interface. When partitioning creates new cells, the kernel reports not only the resulting geometry but also the topological facts: *Cell A and Cell B share Face F and are therefore adjacent,* which feeds the semantic model in the triple store. Example technologies include Topologic, which provides cellular complex operations via Python/C++ for non-manifold modeling, and the Partition Platform, which offers stepwise partitioning with history tracking via a custom Java kernel for manifold modeling. The presented framework is kernel-agnostic: any system that provides partitioning operations with topological relationship extraction can serve this role.

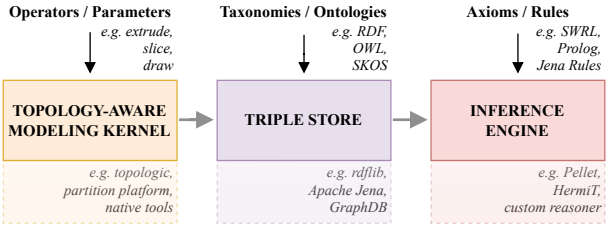

Figure 1: Framework architecture: topology-aware modeling kernel, triple store, and inference engine with their respective inputs and example technologies.

Triple Store

The triple store persists the semantic model as RDF graphs and provides query access to the knowledge base. It serves as the central repository where modeling operations generate triples, spatial relationships are stored, and inferred knowledge is materialized and maintained. RDF represents knowledge as serializable subject-predicate-object statements. Triple stores enable SPARQL queries over persisted graphs, allowing for the retrieval of objects, traversal of relationships, and filtering by properties. Updates to the triple store are managed through an inference model using a reasoner. This way, updates remain synchronized with the underlying storage, coordinating both asserted and inferred triples in their respective graphs.

Multiple named graphs can separate asserted facts (user-specified and algorithmically generated) from inferred knowledge for provenance tracking and inference validation. Implementation options range from embedded libraries to server-based systems. Embedded approaches minimize latency for design-time operations, while server-based deployments enable multi-user access and federated architectures (Werbrouck et al., 2024); however, synchronization complexity increases during iterative modeling.

Inference Engine

Inference engines derive new knowledge from asserted facts by applying logical rules and axioms over RDF triples (Eastman et al., 2009; Pauwels et al., 2011). Deductive reasoners apply description logic axioms to classify instances and derive properties through characteristics such as transitivity, symmetry, and inverse relationships. While axioms work well for property-based classifications, rule-based engines cover conditions beyond the expressiveness

of description logic. Forward chaining materializes all derivable triples upfront, while backward chaining can derive them on demand.

In building modeling, inference engines enable automated regulatory compliance checking, where geometric changes trigger the re-evaluation of derived classifications and requirements (Pauwels et al., 2024). This enables the exploration of regulatory consequences during design iterations. Domain ontologies such as ifcOWL (Beetz et al., 2009), BOT, and FiSa encode spatial relationships and component specifications that inference engines can operate on incrementally (triggered by triple store updates) or on-demand (invoked before queries). Incremental inference maintains a consistent knowledge state but incurs overhead with every update, whereas on-demand inference delays computation but may cause query latency.

Knowledge Derivation Mechanisms

Triple generation occurs through three distinct mechanisms, each suited to different knowledge derivation patterns.

Algorithmic generation produces triples directly from modeling operations and topological queries. Space partitioning operations enable object type assignment and hierarchical instantiation. Topological queries, e.g., extracting adjacency from shared faces, and geometric computations yield quantitative properties from spatial dimensions and positions. This mechanism handles knowledge derivable through direct computation on geometry and topology without requiring logical inference.

Axiomatic reasoning leverages description logic semantics to derive class membership. Reasoners evaluate class restrictions and property characteristics to materialize implicit knowledge. Classification emerges through restriction-based reasoning when instances satisfy class definitions.

Rule-based inference addresses conditions that exceeds the expressiveness of description logic. Custom rules encode arithmetic comparisons, multi-object properties, and regulatory threshold evaluation. This mechanism can handle procedural knowledge and numeric reasoning.

The framework's effectiveness derives from this separation, preserving each layer's responsibilities while leveraging the strengths of each formalism.

Space-Driven Knowledge Design Workflow

The workflow proceeds through iterative cycles, progressing to finer levels of detail (Figure 2). Architectural design development follows different spatial strategies: subdivision decomposes larger volumes into smaller ones, while aggregation composes spaces from individual units. The workflow presented here follows a subdivision strategy, progressively partitioning space from coarse to fine granularity. While aggregation-based and hybrid strategies exist in design practice, subdivision aligns naturally with the space partitioning paradigm, where the entirety of space is recursively divided into non-overlapping domains. At each stage, four activities occur: modeling (geometric partitioning), semantics (type assignment), compute (quantity extraction and topological queries), and inference (classification and reasoning). Each geometric cell created through partitioning receives a unique URI, initially asserting minimal type information. Semantic assignment then specifies object types, while computed quantities and queried topological relationships enrich the object's semantic description through subsequent workflow stages. As properties accumulate through stages, more rules apply, and further knowledge becomes inferable. The following description uses the BOT ontology extended by FiSa concepts, although this approach transfers to other ontology-based knowledge formalizations.

Stage 1: Partitioning by Terrain

The workflow begins with site context. Partitioning space into *'air'* and *'earth'* establishes the ground plane and terrain geometry. Semantically, this creates a `bot:Site` instance. Extracted quantities include terrain height, geographic coordinates, parcel boundaries, as well as relationships to adjacent zones. Inference at this stage determines the applicable regulatory framework based on geographic location through jurisdiction-specific variants, establishing the assessment basis for subsequent classifications.

Stage 2: Partitioning by Building

Within the site, further subdivision partitions 'air and earth' into building volumes. A building becomes a `bot:Building` instance with the sites containment relationship (`bot:hasBuilding`). Adjacent sites establish `bot:adjacentZone` relationships relevant to regulatory requirements. Computed quantities include gross floor area and the number of utilization units. Topological queries determine whether the building is freestanding (no adjacencies to other buildings), while geometric computation can further derive whether special building conditions prevail, such as sales premises or high-rise building classification.

Stage 3: Partitioning by Storey

Horizontal planes partition buildings into storeys. Each storey is instantiated as `bot:Storey` with hierarchical relationships (`bot:hasStorey`). Semantic assignment specifies usage types (`fisa:hasUsage`) and further defines utilization units within the building hierarchy. Computed quantities extract ceiling heights (`fisa:hasUpperCeilingHeight`) and average floor elevations relative to ground (`fisa:hasAverageHeight`). Queries determine the vertical position within the building and count the residential units per storey. These quantities enable storey classification through axiomatic reasoning, which derive storeys as `fisa:AboveGroundStorey` or `fisa:Basement` based on height and elevation properties, and further sub-classification into `fisa:UpperStorey` and `fisa:GroundFloor` according to position. Building class inference also occurs at this stage through rule-

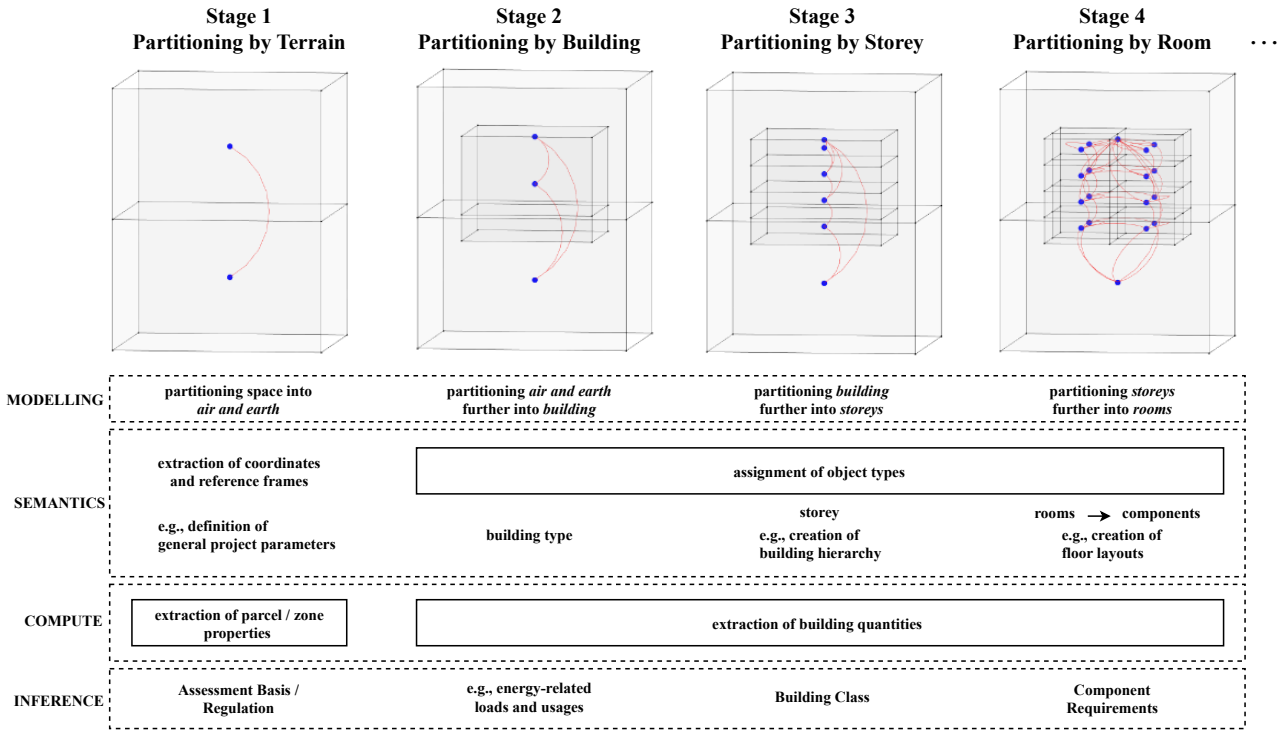

Figure 2: Iterative workflow through four stages of partitioning. Each stage involves geometric modeling, semantic assignment, quantity computation and topology querying, and inference, with results feeding back into subsequent design iterations.

based reasoning. Rules evaluate accumulated properties, such as building height, freestanding status, number of utilization units, and gross floor area, to derive a `fisa:BuildingClass`. This class inference determines component fire resistance and behavior requirements applied in subsequent stages.

Stage 4: Partitioning by Room

Further partitioning operations subdivide storeys into spaces, here also termed rooms. Each space is assigned a `bot:Space` instance. Walls separating rooms instantiate as `fisa:Wall` elements with relationships to adjacent spaces (`bot:adjacentElement`). Semantic assignment specifies space usage, necessary stairs, corridors, and other relevant types. Topological queries directly instantiate semantic knowledge, such as detecting faces with adjacency to outside zones identifies external walls (`fisa:isExternal`), while containment analysis conclude space-enclosing components (`fisa:isSpaceEnclosing`). Inference at this stage derives component requirements. Based on the building class (inferred in Stage 3), component position and properties (external, load-bearing), and adjacency relationships, rules infer the required fire resistance (`fisa:hasRequirementOfFireResistance`) and fire behavior (`fisa:hasRequirementOfFireBehaviour`) for each component.

Iterative Design Refinement

The workflow operates through feedback loops. Geometric modifications trigger quantity recomputation, which affects requirement inference. For example, when storey height changes, the system updates derived properties, re-evaluates the building class, and derives component requirements accordingly. The iterative stages, from geometry change through quantity update to classification inference and requirement derivation, provide feedback on the regulatory consequences of spatial decisions, enabling informed exploration of design alternatives.

Proof of Concept

A proof-of-concept implementation demonstrates the framework's space-driven knowledge generation capabilities. The implementation generates triples from spatial operations for space classification, as well as regulatory requirement inference at the component-level.

Implementation Overview

The Partition Platform (Sternal, 2025) used in this proof of concept serves as the topology-aware modeling kernel, providing stepwise space partitioning from coarse (air/earth, parcel, building envelope) to fine (storeys, rooms, walls) granularity. Each partitioning operation subdivides geometric cells and stores their topological relationships, e.g., the adjacency of each cell through shared faces and containment through hierarchical nesting. The platform's GUI is built using JavaFX, enabling interactive visualization and manipulation of the partitioning process. The semantic model builds on BOT for spatial structure and extends it with FiSa for fire safety concepts. The implementation uses Apache Jena 5.6.0 for RDF graph management and SPARQL querying, with Openllet 2.6.5 pro-

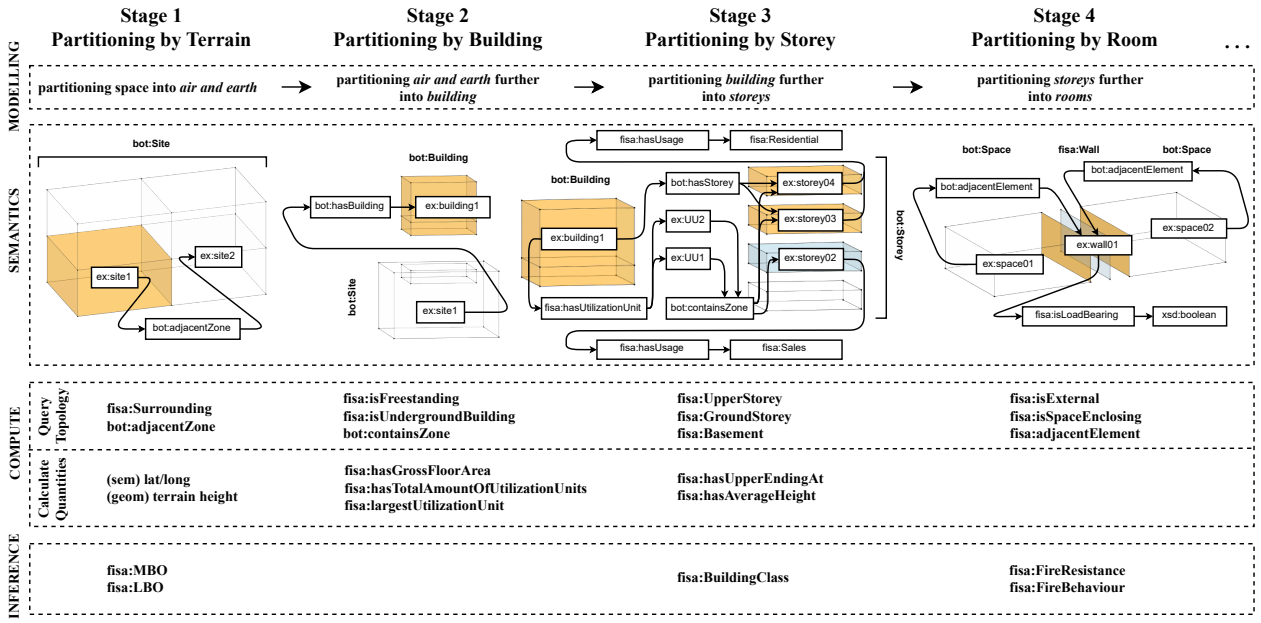

Figure 3: Proof of concept demonstrating semantic triple generation at each partitioning stage, from site context through room subdivision, with corresponding inferences.

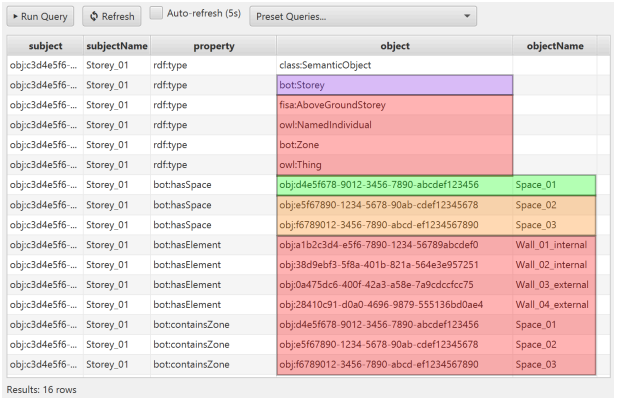

viding OWL reasoning capabilities. Algorithmic triple generation translates partitioning operations into object instantiations and BOT object properties directly in Jena's TDB2 Triple Store. Axiomatic reasoning derives classifications from geometric and topological properties. The rule-based inference engine Openllet derives knowledge written in custom SWRL rules within FiSa. Notably, the ontology was verified using the Pellet reasoner during development. The custom inference engine used in this proof of concept only implements the reasoning features required for the present scope, namely transitive property characteristics and SWRL rule execution. Apache Jena's InfModel coordinates the reasoning process, managing the interaction between the TDB2 triple store and the inference engine while maintaining synchronization between asserted and inferred triples.

Demonstration Cases

The following three cases demonstrate the triple generation process across successive partitioning stages, from storey classification (Stage 3) through spatial adjacency to space classifications and component-level inference of fire resistance requirements (Stage 4). Each case illustrates a different source of semantic enrichment, such as topological queries derived from the modeling kernel, computed properties from geometric analysis, and inferred properties from ontology reasoning (see Figure 3).

Case 1: Classification

When a storey is created by partitioning a building in the geometric model and asserted as a `bot:Storey`, properties are automatically derived from geometric analysis and topological queries, triggering classification within the FiSa storey hierarchy. As shown in Figure 4, `Space_01` is automatically classified as `fisa:AboveGroundStorey`. This classification follows from FiSa's axiom defining `fisa:AboveGroundStorey` as storeys whose floor surface has no earth contact and lies at a certain height above terrain height.

Case 2: Adjacency

Spatial adjacency relationships are derived by topological queries. The kernel computes `bot:adjacentZone` relations between spaces sharing boundaries, as shown for `Space_01`'s connections to `Space_02` and `Space_03`, as well as their `bot:adjacentElement` relations to the bounding walls (see Figure 5).

Case 3: Component Requirements

Fire resistance requirements are derived from custom rules. When a wall is asserted with boolean datatypes in both `fisa:isLoadBearing` and

`fisa:isSpaceEnclosing`, those rules infer the object property `fisa:hasRequirementOfFireResistance`. Consequently, `Wall_01_internal` is inferred to require `fisa:feuerhemmend` (Figure 6), following regulatory requirements for load-bearing internal walls in the considered spatial configuration.

Discussion

This paper presents a framework that couples topology-aware modeling with semantic triple generation, classification and inference, enabling real-time feedback on the regulatory implications of geometric decisions. The proof of concept demonstrates that models can be semantically enriched during design stages through the combination of topological queries, axiomatic reasoning, and custom rules.

The current implementation demonstrates feasibility rather than production readiness. Several technical limitations remain unaddressed. The modeling kernel handles straightforward partitioning operations but does not address complex parametric operations or a merging of existing geometric models. Performance at scale, involving thousands of spaces and millions of triples, remains unevaluated. The proof-of-concept implementation operates on a JavaFX 21 UI for the Database View and the Partition Platform, utilizing Apache Jena's TDB2 triple store and the Openllet reasoner, rather than being a fully integrated or web-based application.

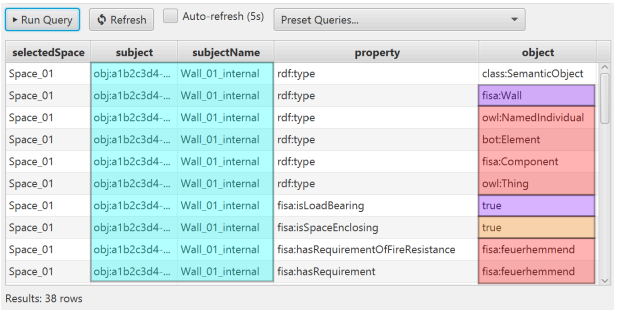

*Figure 6: Results show relationships for `Wall_01`, bounding the selected `Space_01`, in custom Database Viewer (**purple**: user-asserted; **orange**: computed in kernel; **red**: inferred; **lightblue**: `Wall_01`)*

Another trade-off concerns graph management during iteration. Updating existing graphs maintains entity identity but requires synchronization logic, while regenerating graphs sacrifices continuity for simplicity. The framework currently regenerates graphs after each modeling operation, accepting this limitation for implementation tractability. Similarly, the semantic assignment step requires further development. Requiring type assignment during modeling eliminates the generic model problem but may conflict with the exploratory early design, where flexibility takes precedence over fixed commitments. Progressive object type assignment, involving partial assignments that mature with the design, offers a possible resolution but remains unexplored.

Beyond technical constraints, questions remain about how designers will adopt this workflow. Designers who are accustomed to choosing specific types and properties at the end of modeling may resist doing so during the modeling process. Whether handling geometry and semantics at the same time demands too much attention remains untested. The framework assumes that designers benefit from immediate regulatory feedback. However, confirming this would require a carefully developed and constructed user study with designers that compare traditional workflows directly with the proposed approach.

Future work targets full integration with the Partition Platform user interface for parametric operations, which are currently under development. The inference mechanisms demonstrated here for fire safety extend to other regulatory domains where classifications derive from spatial properties and lead to component requirements. Extending the framework to multi-building and urban scales, where site adjacencies and district-level regulations apply, presents additional opportunities for space-driven knowledge approaches.

Conclusion

This paper presents a framework in which modeling operations generate geometric and topological representations and semantic knowledge simultaneously. Partitioning space creates manifold geometries and topological graphs, producing queryable semantic triples, with inferences used to derive classifications and requirements iter-

atively. The proof of concept demonstrated storey classification and the inference of fire safety requirements using the FiSa ontology, thereby establishing the foundations for workflows in which spatial reasoning informs iterative design decisions.

The methodological contribution is a staged workflow that couples topology-aware modeling with inference, applicable beyond fire safety to other regulatory domains where continuous knowledge derivation is preferred over plain validation checking.

THE POTENTIAL OF DIGITAL TECHNOLOGY TO ENGAGE CHILDREN WITH HOSPITAL EXPERIENCE AND DESIGN

Laura Maftei
University of Reading, Reading, UK

Abstract

This study examines how virtual reality (VR) supported co-design methods can help recover children's perspectives in shaping hospital environments. Building on NHS priorities for child-centred healthcare design, the project developed immersive digital replicas of key hospital spaces through 360° video, 3D models, and VR simulations. These were tested with children from local schools to explore their perceptions, reduce hospital related anxiety, and gather design preferences. Findings show that VR supported children engagement, familiarity with clinical spaces, and insights into sound, colour, layout, and wayfinding. The study shows the potential of VR as a participatory tool for inclusive paediatric healthcare design.

Introduction

Creating strategies to educate and prepare children for hospital visits as patients and designing hospital services for children from the child's point of view has been for some time part of the NHS framework (Department of Health, 2003; NHS England, 2014). Recently, increased recognition has been given to the requirement to include the views of child patients in the planning of health care services so that hospitals can be designed to enhance future experience. However, the voices of children remain often under-represented or represented through adult proxies in projects to design, develop and improve healthcare service delivery. Co-design methodologies (Bratteteig and Wagner, 2016; Luck 2018) and digital technology such as VR bring the potential to support user empowerment and participation in the design of buildings and services (Sateei et al., 2025; Roupé et al 2020; Maftei et al. 2018).

This study draws on a co-design approach to explore the use of digital technology such as VR (virtual reality) for engaging children with hospital spaces and experiences, and recovering children's perspectives of what constitutes ideal hospital design. The study is based on a community engagement project drawn on collaboration between the author's University, the local NHS hospital and local schools. The project aimed to: 1) develop a friendly but realistic immersive experience of hospital through digital simulations (including 3D photographic visualisation and surround sound); 2) examine the use of these virtual simulations to familiarise children with hospital spaces they might encounter, and to reduce the apprehension experienced by children as reported anecdotally by the hospital; and 3) use these virtual simulations to understand children's perceptions and preferences to inform the co-design of children hospital spaces.

In collaboration with the local hospital including the Children Strategy, Health Inequalities, and Patients Experience teams, we identified that the project would be particularly useful in understanding the experience of children with special educational needs and disabilities. We ran a demonstration session with the hospital Youth Forum, a group of 16-24 year old young adults who work with the hospital to improve services for young patients.

We co-developed digital replicas of three children's hospital spaces based on advice from the hospital team. This included a journey from the car park to main reception, the children's clinic waiting area, and the X-Ray room. Using a 360° video camera different types of digital replicas were created such as immersive VR films, 2D films, and interactive 3D models developed with laser scanning techniques.

The digital replicas were shown to children in three local schools, including the Junior Carers (an initiative to engage primary school children with the hospital and healthcare services). They were able to experience the spaces virtually in a classroom environment on VR headsets, iPads and laptops. The schools were chosen to represent a diverse range of children from different backgrounds, some with special educational needs and disabilities. The project team asked children for their thoughts and ideas, while showing them what happens in hospital. Through a series of fun story-telling classes developed with teachers and the hospital, the children could ask questions and tell what they think, 'before-they-go' and 'after-they've-been' to hospital (in the virtual simulations), then what they would like to see in the future.

In workshops conducted at the schools, children were able to see parts of the hospital they had not seen before, and reported that they would not be scared if they needed to visit them. They provided useful insights into the design and experience of children's hospital spaces talking about sounds, colours, lighting, seating areas, waiting, and wayfinding. They also enjoyed the experience of using digital technologies, especially the VR headsets and often said it helped them to feel immersed in the space in a 'very real' way.

This paper reports on this project and takes a focus on the participating children's perspectives on the technology and of the hospital virtual simulations for engaging children with hospital experience and co-design.

Background and related literature

Hospitalisation is frequently accompanied by elevated anxiety in children, arising from disruption to routine, exposure to unfamiliar sensory cues, and shaped by the experience of the hospital environment (Signorelli et al., 2023). The design literature similarly recognises that paediatric environments can either amplify or reduce stress, with supportive design elements (e.g., positive distraction, sense of control, and social support) linked to improved affective outcomes for young patients (Sathyanarayanan & Caldas, 2025). Yet, despite the centrality of child experience in paediatric care, children's perspectives remain under represented in both healthcare research and design decision making. Methodological and structural barriers often lead to reliance on adult proxies, resulting in partial accounts of children's priorities.

Co-design and participatory design (PD) with children have gained traction within healthcare facilities planning, but adoption remains uneven and methods are often limited to short, one off sessions that do not translate into buildable specifications (Sathyanarayanan & Caldas, 2023; Schepers et al., 2020).

Architectural engineering and construction management research indicates that conventional tools (plans, renders, physical mock-ups) can fail to capture embodied, affective, and developmental nuances of paediatric users, thereby constraining the fidelity of user requirements that propagate through briefing, design development, and delivery (Sfandyarifard & Tzortzopoulos, 2011; Jurk, 2023).

Against this backdrop, immersive digital technologies—particularly virtual reality (VR)—present the potential to both alleviate anxiety and support co-design processes. On the clinical side, VR can reduce pre procedural anxiety and improve the hospital experience for children and families (Oh et al., 2023; Hu et al., 2024). On the design/construction side, studies in the architecture/engineering domains indicate that immersive HMD VR may enhance stakeholders' spatial understanding, sightline appraisal, logistical flow testing, and identification of latent design conflicts. When VR supports interaction and multi user collaboration, end users can iteratively adjust layouts in real time, accelerating decision cycles from weeks to hours (Sateei et al., 2025). In combination with other digital technologies, VR can support participatory design, user empowerment and better management of user requirements (Maftei et al., 2018). Other healthcare focused AEC work further explores the role of VR for simulating "in between" spaces (waiting rooms, corridors) and diverse user conditions to inform design decisions that address stress and inclusivity, thereby improving experiential quality where anxiety often accumulates (Harkness et al., 2018). For paediatrics specifically, emerging research demonstrates how immersive tools can enable child centred engagement beyond verbal self-reports. For example, architectural experiments pairing VR with eye tracking and physiological measures capture moment to moment emotional responses to spatial variables in paediatric rooms, offering developmentally appropriate pathways to elicit preferences about privacy, control, and positive distraction (Sathyanarayanan & Caldas, 2024). These methods address known shortcomings of traditional PD with children—notably, the difficulty of translating tacit or affective responses into design parameters—by supporting evidence based design (Jurk, 2023; Sateei et al., 2025).

In construction management terms, the capacity of immersive technology such as VR to host multi disciplinary, multi user reviews directly within a navigable, to scale prototype is salient for briefing, options appraisal, and stakeholder sign off—especially when paediatric participants may struggle to read drawings or comprehend scale (Sateei et al., 2025; Sfandyarifard & Tzortzopoulos, 2011). Finally, children's co-design literature highlights the need for deeper participation models—moving beyond episodic ideation toward ongoing roles in defining processes and decisions—suggesting that immersive platforms can enable such "deep participation" by making options experientially comparable and discussions evidence rich (Kheirollahi et al., 2021; Schepers et al., 2020).

Overall, this literature indicates that integrating digital technology such as VR within participatory design frameworks can both mitigate hospital related anxiety and amplify children's voices in the planning and delivery of paediatric facilities. This study builds on this literature by taking a qualitative interpretivist approach to explore how digital technology such as VR can support engaging children with hospital experience and design.

Methods

The study followed a qualitative interpretivist research design consistent with established participatory and co-design protocols used in child-centred healthcare design research (Bratteteig & Wagner, 2016; Schepers et al., 2020). This approach emphasises eliciting children's lived experiences through multimodal, developmentally appropriate formats, aligning with guidance on participatory methods for child participants in both design research and architecture/engineering contexts (Sfandyarifard & Tzortzopoulos, 2011; Sathyanarayanan & Caldas, 2023).

In line with this approach, we adopted a co-design approach to explore children's perspectives on the technology and the hospital virtual simulations for engaging children with hospital experience and co-design. The study aimed to develop a friendly but realistic immersive experience of hospital through digital simulations (including surround image and sound), to familiarise children with hospital spaces they might encounter, and to understand children's perceptions and preferences to inform the co-design of children hospital spaces.

Technology used and content creation

The equipment used comprised an Insta360° surround image and sound camera, Oculus/Meta Quest VR headsets, a 2D camera, a laser scanner, iPads, and laptops. In the first phase, the 360° camera and headsets were tested by filming the author's department building. Based on these tests and demo sessions with hospital collaborators and the Youth Forum (YF), we decided to augment 360° recordings with 2D films and laser scanned interactive models for creating journeys and higher interactivity with the virtual models. The final hospital simulations recreated a child patient's visit from the car park to main reception, through the children's clinic waiting area, and into the X ray room. These virtual simulations were co-created with volunteer actors (child patients, parents, hospital staff).

Participating groups

A purposive sampling strategy was adopted to involve groups for whom the intervention would be most relevant. In collaboration with the local NHS hospital (Community Engagement, Health Inequalities, Patient Experience and Children Strategy teams), we prioritised groups for whom the intervention might be particularly useful, notably children with Special Educational Needs and Disabilities (SEND). This sampling approach aligns with participatory design guidance encouraging recruitment of participants with lived or contextual experience relevant to the design domain (Bratteteig & Wagner, 2016; Schepers et al., 2020).

Following this sampling strategy, we worked with three schools: two mainstream primary schools in the Junior Carers programme (about 30 children total, ~10 years old, split into two workshops, W1 and W2) and one highly special educational needs school (12 children, 13–16 years, mixed disabilities and neurodivergence; W3). The Junior Carers children had ongoing, non-patient engagement with the hospital. The SEND group included children with frequent or extended hospital visits. This sampling strategy mirrors participatory approaches in healthcare design that emphasise working with children who are either direct stakeholders or frequent service users (Sfandyarifard & Tzortzopoulos, 2011).

Workshop design and flow

Each workshop followed a structured sequence. First, children developed short written stories about hospital "before" the virtual experience. Next, they experienced the simulations across three display modalities—VR headset, iPad, and laptop—rotating through sub areas of the room arranged to follow the hospital journey. This was followed by mini focus groups (≈30 minutes per subgroup) and a whole group debrief (≈15 minutes). In W1 and W2 (≈1.5 hours each), groups of ~15 were divided into subgroups of five to balance group dynamics and avoid unification and standardisation of opinions, while remaining practical for facilitation time. In W3 (~2.5 hours), 12 children worked in pairs, with ~1h40m hands-on time across devices, followed by a ~30 minute whole group debrief.

Figure 1: Image from the school-based workshops

This workshop design followed established child-centred co-design procedures. Warm up activities (in our case written "before" stories) bring the potential to activate prior knowledge and reduce cognitive load, a method routinely employed in PD with children (Schepers et al., 2020). Multimodal interaction -in our case with three display types (VR headset, iPad, laptop)- has been recognized to be useful for inclusive technology mediated engagement (Sathyanarayanan & Caldas, 2023; Roupé et al., 2020). Organizing small-group mini focus groups using interactive prompts reflects PD protocols that minimise peer influence and support diverse participation (Bratteteig & Wagner, 2016). Whole-group debriefs as employed in our study are consistent with iterative reflection cycles common in co-design and evidence-based design (Sateei et al., 2025; Jurk, 2023). Subgroup sizes (in our case, 5 in W1/W2 and pairs in W3) were selected to align with guidance on balancing conversational richness with facilitation manageability (Schepers et al., 2020).

Data collection and analysis

In line with qualitative and PD research methods of data collection, we collected: (i) written "before" stories; (ii) audio recorded mini focus groups on "after" perceptions, including what children would like to change; and (iii) whole group debriefs. Interview prompts focussed on likes/dislikes of hospital experience and space/design before and after the simulations, and explicitly invited reflections on the technology and films (in terms of usefulness for potentially helping other children familiarise with the hospital).The written stories provided pre-experience framing, aligned with narrative elicitation protocols used in paediatric design studies (Sathyanarayanan & Caldas, 2023). The audio recorded

mini focus groups drew on semi structured thematic protocols common in architectural PD research (Sfandyarifard & Tzortzopoulos, 2011; Jurk, 2023). The whole group debriefs enabled collective reflection, frequently recommended in co-design workflows (Schepers et al., 2020). Prompts were designed to capture perceptual, emotional, and spatial responses—an approach supported by VR assisted evidence-based design methods (Sateei et al., 2025).

Audio recordings were transcribed and thematically analysed. In this paper, particular attention is given to the analytical themes around the technology perception and use (device preference; immersion vs distraction; usability; comfort and accessibility) and perceived usefulness (familiarisation, anxiety reduction, wayfinding confidence).

The study complied with University ethics and hospital Information Governance approvals.

Analysis and findings

Engagement, preference, and perceived usefulness

Across the Junior Carers workshops, many children identified VR headsets as the preferred display, often highlighting the 360° look around affordance: "I liked it when we could look around through the X ray room" (Participating Child in W2). The interactivity of the laser scanned model was also appreciated—"I liked the one where you can move around… so you can, yeah, feel like you're there, instead of watching someone else do something" (Participating Child in W1)—suggesting agency and navigation mattered at least as much as immersion. Children repeatedly proposed the simulations as tools to prepare and reassure peers: the films "can help the children about knowing… what's going to happen and calm, cool them down… if they did know what was going to happen they're like, 'all right, it's going to be fine…' I think it's good to let them know what's going to happen" (Participating Child in W1). Some noted the simulations resembled real visits: "I have been to X ray before… It was the same as in the films" (Participating Child, W2).

SEND participating children and school staff framed the simulations as a useful alternative/complement to existing preparation practices (e.g., social stories, photos), emphasising choice of device: "Some people need the VR headset, but some people don't need it… it could be on a phone… an iPad… or a VR [headset]" (Participating Child, W3). For this group, the value of multiple modalities (2D, 3D, interactive, non-interactive) was explicit, reinforcing that iPads and laptops were "as useful as the VR headset" (Participating Child, W3), and sometimes more comfortable or accessible.

Immersion, novelty, and distraction

The same features that made VR compelling could disrupt focus. In W2, the headset became the attraction of the workshop, with competition for turns—"How did she have the long go? She had longer. I'd like to have another go too" (Participating Child in W2)—shifting attention away from hospital design reflections. Some children focussed on production technicalities (e.g., people disappearing and reappearing in Matterport style models) rather than spatial qualities. Others encountered navigation issues: "I didn't really get to see much of the hospital, I just went straight into this other world, and I didn't get any time in the actual hospital" (Participating Child in W2). These moments illustrate how medium driven attention capture can overshadow the message without allowing the potential to support the focus of the workshop.

Perceived usefulness: familiarity with clinical processes and spaces

Children engaged closely with clinical procedures—notably X ray—and reported recalibrated expectations from "scary" to "not scary." Seeing "what they're doing" and "what the facilities are about each room" was valued, with previewing activities in medical rooms recommended to build understanding (Participating Child in W1). This aligns with comments that simulations may reduce anxiety by clarifying who does what, where parents wait, and how the process unfolds. In Junior Carers groups, prior visits (e.g., cardiology) blended with the virtual encounter (X ray) to form an overall familiarity that children found useful.

Comfort, accessibility, and session design (SEND insights)

For SEND participants, personalisation was key. Some found VR engaging "partly because of its novelty," while others were uninterested—"I'll never get used to it… you have to want to do it" (Participating Child in W3). Practical recommendations included shorter VR experiences to avoid dizziness and pre familiarisation: "with VR you have to actually get used to it" (Participating Child in W3). Children also articulated desired technical refinements—"I wish the lens didn't have to be circular, wish I could fully immerse myself"—and affirmed that iPads/phones were equally useful, reinforcing the need for optional pathways through the content.

Children's design insights through digitally mediated participation

Across workshops, children indicated design perceptions (e.g., sounds, light, wayfinding, waiting), often proposing adjustments —quieter/ambient soundscapes; more colour; the provision of more engaging activities in the waiting area ("add iPads and books for 8–10 years old"). These place-based concerns often interacted with technology use: when audio in films included a child crying, some found it disturbing; conversely, appropriate sound design enhanced presence. For SEND participants, discussions expanded to outdoor/open air spaces, polysensory seating (softer, "hugging" seats alongside standard chairs), handrails along long routes, and strategies to mitigate waiting time challenges for autistic children who cannot physically wait. Technology was thus perceived not just as a medium, but as part of a broader toolkit and methodology for inclusive preparation and design feedback.

Discussion

Using digital technology to improve the design and children's experience of hospitals?

The technology was widely perceived as useful for engaging children with hospital environments, increasing familiarity, and "calming worries" before visits. Interestingly, the same features that make VR compelling—immersion and novelty—could also be disruptive, pulling focus away from the workshop's purpose of discussing hospital experience and design. Instances of children competing for VR time, becoming preoccupied with production technicalities, or getting "lost" in navigation illustrate how the medium may overshadow the message/purpose if not carefully used. These observations point to the importance of facilitation strategies (e.g., clear turn-taking, guided tasks, and wayfinding prompts within the VR interface) to keep attention on the spatial and experiential content rather than the device itself. At the same time, the SEND group's emphasis on choice demonstrates that, although VR was preferred by some, other children found iPads and laptops equally useful, and in some cases preferable for comfort, accessibility, or sustained focus. Designing technology-mediated participation should therefore provide multiple display options, flexible session lengths, and staged familiarisation.

Overall, the findings show that VR-supported digital simulations can meaningfully engage children in exploring hospital environments, yet the immersive qualities of VR can both support and hinder design-focused dialogue. While many participants valued the 360° affordance and sense of presence, others became preoccupied with the novelty of the device or encountered navigation challenges. These dual effects highlight the importance of structured facilitation—guided tours, turn taking protocols, and clear task prompts—to ensure that immersion enhances rather than distracts from design discussion.

Across all workshops, children articulated design-relevant preferences relating to colour, sound, lighting, waiting experiences, and wayfinding. SEND participants emphasised sensory comfort, predictable routes, and the usefulness of multiple device modalities. These observations demonstrate how multimodal, digitally enabled simulations can reveal tacit experiential knowledge difficult to express using traditional PD tools.

Implications for hospital design

The study contributes evidence that VR-supported co-design can uncover child centred insights into hospital environments. Children's suggestions—ranging from quieter soundscapes and clearer wayfinding to softer seating and reduced visual clutter—align with recognised paediatric design principles and offer specific, actionable recommendations for design teams. As shown in our study, interactive models and VR combined with 2D animated options, also support accessibility and differentiated sensory needs. Overall, the findings demonstrate how VR-supported sessions can reveal design aspects that traditional participatory tools may not capture.

Relation to Prior Literature

The findings support AEC research indicating that immersive VR enhances spatial understanding and supports stakeholder dialogue (Roupé et al., 2020; Sateei et al., 2025). At the same time, the need to manage distraction aligns with literature emphasising careful facilitation in participatory sessions with children (Sfandyarifard & Tzortzopoulos, 2011). The multimodal digital simulations preference of SEND children extends emerging work calling for flexible, accessible co-design tools in paediatric environments.

Limitations

Many participating children—particularly those in the Junior Carers programme and the SEND school—had prior or frequent hospital experience. In combination with the digital hospital simulations, this familiarity enabled children's rich insights of hospital experience and design, and it supported useful background for the participating children assessment of the realism of the hospital virtual simulations. However, this familiarity may have influenced the participating children's perceptions of the simulations, their reported levels of anxiety, and the specificity of their design suggestions. Future work could include children with little or no prior hospital exposure to explore whether the technology supports first-time preparation differently.

Conclusions and Future Work

This study shows that multimodal digital simulations—360° VR films, 2D videos, and interactive laser-scanned models—can meaningfully engage children, including SEND participants, in understanding hospital environments and expressing design-relevant preferences. VR supported participation and familiarisation, yet immersion also introduced distractions, highlighting the need for clear facilitation, guided navigation, and multimodal display options.

As in all research, there are limitations to this study. Many child participants had prior hospital experience, which may have shaped perceptions and reduced anxiety. Future work could include children with little or no prior hospital experience to examine whether the technology supports first-time preparation differently. Group-based school workshops may have also limited the depth of individual feedback. Relatedly, future work might focus on individual sessions to capture more fully personal feedback from child participants. Further avenues for future work may also explore iterative co-design with children, and may include longitudinal studies examining anxiety reduction ahead of real hospital visits.

Acknowledgments

The author gratefully acknowledges the support of the University of Reading for funding this project. Special acknowledgements are made to the local NHS hospital (Royal Berkshire NHS Foundation Trust), and the local schools teachers and children for their collaboration in

this project. Special acknowledgements are also made to Dr Ian Ewart, the co-investigator on this project, for the support and inspirational drive on the study.

Abstract

Building operations account for 30\% of global energy consumption, necessitating performant, multi-scale modelling to optimize carbon reduction. While Machine Learning (ML) offers significant promise, significant issues prevent its full adoption. This paper proposes a specific Low-Code/No-Code (LCNC) approach as a solution to democratize analytics software development, allowing stakeholders to focus on their operation needs while removing the programming syntax barrier. We show how we use the WAVE platform, a cloud-based, collaborative LCNC platform based on formal models, for the graphical composition of workflows for multi-scale energy modelling. A LCNC solution to national scale energy modelling is described and compared to traditional implementations.

Introduction

Building operations accounted for 30% of global energy consumption and 27% of energy-sector emissions in 2021 (Skillington et al., 2022). Data-driven decisions are now vital to address the issues of global warming, building comfort and stock availability (Katavoutas et al., 2022). Developing performant methods of modelling and analyzing the built environment across multiple scales, from individual buildings to national building stocks, is essential. Machine Learning (ML) offers a reliable and affordable mechanism to achieve this (Manfren et al., 2022). By fusing various information sources, such as building data, energy infrastructure and population data, and applying ML, planners can perform sophisticated analyses, to identify energy performance trends and optimize large-scale carbon reduction strategies (Ali et al., 2024).

Creating data-driven models using machine learning is non-trivial, particularly within the built environment where data are often fragmented and heterogeneous. As in any domain, a machine learning deployment workflow consists of four main stages: data management, model learning, model verification, and model deployment (Paleyes et al., 2022). In the context of energy modelling, these stages are complicated by the need to integrate disparate sources such as building models, demographic data and utility topologies.

Each stage requires a specific intersection of practitioner skill sets. For instance, data management in this sector requires not only data cleaning but an understanding of physical building properties to ensure that feature selection is based on domain fundamentals. Stakeholders in residential energy modelling report a significant AI Skills Gap (OECD, 2025). This is not merely a lack of coding ability, but a shortage of professionals who possess both energy-modelling knowledge and AI technical proficiency. For SMEs and Government agencies, this gap creates a bottleneck where the potential of data remains unfulfilled, leading to a disadvantage as they plan carbon reduction strategies (Muminova et al., 2024).

Low-Code/No-Code (LCNC) is a visual programming paradigm where developers define an application's logic through workflows, palettes of reusable component, and data models rather than text-based scripts. This paradigm emphasises the business case, which is assembled from pre-configured modules (O'Brien et al., 2025). LCNC provides several advantages for enterprises, including:

- *Democratisation of software development* - LCNC approaches remove the syntax barrier, the need to master programming syntax and, by extension, software engineering skills (Denny et al., 2011). Removing this barrier allows stakeholders in the energy modelling domain to build bespoke solutions. This paradigm shift results in applications and tools that are designed by those who understand the operational needs best.
- *Toolchain development* - by extension, LCNC facilitates the creation of toolchains and workflows where small data manipulation software components trans-form data as it is passed through a chain of established software tools.
- *Lower development costs, higher speed* - the cost of creating bespoke tools is reduced both by improving the ability to combine and reuse code, as well as overcoming the skills gap. This also brings much faster turn around times, as the design happens at the logical level, and changes are quickly made and quickly operational.

Typically, LCNC software is developed in platforms that provide development tools and frameworks (Prinz et al., 2021). Many flavours of LCNC aim at more or less professional outcomes. The WAVE platform is an example of a LCNC platform that follows the eXtreme Model Driven Development approach (Margaria and

Stef-fen, 2020). WAVE addresses many of these needs at the professional level needed for high assurance software. It is a cloud-based, collaborative application development environment that adopts a LCNC paradigm founded in formal models, with graphical composition of hierarchical workflows (control and data flow) on the basis of libraries of components that express the *skills* (or capabilities, or actions, as community-specific terminology) of the domain-specific entities to be coordinated. WAVE is domain-agnostic and employs formal methods to ensure workflow correctness, a capability absent in other platforms. This contrasts with other workflow orchestration tools such as Node-RED, which is limited to event-driven applications and KNIME which focuses on data science applications.

The paper introduces WAVE as a LCNC platform that can enable domain experts to build multi-scale energy models via graphical workflows instead of complex scripts. By showcasing specific workflows for archetype calculation and Building Energy Ratings (BER) prediction, we show that data-driven decarbonization efforts can be accelerated by abstracting from the technical MLOps' complexity. Having explored the background to this work, we introduce the WAVE platform and associated concepts. Finally, we present a use-case that focuses on the development of a multi-scale energy modelling solution.

Background

The need to decarbonize the built environment requires efficient methods for modeling building stocks across multiple scales, from individual thermal components to national energy infrastructure (Ali et al., 2024; Hoare et al., 2022). Historically, this field relied on physics-based approaches that use heat-transfer and thermodynamic equations to simulate physical behavior (Ahmad et al., 2018). However, these models require high-granularity data such as specific geometry and thermal properties (U-values), while being also computationally expensive (Ali et al., 2024; Ahmad et al., 2018).

To address these data gaps, data-driven models have gained prominence. These models leverage machine learning (ML) algorithms to predict energy use without requiring a deep understanding of modelled system (Ahmad et al., 2018; Manfren et al., 2022). To achieve multi-scale capabilities, researchers use Building Energy Modelling (BEM), which employ building archetypes, i.e., representative baseline models capturing typical characteristics of building groups, to scale individual estimates to regional or national levels (Ali et al., 2024). Furthermore, Linked Data approaches admit the integration of heterogeneous information sources, such as energy infrastructure and population data (Hoare et al., 2022). Recent advances have also integrated Geographic Information Systems (GIS) into these workflows to enhance spatial analysis of energy consumption patterns (Ali et al., 2024).

Despite the potential of ML, significant obstacles hinder its widespread adoption, particularly for Small and Medium Enterprises (SMEs) and government agencies. A primary barrier is the AI Skills Gap; firms often struggle to find personnel who possess both domain expertise and the specialized technical skills required to implement complex ML algorithms for energy models (Carioli et al., 2024; OECD, 2025). Smaller organizations often lack the financial resources to compete for data analysts familiar with energy modelling, leading to a competitive disadvantage and unfulfilled potential for the technology (Muminova et al., 2024; Dzhusupova et al., 2022).

Beyond personnel, the Machine Learning Deployment Workflow (MLOps) presents significant architectural and process challenges. Practitioners report that data management, including data discovery, cleaning, and joining dispersed datasets, consumes the vast majority of time in ML projects (Paleyes et al., 2022; Dzhusupova et al., 2022). Data often exist in *functional silos* making large-scale integration difficult (Paleyes et al., 2022; Dzhusupova et al., 2022). Additionally, the opaque nature of ML algorithms creates a *trust deficit* among stakeholders who require interpretability and formal verification to comply with high safety and regulatory standards (de Marco et al., 2025). *Low-Code/No-Code* (LC/NC) development is an emerging technology paradigm that enables individuals with no advanced computing or coding skills, collectively referred to as *Citizen Developers*, to create custom applications through visual drag-and-drop interfaces and pre-configured modules (El Kamouchi et al., 2023; Martinez and Pfister, 2023). By removing the *syntax barrier* these platforms allow domain experts to be closer and participate to code development on the basis of their own professional skills, thereby democratizing software development (Sundberg and Holmström, 2023).

The LC/NC paradigm has demonstrated success across several domains. It has been used to develop solutions for healthcare, for example diagnostic systems and virus tracking applications (Margaria and Schieweck, 2019). Similarly in manufacturing, the digital thread (Margaria and Schieweck, 2019) and automation of inventory management have been developed using LC/NC (El Kamouchi et al., 2023). It has also been used to support the development of decision support systems (Karusseit and Margaria, 2006) and for educational training at many levels (Gossen et al., 2018; O'Brien et al., 2025).

LC/NC offers a mechanism to overcome the skills gap by facilitating rapid tool-chain development (Sundberg and Holmström, 2023). These tools reduce implementation costs because organizations have their own staff to build bespoke models, bypassing the need for expensive IT consultants (Muminova et al., 2024). Platforms such as WAVE, and before it DIME (Boßelmann et al., 2016) and the jABC (Margaria and Steffen, 2009) address multi-scale modeling needs by utilizing hierarchical workflows that coordinate domain-specific skills into complex automated pipelines.

The WAVE architecture

The WAVE platform is described next. The architecture is summarized in Fig. 1. *The Formal Modelling Language* (orange layer in Fig. 1), provides the modelling languages

used in the platform. It is provided and maintained by the WAVE delveloper and support team. The Application Design layer (in blue in Fig. 1) is where the researchers from various communities use the WAVE facilities to design and execute their applications.

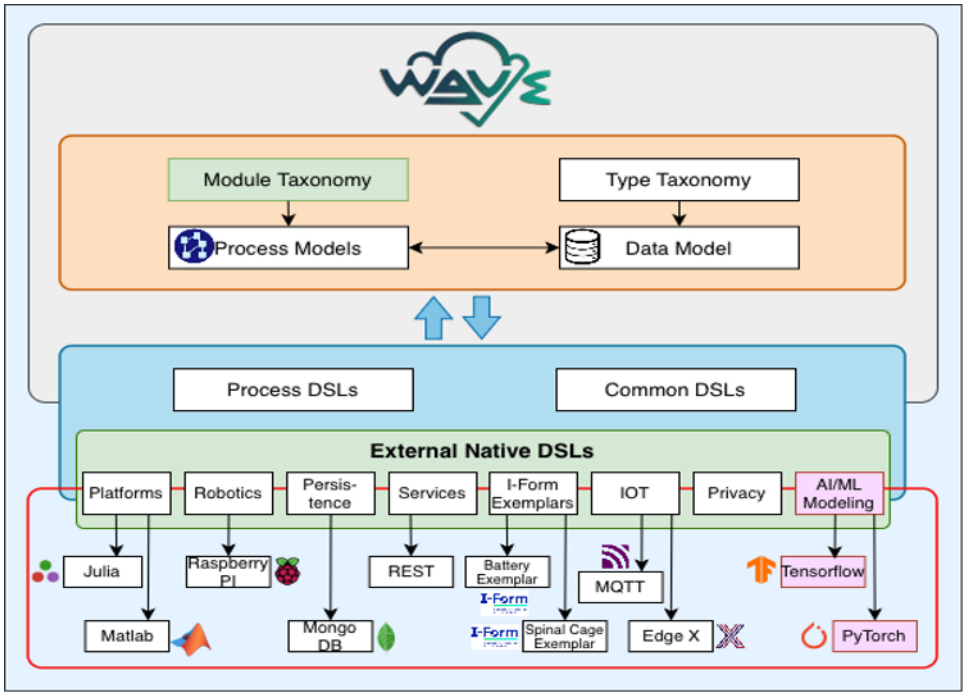

Figure 1: Architecture of the WAVE platform: the layers correspond roughly to different professional figures found in many communities

When LCNC is used to develop code, the final end-to-end logic that solves a business problem (traditionally coded as a script or program) is commonly called the workflow or process of the application under development and is modelled using compositions of components. This workflow describes how the control and the data flows from one step of the workflow to the other. The steps are designed using components called Service Independent Building Blocks (SIBs), each one embedding a domain specific functionality that executes a specific task. The task can range from simple operations, such as converting file formats, to complex ones like connecting to external APIs or training ML models. The complexity of API development, writing scripts for Python libraries such as Keras, scikit-learn, and TensorFlow, is fully abstracted. Users interact only with visual representations that expose the necessary configuration parameters. Built using the *Correctness by Construction* (CoC) approach, each SIB in the WAVE is a pre-validated block with established functional correct-ness and an associated model (Margaria et al., 2005) akin to a digital shadow. As shown in Figure 2, each SIB has well-defined, typed inputs and outputs. For each potential execution outcome there is a separate outgoing branch, labelled accordingly. The label also includes the outputs produced in that case. So even a simple visual inspection identifies what is produced (data, messages) for each specific outcome. Next steps are determined by the outcome of the current SIB, thus the outgoing branches are connected to the ”suitable” subsequent SIBs, defining the control flow. SIBs are thematically organized in palettes of related functionalities.

The collection of SIB palettes pertaining to a given application domain constitutes a Domain Specific Language (DSL) for that application domain. In our case, the DSL concerns the domain of energy consumption analysis, pre-diction and mapping.

The WAVE uses Software Engineering methods and techniques to enable researchers to design, implement and execute verified and tested applications by modelling their workflows using application-domain DSLs. If the DSL and SIBs for a particular workflow are available, designing new applications simply reuses those ready SIBs: a no-code activity. If functions are missing, they need to be either integrated from existing libraries or tools, or programmed afresh. This is the *External Native* DSL, in green in Fig. 1. There, existing or new software components, hardware, APIs or other resources (red layer in the Figure) are made available to the WAVE users as collecitons of SIBs. This is a low-code task, as it concerns a specific, well defined component to be added. This step requires some programming skills, but not complex architectural knowledge, and it is the step that produces the palettes of reusable components.

WAVE will employ formal methods like the GEAR model checker (Steffen et al., 2007) and the MC3 infinite state model checker (Steffen and Murtovi, 2018) to ensure workflow correctness at design time. Those model checkers are specialized for deep diagnostic support and procedural (i.e, hierarchical) systems respectively. While users are modelling their workflow, syntactic and static semantics check will ensure that workflows are valid. For example, verifying the absence of deadlocks and

guaranteeing that critical steps are always executed, or guaranteeing precedences. Additionally, the platform will offer support for integration of new components, execution of the workflows and adequate monitoring and logging mechanisms.

Using the WAVE

When researchers from various communities use the facilities offered by the WAVE platform to design and execute their applications, they reuse over and over again the general purpose components of the Common DSLs and the domain specific DSLs. This way, users produce the do-main and application specific workflows of the Process DSLs. As WAVE has the same common modelling language for its components and workflows, that is shared across any application domain, diverse research communities can share components with other communities, speed-ing up significantly the work of other users. For example, data analytics and visualization components and even workflows are frequently shared across several communities active in diverse research domains such as bioinformatics, history and advanced manufacturing.

Any applications, and many of the features of the WAVE platform itself, are implemented as workflows that use ap-plication domain specific libraries of components called AD-DSLs. The specialization to a domain does not require a new workflow language or composition model, but it simply happens by adding collections of skills through libraries of components that provide access to (in-terface) and execution (on an adequate runtime) of those skills. Robotics applications, data transcription applications, biomedical imaging applications (Brandon et al., 2024) have recently been realized this way.

A slightly more technical view of the components and workflows will be illustrated in the case study.

The feedback from the different communities of practice drives the growth and evolution of the platform itself. This happens through requests for additions, like recently the need of support for larger data files.

Integrating existing capabilities

The encapsulation of external resources providing data (databases, input streams), communication (http, wifi, 5G networks, ORAN), hardware (sensors, actuators, computation, robots), software (analytics libraries, graphics, simulators, geovisualisation systems) and models (AI models, recommenders, ontologies, classifiers, simulation models, digital twins) and other services follows API integration, or uses higher level community-driven services like e.g. the EdgeXfoundry services for edge IoT peripherals and computing tools.

In this way, it is possible to grow the capability of each community in according to their domain's needs, and thus happens in the context of ensured compatibility across communities. This is the key design decision that allows sharing and reuse across the entire WAVE.

Learning Support

LCNC is a new concept for many. The WAVE developers are designing and delivering training materials targeted to specific communities. For example, with education experts, they have produced both a *train the trainer program* (O'Brien et al., 2025) as well as training material on technical skills needed to use the platform. A MOOC on LCNC is currently under production. For example, topics such as hardware integration skills for robotics and advanced manufacturing researchers and workflow modelling skills for application designers have been developed.

Case study: predicting energy performance

A typical prediction methodology for energy performance of urban buildings involves the following steps:

1. Collecting data from various sources such as building stock, census, weather, and geographical data.
2. Developing building archetypes using building stock data to identify representative baseline models.
3. Parametric simulation is then conducted to develop appropriate synthetic data, followed by
4. the development of machine learning models to predict building energy performance.
5. Finally, the urban building energy performance analysis step analyzes the modeling process results for planning and decision-making purposes.

The data collection phase is non-trivial. In this country, it involves ingesting and harmonizing approximately 2.4 mil-lion residential records (in this instance, a GeoDirectory). Other heterogeneous data sources (census data from the national Central Statistics Office and Energy Performance Certificate (EPC) data from the national Sustainable Energy Authority (SEA)) are also ingested and fused with the building records to produce an overarching knowledge graph that captures both the individual data records and their relationships with other records in the graph.

When a similar methodology is applied to other jurisdictions, different data sources are ingested and fused, but the software processes for doing this are similar and suggest that code should be extensively reused with minor modification. However, in a traditional software environment, implementing this ingestion would require coordination between a domain expert (e.g., a housing analyst) and a software engineer to produce the modification. The WAVE platform replaces this requirement with the design of a workflow orchestrating SIBs according to shared, reusable components defined in a domain specific palette of SIBs. We show how to develop these workflows and related SIBs to demonstrate how the WAVE platform can be applied to develop software for multi-scale energy modelling.

Figure 2 represents (part of) the SIB library for multi-scale energy modelling within the WAVE platform. The library is organized into five distinct palettes: *Common*, *Data Ingestion*, *File Parsing and Formatting*, *Arch*

Count, and *Predict BER*. The *Common* palette contains general purpose SIBs: they are not specific to a given domain. The *Data Ingestion* palette contains SIBs to retrieve valid datasets from AWS, Azure, REST APIs and SFTP servers. Once the data is successfully stored into the local workspace, *File Parsing and Formatting* SIBs are used to homogenize data across file encodings and formats. During data engineering phase, *Arch Count* palette SIBs are used to query the Neo4J graph database and retrieve building counts whose features match those specified by the *ArcheTypesCombination* parameter. Finally, *Predict BER* SIBs are used in workflows that utilize pretrained ML models for predicting Building Energy Ratings.

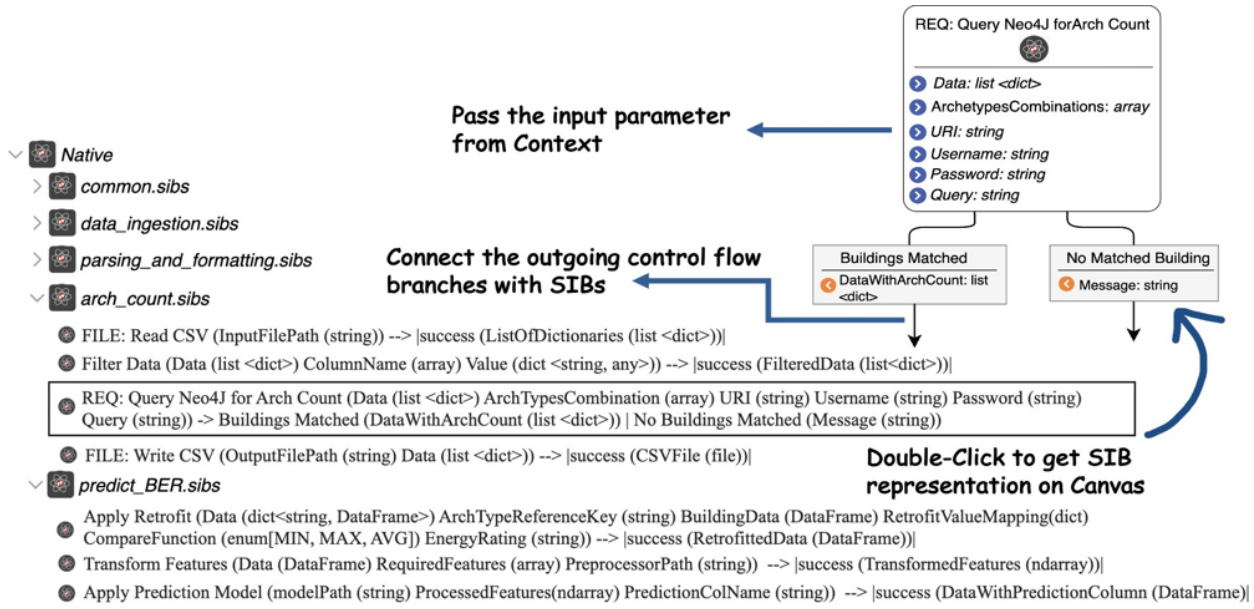

Figure 2:SIB transition from the SIB Library for multi-scale energy modelling into the WAVE Canvas

To create custom data ingestion pipelines, stakeholders select the appropriate SIBs from the palettes and use them to develop workflows. We show and discuss here two of the workflows defined for this case study: (a) Calculate Arch count (Neo4j connection and building count retrieval) and

(b) part of Predict BER (Data transformation and prediction using a pre-trained Machine Learning model). These workflows can become themselves process SIBs, and be reused for similar tasks, for example, for energy modelling in other jurisdictions.

We now show and briefly discuss two of the energy modelling workflows to demonstrate how the WAVE LCNC approach can support the full ML lifecycle.

Anatomy of a workflow

A well-formed workflow is composed of a *Start* node, one or more *End* nodes, one or more Service Independent Building Blocks (SIBs), and both the control flow of the application (solid line connectors) and its data flow (dashed line connectors). The Start node marks the initialization of the workflow with the input parameters passed from the context. Each SIB in the workflow has a name that reflects its purpose, and one or more outgoing control flow labelled *branches* that lead to the successive SIBs. Each branch corresponds to an outcome of the execution (e.g. the branches of the *REQ: Query Neo4J for Arch Count* SIB in Fig.3 are labelled *Buildings Matched*, and *No Matched Building*, respectively. In terms of the data flow, the SIB inputs are indicated in blue, and the outputs are placed on the branches, as they are typically specific to the execution outcome and thus branch specific.

Predict building energy ratings (BER)

This workflow predicts Building Energy Ratings by applying a pre-trained ML model to simulated envelope retrofits. It combines domain independent data-preprocessing SIBs, such as Load Datasets, Filter Data, and Dictionary Mapping, with application-specific ones, like Apply Retrofit. Technical complexities, including file I/O, data transformation, and running ML models via libraries like *os, pan-das*, and *joblib*, are fully abstracted. The visual modules accelerate model comparison and selection, as users can experiment with different ML models on the same or heterogeneous datasets simply by switching configurations in the Apply Prediction Model and Load Dataset SIBs. Additionally, the entire workflow can be encapsulated as a Process SIB, enhancing collaboration and reproducibility.

Calculate arch count workflow

This workflow processes a dataset that contains various archetype combinations such as Building Type, Building Energy Rating, Occupancy and Heating System, and queries a national-scale graph for the count of buildings with similar characteristics. By abstracting the technical details of connecting to Neo4j hosts, the workflow enables straightforward retrieval of building counts. The Neo4j query is passed as a parameter, allowing the matching criteria to be modified without requiring changes to the code files.

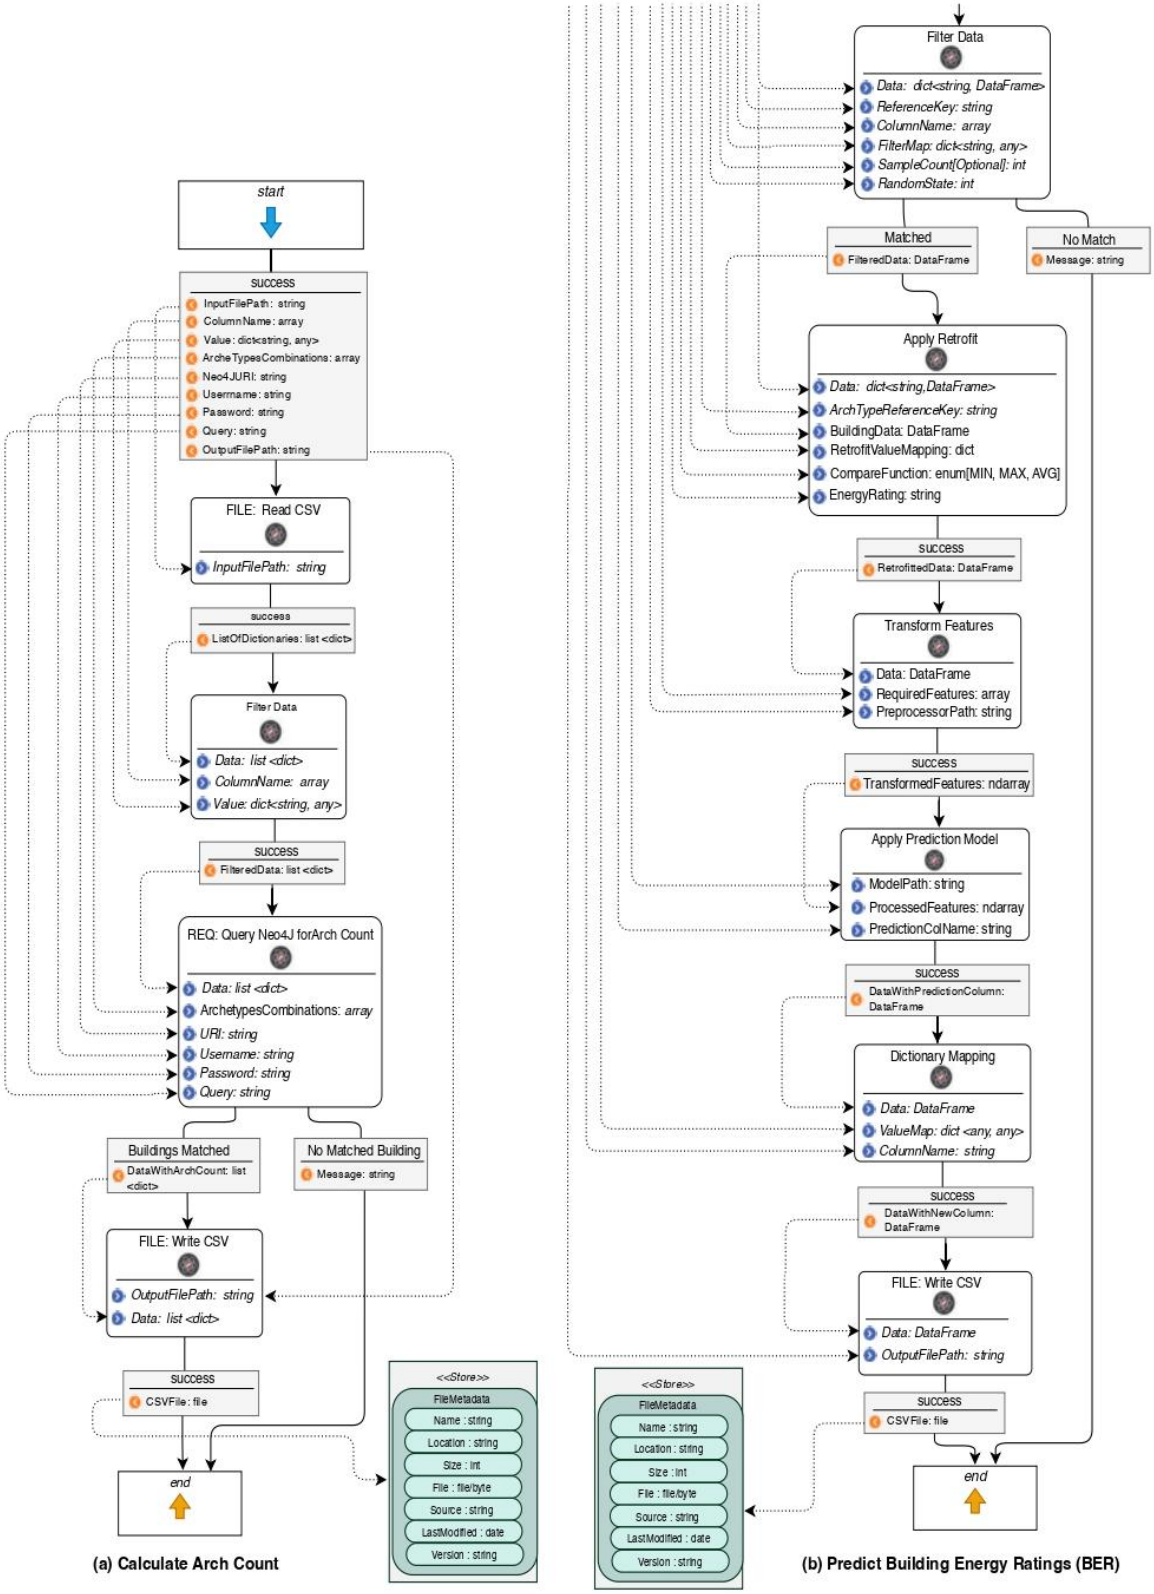

Figure 3:The WAVE workflows for (a) Calculating Archetype Counts, (b) (core part of) Predicting Building Energy Ratings (BER)

Similarly, parameters can be adjusted to calculate Arch counts for datasets filtered by a combination of columns (e.g., where ”BER” = ”A” and ”Occupancy” = 2).

Comparing traditional and LCNC approaches

While comparing the WAVE LCNC approach with a script-based pipeline, an assessment of their respective development time was done. The developer of the original

code scripts is both an expert in energy modelling and a competent programmer. In total, approximately 2000 lines of code were developed, talking approximately 3 days to develop and validate the code. A second developer created the LCNC workflows. Each one was developed and validated in approximately 4 hours. In addition to the reduced development time, the maintainability and reusability of the LCNC code also improved, as the corresponding code is componentized at a fine granularity and complies with the architectural characteristics of SIBs, and the control and data flows are explicitly modelled and thus easy to understand and to debug.

Workflows will be developed to support full electrification scenario modelling such as the effect of heat-pump adoption and EV charging within the housing stock. The resulting demand will be spatially allocated to low-voltage sub-stations, allowing feeder peak load and transformer over-load to be calculated. This will be displayed in multiscale geographical reports such as those in Fig. 4. This demonstrates how graphical workflows enable non-programmers to move from heterogeneous datasets to infrastructure-level planning insights across multiple modelling scales. Moreover, WAVE decouples workflow design from the computation, thereby enhancing execution performance. Workflows are stored in Common Workflow Language for-mat1 and executed on high-capacity server clusters, allowing users with low-specification laptops to initiate large-scale data-processing and machine learning pipelines. The backend manages metrics such as memory usage and CPU cycles through an orchestrator, eliminating the need for users to oversee these technical aspects.

Conclusions

The need to decarbonize the built environment requires a shift toward data-driven modeling. Although machine learning (ML) provides a powerful mechanism for optimizing energy performance across multiple scales, the skill gap around implementation remains a primary barrier to widespread adoption. This gap is characterized not just by a lack of technical coding ability, but by the difficulty of merging domain-specific energy expertise with complex software engineering.

LCNC platforms such as WAVE offer a convenient solution by democratizing software development. By re-moving the syntax barrier yet increasing checks and the use of domain knowledge, Wave allows domain experts who best understand building physics and operational needs - to lead the development of bespoke energy models. As demonstrated, this paradigm reduces development costs, accelerates toolchain creation, and bridges the professional skills gap. Ultimately, leveraging platforms like WAVE ensures that SMEs, policymakers and other stakeholders can fulfill the potential data-driven energy modelling.

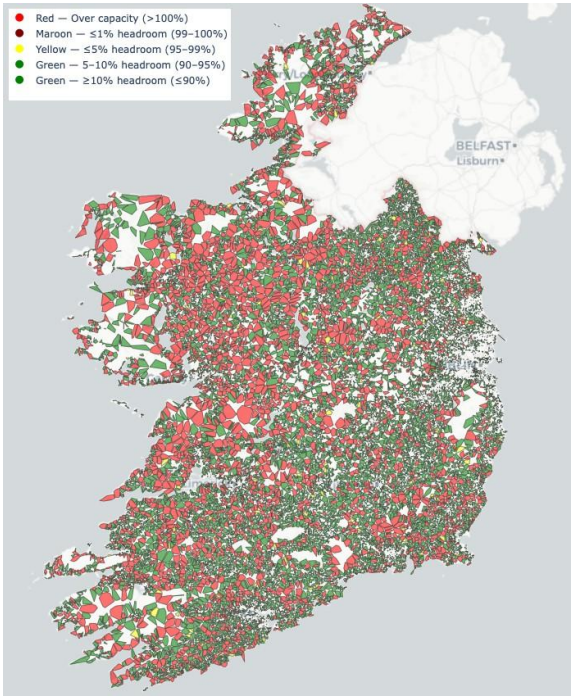

Figure 4: Results of multiscale energy modelling for scenarios including heatpump and EV adoption by residential households.

ASSET-CENTRIC KNOWLEDGE SHARING FOR PERMITTING AND COMPLIANCE WITH DIGITAL TECHNOLOGIES

Alhadi Alsaffar[1], Professor Thomas Beach[1], and Professor Yacine Rezgui[1]
[1]Cardiff University, Cardiff, UK

Abstract

Digital transformation in construction asset management is advancing through Building Information Modelling (BIM) and emerging tools such as Digital Twins (DT), Blockchain (BC), and Artificial Intelligence (AI), yet knowledge sharing in permitting and compliance remains fragmented. A survey of 110 professionals, including 30 open-ended responses from the same sample, was analysed using descriptive statistics, chi-square tests, ordinal logistic regression, reflexive thematic analysis, and concept mapping. Email and collaboration platforms dominate (70%), while external sharing remains limited. BIM (93%) and AI/ML (79%) show the highest adoption. The study develops a refined hierarchical conceptual map for digital permit certification and compliance checking.

Introduction

The construction industry faces critical challenges in which effective Knowledge Management (KM) is essential for successful asset management (Rezgui, 2001; Boamah et al., 2022; Yepes and López, 2021; Rezgui, 2011), especially in permitting and compliance checks. Regulatory complexity increases uncertainty and costs due to evolving codes and lengthy permit reviews involving multiple steps and stakeholders, resulting in inefficiency, rework, and delays (Yang and Zhang, 2024; Bloch and Fauth, 2023; Ataide et al., 2023; Fauth et al., 2023). Fragmented information silos, project data trapped in disconnected teams and proprietary formats, undermine traceability; without unifying standards or integrated technologies, teams may apply different or out-of-date rules, making compliance reviews inconsistent and complicating constraint management and decision-making (He et al., 2025; Beach et al., 2024). Skills gaps and cultural resistance, including continued reliance on paper/email workflows and limited Construction 4.0 competencies, further hinder the adoption of advanced digital technologies such as Building Information Modelling (BIM), Digital Twins (DT), Blockchain (BC), and Artificial Intelligence (AI) (Alsaffar et al., 2025; Siddiqui et al., 2023; Rinchen et al., 2024).

KM is vital for organisational success because it ensures that knowledge is effectively stored, shared, and applied to achieve strategic impact (Yeboah, 2023). In construction, this underpins traceability of decisions, supports legal defensibility, and reduces redundant rework (Wang and Meng, 2021; Sik-wah Fong et al., 2005; Xiahou et al., 2025). As projects grow in complexity and regulatory requirements become more demanding, effective knowledge sharing, accessibility, and utilisation across organisational boundaries become increasingly crucial (Maheshwari et al., 2025). Knowledge sharing also requires balancing explicit knowledge (documents and reports) with tacit knowledge (experience-based know-how), which is harder to transfer due to structural differences and expression challenges (Chumg et al., 2014; Wang et al., 2014). A widely used lens for understanding this process is the SECI model, shown in **Figure 1**, which explains how knowledge cycles between tacit and explicit forms through socialisation, externalisation, combination, and internalisation (Nonaka and Takeuchi, 1995; Aldmour, 2012; Gandomani and Tavakoli, 2016; Shull et al., 2004).

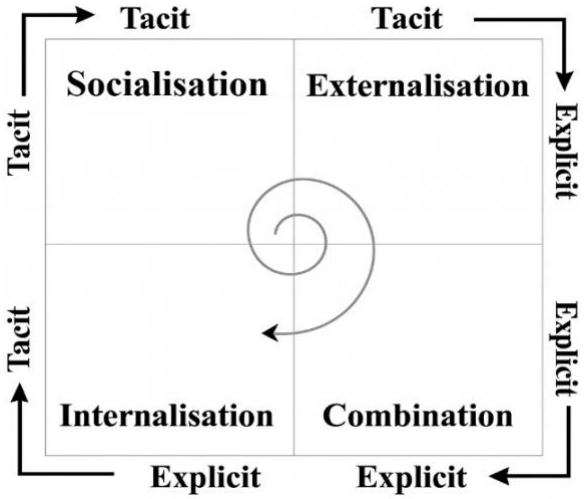

Figure 1: SECI knowledge creation model (Nonaka and Takeuchi, 1995).

The SECI model provides a valuable framework for analysing knowledge sharing in permitting and compliance processes. This is particularly relevant in construction, where knowledge sharing must account for both documented information and experience-based judgement (Chumg et al., 2014; Wang et al., 2014).

The ongoing Fourth Industrial Revolution (4IR), described as a "*fusion of technologies blurring the lines between physical, digital, and biological spheres*," has transformed how people connect and access knowledge (Klaus, 2016). In construction, this convergence is

reflected in technologies such as BIM and platform-based collaboration, where increased BIM implementation has been shown to enhance knowledge sharing and inter-organisational cooperation (Cheng et al., 2023). DT technologies have also been associated with improved efficiency and operational transparency in construction and asset management (Alsaffar et al., 2025). BC technologies further contribute to this convergence by providing immutable, decentralised records that enhance trust, traceability, and secure information exchange across project stakeholders (Alsaffar et al., 2024). These tools can support knowledge-creation and utilisation activities broadly consistent with SECI (Nonaka and Takeuchi, 1995). BIM makes design intent explicit and shareable (externalisation/combination), while DTs may, in later lifecycle stages, support forms of learning and reuse that are broadly aligned with internalisation. Importantly, BIM-based as-designed information can support later operational DT development across the asset lifecycle, offering new opportunities for integrated, knowledge-rich approaches to the built environment, although this role remains emerging (Cheng et al., 2023; Alsaffar et al., 2025; Peng and Liu, 2023).

Despite progress, the construction industry remains fragmented, with knowledge confined to specific trades, organisations, or project phases (Daniel et al., 2024). Although there have been notable advancements in capturing and sharing construction knowledge (Deng et al., 2022), permitting and compliance processes remain knowledge-intensive and still frequently rely on manual expert review (Peng and Liu, 2023). Recent research also reports that building-permit processes remain manual and fragmented (Hagedorn et al., 2025) and that traditional permit-management systems often lack transparency, thereby complicating certification verification and regulatory compliance (Alsaffar et al., 2024). This lack of transparency underscores the need to consider Blockchain-enabled certification mechanisms alongside BIM and Digital Twins to support verifiable, trustworthy permitting and compliance workflows (Alsaffar et al., 2024). In practice, permitting involves multiple stakeholders, including owners, designers, engineers, contractors, and authorities, and requires extensive coordination of technical and procedural knowledge. However, barriers such as technical compatibility issues, costs and limited digital literacy continue to constrain the adoption of digital permitting solutions (Daniel et al., 2024).

Nevertheless, empirical evidence remains limited regarding how knowledge-sharing practices and enabling digital technologies are used together in permitting and compliance checking, and on the relationships between key concepts involved in digital permit certification and compliance checking. Accordingly, building on the SECI knowledge lens and the context of digital transformation, this study examines current knowledge-sharing practices and evaluates the enabling digital technologies, including DT, BIM, BC, and AI. It is guided by the following research questions:

RQ 1: *"What knowledge-sharing practices and enabling digital technologies are used in permitting and compliance checking for construction asset management?"*

RQ 2: *"What are the relationships between key knowledge-sharing concepts in digital permit certification and compliance checking?"*

Here, "*digital permit certification and compliance checking*" refers to digital workflows for sharing, checking, and verifying permitting and compliance evidence across stakeholders in construction asset management. This paper makes two contributions. First, it reports empirical findings on knowledge sharing and enabling digital technologies in permitting and compliance checking. Second, it synthesises these findings into a refined hierarchical conceptual map for digital permit certification and compliance checking, linking DTs as as-designed information extensions of BIM, BC-enabled certification, AI-enhanced knowledge management, and organisational/regulatory enablers. The remainder of the paper presents the survey-based methodology, discusses the results, and concludes with implications and directions for future research.

Research Methodology

The research design follows the Research Onion framework (Saunders, 2019) and adopts a mixed-methods, cross-sectional survey strategy. The quantitative component provides the primary empirical evidence, while the qualitative component adds contextual depth to interpret patterns in the numerical results. **Figure 2** summarises the overall research workflow, from survey development and data collection to analysis and hierarchical conceptual mapping.

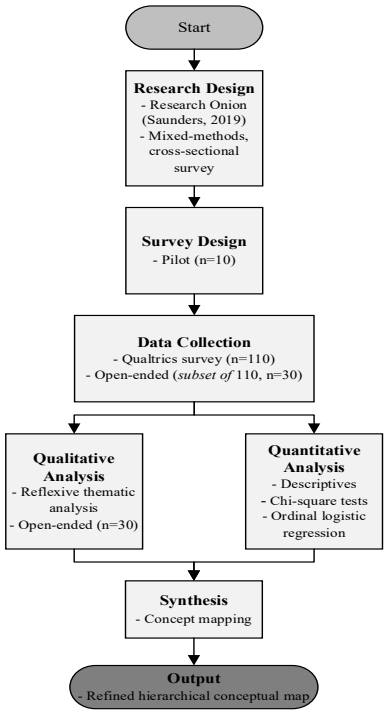

Figure 2: Research workflow summarising the mixed-methods design and analysis

Figure 2 also reflects the paper structure, in which survey design and data collection are described in this section; the quantitative and qualitative findings are reported in the "Discussion and Result Analysis" section; and the concept mapping synthesis and refined hierarchical conceptual map are presented in the final part of that section (**Figure 4** and **Table 7**).

Data were collected through an online questionnaire administered via the Qualtrics XM platform, targeting construction professionals involved in asset management, permitting, and compliance. The instrument comprised 25 questions: multiple-choice items (e.g., "Which of the following digital technologies do you use to support knowledge sharing in compliance and permitting?"), 5-point and 6-point Likert-scale evaluations (e.g., rating knowledge-sharing effectiveness), and open-ended prompts (e.g., exploring barriers to knowledge sharing). A pilot study (n=10) improved clarity and reliability before full distribution (Dudovskiy, 2024). The final dataset comprises 110 valid responses for quantitative items, with a subset of 30 respondents also completing qualitative open-ended prompts. The sample includes respondents with substantial domain experience, with over 87% reporting more than three years in compliance and permitting roles. Participants represent engineers (62%), project managers (52%), compliance officers (43%), and regulatory authority staff (40%).

While the quantitative component primarily captures what practices are used and to what extent technologies are adopted, the concept-mapping synthesis identifies and represents the relationships between key knowledge-sharing concepts in digital permit certification and compliance checking in a structured conceptual form.

Quantitative analysis used descriptive statistics (frequencies, percentages, and means) to summarise knowledge-sharing tools and practices, perceived effectiveness, adoption levels of digital technologies, and perceived barriers/benefits. Chi-square tests were applied to explore whether selected perceptions differed across respondent groups (e.g., by experience) (Kremelberg, 2010). To compare internal and external knowledge-sharing frequency, an ordinal logistic regression was conducted in R using the *polr* function from the MASS package for ordered response categories (Agresti, 2019; Chihara, 2011).

Qualitative responses were analysed using reflexive thematic analysis (Byrne, 2022), in which data were manually coded in Excel across six stages: familiarisation, generating initial codes, searching for themes, reviewing themes, defining themes, and reporting. This approach enriched contextual insight and strengthened the quantitative results, thereby providing deeper analysis and a clearer understanding of the use of digital technology in construction compliance.

Finally, concept mapping was used to synthesise the survey findings into a refined hierarchical conceptual map. Following Cañas and Novak (2008), the process involved defining the domain, listing key concepts ("parking lot"), organising concepts hierarchically, constructing a preliminary map, identifying cross-links, iteratively refining the structure, and checking it against the empirical evidence. The central domain is "Asset Management in Permitting and Compliance." Key concepts include Digital Technologies (BIM, DTs, BC, and AI), KM (Knowledge Management System (KMS), knowledge sharing, and documentation consistency), Compliance Processes and Assurance, and Strategic Barriers (communication gaps, training/technical expertise gaps, cultural resistance, infrastructure deficiencies, and regulatory barriers).

To ensure methodological rigour and trustworthy findings, the study adhered to ethical practices, including obtaining informed consent, maintaining anonymity and confidentiality, and handling data securely (Saunders, 2019; Creswell, 2023).

Discussion and Result Analysis

This section presents and analyses the findings in two parts. First, it examines current knowledge-sharing practices and enabling digital technologies in permitting and compliance checking. Second, it presents a refined hierarchical conceptual map of the relationships between key knowledge-sharing concepts.

To address **RQ1**, the current practices and gaps analysis shows that the 110 valid respondents hold roles directly relevant to permitting and compliance workflows, including Engineers (62%), Project Managers (52%), Compliance Officers (43%), Regulatory Authority staff (40%), and IT/BIM specialists (29%). More than 87% report at least 3 years of compliance/permitting experience. This high level of domain-specific experience and the balanced representation across key stakeholder roles (design, management, compliance, and IT) indicate that the sample comprises highly qualified professionals actively engaged in construction asset management and regulatory processes.

As shown in **Table 1**, compliance-related knowledge sharing is dominated by email, repositories (e.g., SharePoint), and collaboration platforms (each at 70%). KMS and Common Data Environments (CDEs) are used by around half of respondents, while paper-based exchange persists (31%), indicating continued reliance on a mix of digital and traditional approaches.

Table 1: Knowledge-sharing methods in use

Knowledge-sharing method	Count (n=89)	%
Email	62	70%
Document repositories (SharePoint)	62	70%
Collaborative platforms (Teams/Zoom)	62	70%
KMS (e.g., Primavera, Confluence)	50	57%
Common Data Environments (CDEs)	52	59%
Paper-based	27	31%

However, perceived effectiveness is mixed, as shown in **Table 2**, where 22% rated them extremely effective, 18% rated them very effective, while 22% rate them ineffective or very ineffective. The weighted average of 3.91/6 (≈65.2%) indicates only moderate performance, while the remaining 34.8% highlights unrealised potential due to inconsistent knowledge-sharing practice.

Table 2: Effectiveness Ratings of Knowledge-Sharing Practices

Effectiveness Level	Count (n=87)	%
1 (Very Ineffective)	7	8%
2 (Ineffective)	12	14%
3 (Somewhat Effective)	17	20%
4 (Effective)	16	18%
5 (Very Effective)	16	18%
6 (Extremely Effective)	19	22%

Internal exchange is substantially more frequent than external exchange, as shown in **Figure 3**. External sharing is "*rarely*" or "*never*" for a large share of respondents, indicating that compliance-related knowledge is more effectively circulated within organisations than across stakeholder boundaries. Ordinal logistic regression indicates higher-frequency sharing in internal channels than in external channels (log-odds ≈ 1.12; odds ratio ≈ 3.07), highlighting a persistent constraint in cross-organisational knowledge flow, which is critical for permitting and compliance where coordination with external stakeholders is essential.

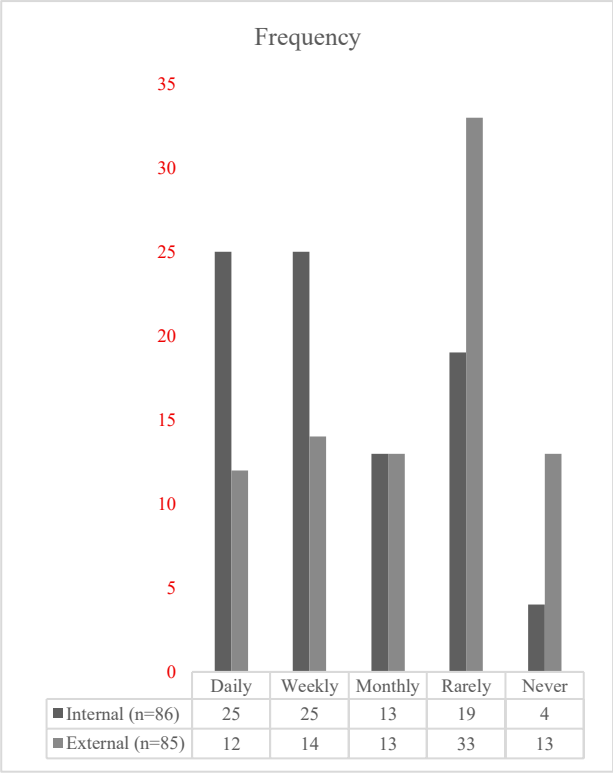

Figure 3: Comparison of the Frequency of Internal vs. External Compliance Knowledge Sharing

This disparity indicates strong but isolated internal communication and reveals significant gaps in external engagement, underscoring the need for better integration and more structured communication with external stakeholders.

The most frequently reported barriers, as shown in **Table 3**, were captured through a multiple-choice question in which respondents could select all applicable options.

Table 3: Common Barriers to Effective Knowledge Sharing

Barrier	Count (n=87)	%
Lack of communication between departments	79	91%
Lack of technology	76	87%
Lack of a formal knowledge-sharing process	69	79%
Inconsistent documentation	57	66%

In addition, a chi-square test indicates no statistically significant association between the experience group and the main barrier category ($\chi 2(3) = 4.78$, $p = 0.189$), suggesting that these barriers are widely shared across respondents.

Separately, when asked about challenges to implementing digital knowledge-sharing tools specifically, respondents identified a lack of technical expertise (87%), resistance to change (76%), high cost (71%), inadequate infrastructure (69%), limited management support (58%), and regulatory restrictions (43%). These results help explain why reliance on email exchange remains high despite interest in more advanced workflows.

In the adoption of digital technologies, as shown in **Table 4**, the findings indicate a layered digital landscape in which mature tools such as BIM coexist with emerging solutions, while widespread AI/ML uptake underscores an increasing reliance on data-driven systems.

Table 4: Digital Technology Adoption

Technology	Count (n=75)	%
BIM	70	93%
AI/ML	59	79%
Blockchain	38	51%
Digital Twins	33	44%
IoT	33	44%

Respondents also report positive operational impacts: 49% report significant improvements in permitting and compliance processes, and 43% report slight improvements. However, gap ratios (considering/using) indicate that DT (0.74) have the greatest near-term scaling potential, whereas BIM appears comparatively mature, with a gap ratio of 0.055.

As shown in **Table 5,** the most valued benefits centre on transparency/traceability and cost reduction, with data security and operational efficiency also ranking highly.

Table 5: Perceived Benefits of Digital Technologies

Benefit	Count (n=86)	%
Enhanced transparency & traceability	63	73%
Cost reduction	62	72%
Increased data security	58	67%
Improved operational efficiency	54	63%
Real-time monitoring/decision making	50	58%
Better collaboration & communication	45	52%

These findings confirm that the industry recognises cost, speed, and security as top priorities, reinforcing the strategic value of digital adoption. Nevertheless, to successfully implement these technologies, respondents highlighted several key requirements. As shown in **Table 6**, the most critical needs are greater cross-departmental integration and better staff training.

Table 6: Key Requirements for Digital Adoption

Requirement	Count (n=82)	%
Greater integration across departments	61	73%
Better staff training on digital tools	59	71%
Clearer regulatory guidelines/acceptance	60	71%
Stronger leadership & stakeholder support	57	68%
Increased investment in digital infrastructure	56	67%

This data confirms that success requires not just the right software but also supportive leadership, cohesive organisational processes, and a friendly policy environment. In addition, willingness to adopt is generally positive, with responses indicating somewhat/very willing (60%), neutral (29%), and unwilling (10%), suggesting readiness if capability and governance constraints are addressed.

In the qualitative analysis, open-ended responses from a subset of the same survey sample (n=30) were synthesised into four themes:

- Staff Training and Knowledge-Building: emphasising skill gaps, need for training courses, and even calls for dedicated KM departments.
- Centralised Systems: advocating for centralised platforms and integrated systems to reduce fragmentation.
- Leveraging New Technologies: highlighting AI-driven systems, advanced KMS, blockchain-based solutions, and the use of modern communication tools.
- Leadership Support and Cultural Adoption: stressing that top management support and cultural buy-in are essential for sustainable change.

These themes indicate that technology adoption must be matched with skills development, process formalisation, and organisational support. Overall, these findings answer **RQ1** by characterising current knowledge-sharing practices and the use of enabling digital technologies in permitting and compliance checking, and by quantifying key gaps (e.g., moderate effectiveness and lower external knowledge sharing).

To address **RQ2**, concept mapping was used to identify and represent the relationships between key knowledge-sharing concepts in digital permit certification and compliance checking within a refined hierarchical conceptual map. The synthesis integrates four connected areas: (i) Digital Technologies (BIM, DT, BC, and AI/ML), (ii) KM (KMS, documentation consistency, and knowledge-sharing practices), (iii) Compliance and Assurance Processes (permit certification, automated compliance checking, continuous compliance/operational feedback, and data security), and (iv) Strategic Barriers (communication gaps, cultural resistance, regulatory barriers, infrastructure deficiencies, and training and technical expertise gaps). The resulting conceptual components, grounded in the survey evidence, are summarised in **Table 7**, providing traceability from the empirical findings to the structure shown in **Figure 4**.

Table 7: Concept-mapping components and survey evidence

Conceptual component	Empirical justification (survey evidence)
BIM for design-stage compliance checking; DTs for lifecycle monitoring	BIM 93%; DTs 44% (gap ratio 0.74)
BC for data security, traceability, and auditable permit certification	51% adoption; data security 67%; transparency/traceability 73%
AI-driven knowledge extraction and KMS enhancement	79% adoption; qualitative theme on AI-driven systems and advanced KMS
KMS, documentation consistency, and integrated cross-department knowledge sharing	KMS 57%; CDE 59%; inconsistency 66%; effectiveness gap 34.8%; paper-based 31%
Organisational and regulatory enablement	Communication gaps 91%; expertise deficits 87%; resistance 76%; infrastructure 69%; regulation 43%

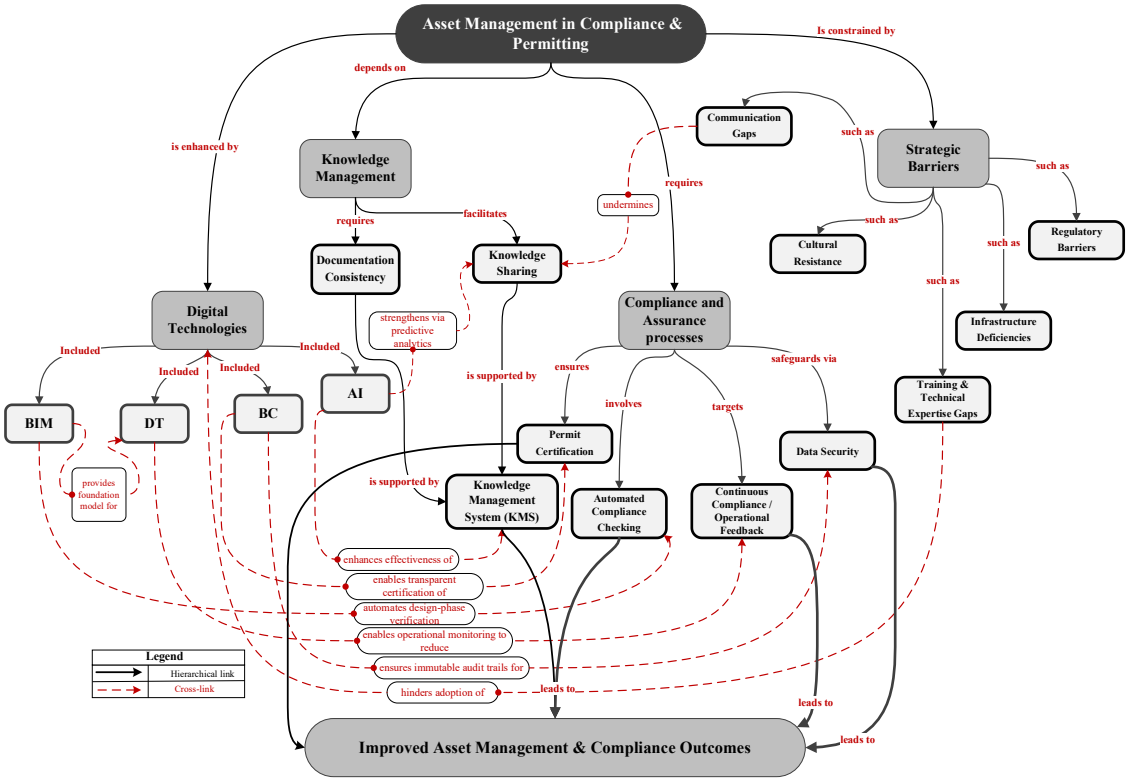

Figure 4: Refined hierarchical concept map for compliance-oriented asset management

Together, these components form an empirically grounded conceptual mapping linking technologies, knowledge processes, and implementation conditions. BIM's design-stage role is distinguished from DT's lifecycle-oriented monitoring role, with knowledge sharing being re-established as a cross-cutting theme. A lifecycle cross-link connects BIM-based design information to an emerging operational DT beyond the permit stage, and in this context, BC supports immutable audit trails and auditable permit certification, while AI contributes to knowledge extraction and KMS enhancement.

Within permitting, DTs are treated as as-designed information structures derived from BIM and documentation, aligned with ISO 19650's information-management principles (BS ISO 19650-1, 2018), rather than as mature permit-stage substitutes. They provide a practical foundation for later operational DT development and continuity from design information to inspection and monitoring. Although not yet widespread, survey results indicate emerging interest, with DT adoption at 44%. **Figure 4** integrates these relationships.

Overall, this synthesis answers **RQ2** by representing the relationships between key knowledge-sharing concepts in digital permit certification and compliance checking through the refined hierarchical conceptual map (**Figure 4**), supported by the survey evidence in **Table 7**.

Conclusions

This study examined how knowledge sharing and digital technologies are currently used for permitting and compliance, and how these findings inform a hierarchical conceptual map of knowledge-sharing practices for permitting and compliance checking in construction asset management. The analysis draws on a survey of 110 professionals, with 30 respondents from the same sample providing open-ended responses for reflexive thematic analysis. In answer to **RQ1**, knowledge sharing on permitting and compliance remains reliant on conventional tools such as email and document repositories, with external sharing notably limited. Digital technology adoption is uneven: BIM and AI/ML are well-established, while BC and DTs remain emerging, despite recognised benefits in transparency, cost reduction, and data security. These patterns are constrained by interdepartmental communication gaps, limited technical expertise, and cultural resistance.

To address **RQ2**, the empirical findings were synthesised through concept mapping to represent the relationships among key knowledge-sharing concepts in digital permit certification and compliance checking within a refined hierarchical conceptual map.

The study has limitations, as the sample may not reflect global construction practice, self-reported data may introduce subjectivity, and the cross-sectional design cannot capture temporal changes in adoption. Correlations between knowledge-sharing effectiveness and mechanism type, or between sharing frequency and organisational size, were not examined. As DT use in permitting is still emerging, its internalisation benefits remain prospective. Future work should operationalise the conceptual components in prototype solutions, validate them through case-based and longitudinal studies, and explore such correlations to provide more granular insights into optimal knowledge-sharing configurations. Overall, the study clarifies current practice and provides a

structured conceptual map to guide digital permit certification and compliance checking.

Acknowledgments

I gratefully acknowledge Professor Thomas Beach for his guidance and Professor Yacine Rezgui and the School of Engineering at Cardiff University for their support. I also extend my thanks to the General Secretariat of the Supreme Council for Planning and Development in Kuwait for its sponsorship.

Abstract

Automatic generation of Building Information Models (BIM) from building scans is a key challenge in architecture and construction. We present a modular pipeline for generating IFC-compliant BIM from 3D point clouds. The hybrid approach combines learning-based semantic segmentation with topology-aware geometric reconstruction to model structural elements accurately. We propose vIoU, adapting voxel-based overlap evaluation to Scan-to-BIM by enabling holistic, instance-matching-free comparison of reconstructed and ground-truth models. We release the German Hospital dataset (DeKH), including high-resolution point clouds, ground truth BIMs, and semantic annotations. Experiments on DeKH and CV4AEC datasets show significant improvements over a RANSAC-based baseline, demonstrating robustness and scalability.

Introduction

Capturing spatial data of existing built environments can be efficiently achieved using mobile (Kanayama et al., 2025) and terrestrial scanning systems (Chang et al., 2017; Armeni et al., 2017). To leverage such data in construction (Wu et al., 2021) and facility management (Xu et al., 2021), it must be converted into semantic models in accordance with the Building Information Modelling (BIM) methodology. Given the volume of data and the complex steps required to transform raw 3D point clouds into BIM models, full automation of this process is highly desirable. However, this transformation remains a challenge.

Despite the importance of the task, scan-to-BIM is rarely treated as a comprehensive, end-to-end problem with standardized benchmarks; however, some effort is being made through initiatives like the CV4AEC challenges (Armeni et al., 2024). In this work, we introduce BIMStruct3D, one of the first comprehensive frameworks for automating the conversion of noisy and incomplete 3D point clouds into IFC-compatible BIM models. Our BIMStruct3D pipeline employs a hybrid approach that integrates both learning-based and classical point cloud processing techniques. It includes modules for 3D point cloud segmentation, geometric reconstruction and primitive extraction, as well as model post-processing, as illustrated in Figure 1.

BIMStruct3D is designed to process data from multi-storey buildings such as offices, hospitals, and residential complexes, and generate BIM representations of architectural

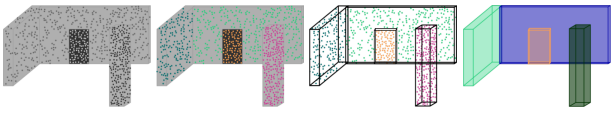

Figure 1: BIMStruct3D is a hybrid pipeline for generating IFC BIM models from 3D point cloud scans

elements including walls, doors, and columns. Accompanying our framework is `pystruct3d`, a modular library tailored for processing 3D point cloud data of buildings.
To support reproducibility and facilitate benchmarking in the scan-to-BIM domain, we provide a comprehensive evaluation of our method at both modular and end-to-end levels. This includes tests on publicly available datasets and newly acquired data, featuring high-precision, handcrafted ground truth BIMs. We also propose volumetric Intersection over Union (vIoU), which adapts voxel-based IoU evaluation to the Scan-to-BIM domain. Unlike per-object voxel IoU used in 3D shape reconstruction, vIoU operates at the class level without instance matching, making it robust to the fragmented and variably segmented wall representations common in BIM reconstruction.
In real-world scenarios, building point clouds are often incomplete due to factors such as the limitations of scanning technology, human error and environmental conditions like lighting, occlusion, and material reflectivity (e.g. glass surfaces). BIMStruct3D is built to handle such noisy and incomplete data to create usable BIM representations.
In summary, our contributions are as follows:

- BIMStruct3D, a fully automated hybrid pipeline generating IFC BIM models from 3D point clouds using semantic segmentation and geometric reconstruction.
- Specialized algorithms for primitive extraction and BIM model generation.
- vIoU, an adaptation of voxel-based IoU to Scan-to-BIM evaluation, enabling class-level comparison without instance-level matching.
- `pystruct3d`[1], an open-source library for processing 3D building point clouds, released with DeKH[2], a new dataset including high-resolution scans, semantic annotations, and handcrafted ground truth BIMs.

Related Work

Point Cloud Semantic Segmentation

Semantic segmentation of point clouds is a fundamental computer vision task, currently dominated by deep neural networks. Early approaches include projection-based (Chen et al., 2017), voxel-based (Graham et al., 2018), and point-based networks (Qi et al., 2017), each trading off between computational cost, geometric fidelity, and flexibility. More recent developments have incorporated self-attention mechanisms, demonstrating strong performance in large-scale 3D scene understanding (Wang et al., 2019). Point Transformer by Zhao et al. (2021) advanced point-based segmentation by integrating local self-attention (Vaswani et al., 2017), vector attention (Zhao et al., 2020), and appropriate positional encodings. Subsequent iterations (Wu et al., 2024) introduce architectural improvements leading to better segmentation accuracy and model efficiency.

Scan-to-BIM Approaches

To align with the scope of this work, we focus on research targeting fully automated (end-to-end) scan-to-BIM conversion from point clouds. Gourguechon et al. (2022) and Bassier and Vergauwen (2020) distinguish between room-based and wall-based (or structural component-based) reconstruction approaches. The former identifies rooms and then reconstructs surrounding elements, while the latter directly targets structural components such as walls. Unfortunately, to this day, there are no open-source implementations of complete scan-to-BIM pipelines or benchmark datasets for evaluation.

Room-based reconstruction

Room-based methods segment indoor spaces and reconstruct surrounding elements. Representative approaches address plane fitting and wall estimation (Ochmann et al., 2016, 2019), 2D region growing with slab reconstruction (Macher et al., 2017), comprehensive element reconstruction including windows and fixtures (Xiong et al., 2023), hybrid IFC wall reconstruction with topology refinement (Bassier et al., 2018), and learning-based segmentation followed by space decomposition (Tang et al., 2022; Hu et al., 2020). While these methods offer good indoor segmentation, Bassier and Vergauwen (2020) note their limitations in modelling non-room structures and handling clutter. Thus, component-based approaches targeting structural elements have gained traction.

Structural component reconstruction

Component-based reconstruction identifies and models structural elements like walls and columns through clustering, semantic segmentation, and primitive fitting. Bassier and Vergauwen (2020) focused on extracting standard wall objects with topological rules for merging, while follow-up work (Bassier et al., 2020) compared 2D and 3D reconstruction methods. Other approaches combine 2D and 3D processing with point cloud upsampling (Gankhuyag and Han, 2021), use RANSAC and convex hull-based boundary extraction (Thomson and Boehm, 2015), reconstruct walls and spaces from enclosed rooms (Anagnostopoulos et al., 2016), or segment concrete components via concavity/convexity criteria (Son and Kim, 2017). The closest work to ours is by Kim and Kim (2021), which uses synthetic data to train a segmentation model, followed by instance clustering and planar patch segmentation. Element relationships are modelled with graph networks to infer missing links and extend incomplete elements.

Our approach differs in that we do not rely on synthetic data and instead address several common limitations, including limited generalization and reliance on manual parameter tuning. We integrate semantic segmentation, geometric reconstruction, and topological reasoning into a unified scan-to-BIM pipeline.

Methodology

Our method, outlined in Figure 2, consists of semantic and instance segmentation, geometry reconstruction, topology refinement, and BIM object creation from a 3D point cloud. IFC export is handled via *IfcOpenShell*[3], generating a project–site–building–storey hierarchy and assigning reconstructed geometry as corresponding IFC entities (`IfcWall`, `IfcDoor`, `IfcColumn`). During the reconstruction process, we adopt the Manhattan world assumption (Coughlan and Yuille, 1999), which holds for the majority of structural objects in typical building environments.

Initially, levels/storeys are identified by analysing vertical point density distributions, using surfaces like floors and ceilings to detect significant point concentrations (Bassier et al., 2020; Macher et al., 2017). Semantic segmentation using state-of-the-art deep learning models (Wu et al., 2024) serves as the basis for reconstructing walls, doors, and columns. The reconstruction pipeline follows a common structure: instance segmentation, geometry reconstruction, topology refinement, and IFC BIM object creation.

Wall reconstruction is based on axis-aligned point grouping. DBSCAN clustering (Ester et al., 1996) is applied per axis to form spatial clusters, discarding sparse noise as seen in Figure 3. HYSAC, our RANSAC (Schnabel et al., 2007) based plane segmentation algorithm with optimized seed selection, is used to extract wall surfaces. These are enclosed using Horizontal Oriented Bounding Boxes (H-OBB), followed by topological refinements to ensure geometric correctness.

Door points are initially identified via semantic segmentation and then treated as child objects of walls, relying on the reconstructed wall geometry as a starting point. The process first identifies door points within the wall bounding boxes, which typically correspond to frames, linings, or closed door leaves captured during scanning. If such points are found, the bounding box is expanded to include additional door geometry, such as open door leaves, ensuring doors are correctly associated with their respective parent walls. Our two-step approach reduces errors caused by

open doors adjacent to perpendicular walls.

Column points are clustered using DBSCAN (Ester et al., 1996) and filtered by minimum point thresholds to reduce artifacts. Shape classification is achieved through curvature analysis based on eigenvalue decomposition from k-d tree neighbourhood searches. Curvature distributions are modelled with Maximum Likelihood Estimation to distinguish round (low standard deviation) from square or rectangular columns (high standard deviation). We then use RANSAC cylinder fitting for round columns and H-OBB fitting square/rectangular columns.

Semantic Segmentation

Semantic segmentation is essential for producing accurate IFC models, as it forms the foundation for all subsequent steps. High-quality segmentation ensures later geometry reconstruction stages are based on reliable object labels.

We use Point Transformer V3 by Wu et al. (2024), trained on a combined dataset from three public datasets: S3DIS (Armeni et al., 2016), Structured3D (Zheng et al., 2020), and ScanNet (Dai et al., 2017). Training on a joint dataset prevents the model from over-fitting to the data and sensor used in one dataset. To further improve generalization, additional data augmentation techniques were used, such as removing color information to simulate scans from grayscale 3D sensors. This is particularly relevant because the CV4AEC datasetused for the evaluation contains colored and grayscale point clouds. This segmentation pipeline ensures robust performance across diverse scan types and scene complexities, enabling reliable downstream reconstruction of BIM elements.

Topology aware geometry reconstruction

The reconstruction pipeline leverages both state-of-the-art techniques and our novel contributions. The following sections describe our key innovations in wall reconstruction, oriented bounding box fitting, and topology correction.

HYSAC wall reconstruction

The RANSAC-based plane fitting methods (Schnabel et al., 2007) are highly sensitive to parameter settings like the minimum number of inliers and distance thresholds. Improper parameter tuning often results in under-segmentation, where a single plane, instead of two, is incorrectly fitted to an entire wall instance.

To address this, we propose Hypothesis-based Sample Consensus (HYSAC), a modified RANSAC approach that improves seed point selection. Instead of sampling seed points randomly, HYSAC benefits from the point density distribution perpendicular to the primary wall orientation. Inspired by Armeni et al. (2016), we compute a 1D density histogram along the axis orthogonal to the wall surface and select seed points from regions of highest density. Planes are fitted using Singular Value Decomposition (SVD), which provides a least-squares optimal plane fit robust to point cloud noise, and accepted based on a minimum inlier ratio. Algorithm 1 shows a pseudo code implementation of HYSAC.

As shown in Figure 4, HYSAC reliably detects multiple planes within a wall cluster, distinguishing between valid wall surfaces and outliers. The resulting inlier points are grouped and forwarded for further geometric processing.

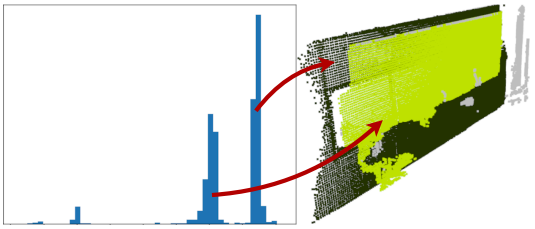

Figure 4: HYSAC plane fitting. Result of plane fitting (plane points coloured, outliers grey) with corresponding histogram of point distribution.

Horizontal Oriented Bounding Boxes Fitting

To approximate the geometry of wall instances, we fit Horizontal Oriented Bounding Boxes (H-OBB) to the previously segmented plane clusters. Given that architectural structures typically conform to horizontal and vertical alignments, we restrict the bounding boxes to axis-aligned orientations within the XY-plane.

The H-OBB fitting procedure follows a 2D projection strategy. All segmented points are projected onto the XY-plane, and a convex hull is computed. The convex hull is restricted to a quadrilateral, and each edge is evaluated as a potential candidate for the bounding box length. We rotate each edge to align with the X-axis, compute the minimum-area axis-aligned bounding box, and then select the configuration with the smallest area. The inverse rotation is applied to return the bounding box to its original orientation. This process is visualized in Figure 5.

Topology Correction

Even with high-quality plane and bounding box fitting, errors in wall topology often persist, typically caused by 3D scanning noise. We implement a topology-aware correction stage to ensure consistent and realistic wall geometries. Three main correction operations are introduced:

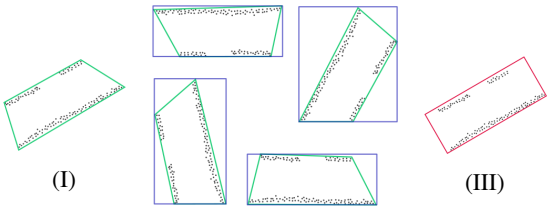

Figure 5: H-OBB fitting procedure on 2D projected data. Left: 2D projected input data with convex hull. Centre: Axis-aligned bounding box fitted to each edge rotated parallel to the X-axis. Right: Inverse rotation to minimal bounding box, final result.

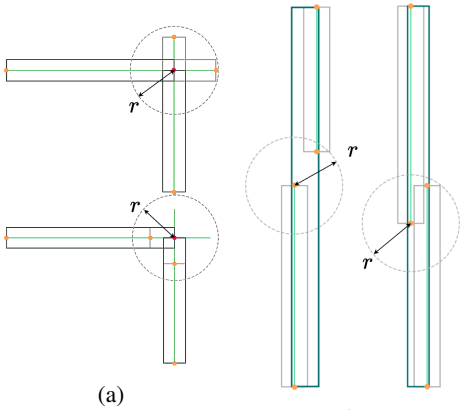
- **Intersection Correction:** Perpendicular bounding boxes that intersect must be clipped or extended to form clean corner connections.
- **Merging:** Collinear bounding boxes with adjacent or overlapping baselines must be merged into longer walls to reduce redundancy.
- **Redundancy Removal:** Smaller boxes fully enclosed by larger ones are treated as artifacts and removed.

Corrections are based on geometric analysis (adjacency, parallelism, orthogonality) as well as domain knowledge. Perpendicular pairs are found by analysing centrelines of all bounding boxes and computing intersection points. If the endpoint of a bounding box lies within a certain distance r of an intersection, the box is clipped or extended accordingly as shown in Figure 6a.



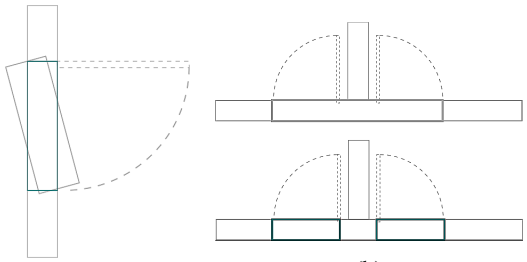


Figure 6: Wall bounding box refinement. (a) Extending and clipping bounding boxes. (b) Merging bounding boxes.

For merging, bounding boxes with endpoints within a distance threshold are joined by averaging the height and Z-coordinates of the endpoints while preserving horizontal alignment as shown in Figure 6b. Intersection correction and merging procedures are applied iteratively, as each operation may introduce new merge or correction candidates. The distance thresholds for these operations (e.g., intersection radius r, merge distance) are set once per project based on domain knowledge such as typical wall widths and corridor dimensions.

Finally, to refine door geometry, we project door bounding boxes into their parent wall to ensure alignment as seen in Figure 7a. For oversized doors, which may arise from

clustering errors, we apply a width threshold and split them into multiple instances. Figure 7b shows the corrected doors after offsets were applied to ensure a realistic spacing between the door instances.

These algorithms yield a geometrically and topologically coherent representation of walls and doors, forming a robust foundation for accurate IFC models.

(a) (b)

Figure 7: Bounding box refinement. (a) projecting the bounding box into the parent geometry. (b) splitting bounding boxes too wide.

Evaluation

The primary method for assessing reconstruction accuracy is to compare reconstructed BIMs against ground truth models. While simple cuboid representations can be directly compared, walls and doors may be reconstructed as more complex geometries, making standard geometric comparison difficult. Therefore, we use several evaluation metrics to quantify reconstruction accuracy.

Metrics

The main metric used is the 3D-Intersection over Union (3D-IoU). However, due to its limitations in handling small spatial misalignments, we introduce the Volumetric Intersection over Union (vIoU) as an alternative.

3D-Intersection over Union

The 3D-Intersection over Union (3D-IoU) is calculated as the ratio of the volume of the intersection to the volume of the union of the reconstructed and ground-truth bounding boxes. This metric captures both shape and spatial alignment, providing a compact representation of how well two volumes overlap. However, 3D-IoU is highly sensitive to minor deviations in size or alignment: for thin elements such as walls, an offset on the order of the smallest dimension (e.g., wall thickness) already drives the intersection-to-union ratio well below 0.5, even when the reconstruction is otherwise correct. Furthermore, 3D-IoU requires instance-level assignment between predicted and ground-truth elements, which becomes ambiguous when walls are fragmented or merged during reconstruction.

Volumetric Intersection over Union

To address these limitations, we propose Volumetric Intersection over Union (vIoU), computed on a voxel grid. Voxel-based IoU is well established in 3D object reconstruction and occupancy prediction Agnew et al. (2021), where it evaluates per-object shape accuracy. However, its direct application to Scan-to-BIM is non-trivial, as standard per-object voxel IoU inherits the same matching dependency as 3D-IoU. Our vIoU addresses this by operating at the class level: all reconstructed geometry of a given type (e.g., walls) and all corresponding ground-truth geometry are voxelized jointly, and overlap is computed holistically without instance assignment. This is conceptually analogous to how semantic segmentation IoU evaluates per-class predictions in 2D, but applied to 3D volumetric BIM evaluation. We use a voxel size of $5\ cm$, corresponding to a tolerance of $\pm 2.5\ cm$, which we consider reasonable for the structural elements addressed here. The 3D space is discretized, and a voxel is marked as occupied if its centroid lies inside a bounding box. For both ground truth and reconstructed geometries, we count all occupied voxels and compute vIoU as the ratio of their intersection and union. An example is illustrated in Figure 8.

This voxel-based approach simplifies comparison by avoiding complex geometric overlap calculations, provides a sub-voxel tolerance to small misalignments, particularly relevant for thin elements such as walls, and eliminates the need for instance-level bounding box matching. The latter is particularly important for walls, which may appear as a single bounding box, be split into segments, or be fragmented due to incomplete scans. Unlike 3D-IoU, which would assign ground truth to only one predicted instance, vIoU evaluates overlap holistically at the voxel level.

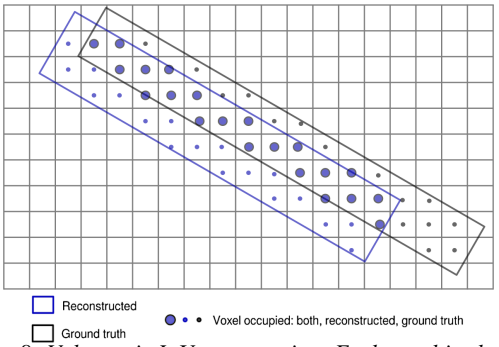

Figure 8: Volumetric IoU computation. Each voxel is classified as belonging to the reconstructed or ground-truth bounding box if its centroid lies within the corresponding geometry.

Results

We evaluate our reconstruction pipeline on two datasets: Our newly proposed German Hospital dataset (DeKH) and the CV4AEC Scan-to-BIM Challenge dataset. While DeKH features largely empty interiors, CV4AEC is fully furnished featuring a lot of clutter and complex occlusions. Furthermore, an ablation study is presented to investigate the impact of individual components in our pipeline and assess the effect of semantic segmentation accuracy.

CV4AEC

The CV4AEC dataset is more challenging due to its cluttered, incomplete scans and presence of interior furniture and occlusions. Six scans from the test set are used for evaluation, with ground-truth BIMs manually created from the input point clouds. Results are presented in Table 1.

Table 1: Results of the evaluation on the CV4AEC dataset test scenes. The vIoU is calculated for a 5 cm voxel size.

Metrics	Office_1	Office_2	Office_3	Office_4	Parking_1	Parking_2	***Mean %***	Segmentation IoU

In the first two scenes, (Office_1 and Office_2) with standard wall and door configurations, our pipeline performs best due to alignment with our assumptions. Scenes Office_3 and Office_4 contain open spaces, cubicles, and complex facade elements, making the reconstruction more challenging. The last two scenes (Parking_1 and Parking_2) are from underground parking structures. Although some improvement in column detection is observed, results remain lower than in the office scenes. Notably, no doors are detected in (Parking_2), likely due to closed doors during scanning and segmentation failure suggesting that a dedicated detection algorithm for doors might be beneficial. The segmentation IoU presented in the last column gives an indication of the challenge these types of data are posing to state-of-the-art point cloud segmentation methods.

German Hospital Dataset (DeKH)

Our DeKH dataset is a new public dataset including four scans from three buildings in an unused, largely unfurnished hospital building in Germany. Building **A**, over 100 years old, features structural walls, central corridors, and a symmetrical layout. Building **B** includes an Intensive Care Unit (ICU) area with integrated equipment, while building **C** contains empty surgical rooms with built-in furniture. In addition to the point clouds annotated following a construction ontology-based guideline (Kaufmann et al., 2023), we provide the manually created BIMs for all of the scans. The results of the reconstruction are presented in Table 2.

Table 2: Results of the evaluation on the DeKH dataset. The vIoU is calculated for a voxel size of 5 cm.

Metrics	**A** 1st floor	**A** 2nd floor	**B** ICU	**C** Surgery	***Mean %***
Wall 3D-IoU [-]	0.395	0.219	0.270	0.328	*30.3*
Wall vIoU [-]	0.553	0.463	0.388	0.451	*46.4*
Door 3D-IoU [-]	0.417	0.104	0.193	0.223	*23.4*
Door vIoU [-]	0.402	0.103	0.219	0.236	*24.0*
Mean 3D-IoU[-]	0.406	0.162	0.232	0.275	*26.9*
Mean vIoU [-]	0.478	0.283	0.304	0.344	*35.2*

Performance in the **A** building's second floor is lower than the first floor. The pipeline faced challenges in reconstructing smaller wall compartments. The door reconstruction had issues due to sparse segmentation. In the **B** ICU building, performance improves. Door reconstruction is accurate but scored poorly due to a mismatch in door representations between the ground truth of thin door leaves and the reconstructed geometry including frame and lining. In building **C**, some furniture surfaces were misclassified as walls, and some open doors lead to double reconstructions.

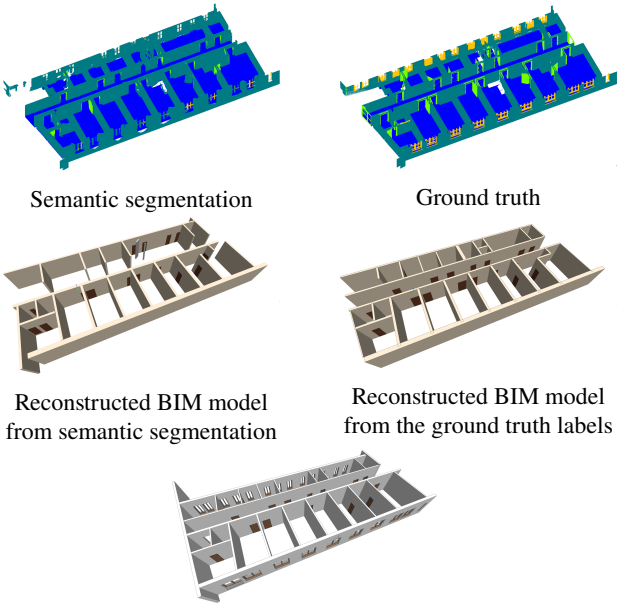

*Figure 9: Comparison of reconstructed BIM models from semantic segmentation vs ground truth in DeKH–building **A**.*

The ablation study in Table 3 presents three configurations: **Baseline**, which follows the reconstruction approach of Kaufmann et al. (2022) using RANSAC for primitive fitting and H-OBB estimation without topology correction; **Ours**, representing the full pipeline with HYSAC, H-OBB fitting, and topology refinement; and **GT labels**, which applies the same method as **Ours** but uses ground truth semantic labels to isolate the effect of segmentation quality. The results confirm our pipeline significantly improves wall and door reconstruction accuracy compared to the baseline. Notably, even with ground truth labels, wall reconstruction does not improve. Our approach achieves a 4.9% higher bounding box IoU while volumetric IoU for walls shows only a slight advantage with ground truth labels. The door reconstruction improves considerably with ground truth segmentation. These results highlight that, while our method can tolerate some incomplete segmentation especially for large structures like walls, accurate semantic segmentation remains crucial for smaller elements like doors. The

qualitative results in Figure 9 also support these findings.

*Table 3: Ablation study on the first floor of the DeKH **A** building.*

Metrics	Baseline	Ours	GT Labels
Wall 3D-IoU [-]	0.371	**0.395**	0.346
Wall vIoU [-]	0.466	**0.553**	0.571
Door 3D-IoU [-]	0.322	**0.417**	0.519
Door vIoU [-]	0.391	**0.402**	0.521
Mean 3D-IoU[-]	0.346	**0.406**	0.432
Mean vIoU [-]	0.429	**0.478**	0.546

Discussion and Conclusion

This work presents a robust and modular pipeline that advances the state of scan-to-BIM automation, generating IFC-compliant BIM models from 3D point clouds. The proposed pipeline achieves competitive reconstruction accuracy across diverse scenes, demonstrating its practical viability and scalability. We contribute to the topic with methodological advances and a new benchmark dataset.

Our approach delivers accurate reconstructions of structural elements using a hybrid methodology of learning-based and geometric processing techniques. Evaluation across two datasets confirms the pipeline's robustness and effectiveness, particularly for walls and doors, where reconstruction quality exceeds a RANSAC-based baseline. Even with incomplete or noisy data, the system maintained reliable performance. Direct comparison with existing scan-to-BIM methods is currently not feasible due to the absence of open-source implementations and standardized evaluation protocols. The CV4AEC challenge provides the closest available shared benchmark, where the proposed method was evaluated competitively. The release of DeKH aims to further support reproducible comparison in future work.

A major contribution is the introduction of the **DeKH** benchmark dataset. The release of DeKH, with high-resolution scans, ground truth BIMs, and semantic annotations, provides a new benchmark for scan-to-BIM.

Additionally, we propose vIoU, which adapts voxel-based IoU to class-level evaluation without instance matching, providing more robust comparison in scenes with misaligned, fragmented, or variably segmented elements.

To strengthen the pipeline, future efforts should expand beyond the current object classes toward more functional BIMs. The reconstruction algorithms are adaptable and could extend to elements such as windows, stairs, and mechanical, electrical, and plumbing (MEP) systems.

The topology refinement procedures showed sensitivity to parameter selection. For instance, these operations can introduce inaccuracies when small segments are wrongly merged. Thus, adaptive, context-aware refinement strategies or learned alternatives could address this vulnerability.

Our pipeline adopts the Manhattan world assumption, which constrains reconstructed geometry to predominantly orthogonal orientations. Consequently, it is best suited to buildings with rectilinear layouts, such as offices, hospitals, and residential complexes, which constitute the majority of typical building stock. Structures with significant non-orthogonal elements (such as curved walls, angled façades, or irregular floor plans) would not be handled correctly, as the axis-aligned clustering would either discard or misassign their points, and the bounding box fitting would produce poor approximations. Relaxing this assumption, for instance through data-driven orientation estimation or by supporting polygonal wall primitives, is an important direction for future work.

Looking ahead, extending the pipeline to support a broader range of object classes and incorporating subcomponent-level reasoning will be important steps toward producing complete and functionally rich BIMs. In parallel, research into end-to-end learning approaches that can infer BIM semantics and geometry directly from raw point cloud data and other sources will help move the field forward.

INFORMATION REQUIREMENTS FOR DIGITAL TWIN INTEGRATION IN FIREFIGHTING: A SURVEY STUDY

Iryna Osadcha[1], Caroline McMullan[2], Andrius Jurelionis[1], Robert Howell[3], and Muhammad Intizar Ali[2]
[1]Kaunas University of Technology, Kaunas, Lithuania

[3]Dublin Fire Brigade, Dublin, Ireland

Abstract

Firefighting operations increasingly use digital tools for situational awareness, yet current systems often provide fragmented information that does not meet operational needs. Digital Twin integration appears to be a potential solution to address this gap. This study reports a survey of Irish firefighters examining information needs, data sources, Digital Twin functionality, and user readiness for adoption. The results show demand for real-time sensing and prediction, while operational decisions still rely mainly on experience and direct observation. The findings highlight the need for information prioritisation and federated rather than centralised data integration, contributing practical requirements for Digital Twin-enabled firefighting support systems.

Introduction

The evolution of the built environment is reshaping the nature of fire hazards, creating new challenges for firefighting operations. Beyond extinguishing the fire, first responders are often tasked with locating and evacuating occupants before conditions deteriorate due to heat and smoke (Khan et al., 2022). On arrival, the Incident Commander must quickly decide whether to take an offensive approach (entering the building to save occupants or property when the expected benefits outweigh risks to firefighter safety) or to remain outside in a defensive mode. This choice is never final and must be updated through dynamic risk assessment as the situation evolves (Han et al., 2010).

In practice, however, fire-ground conditions are often chaotic and unclear, making them difficult for first responders to interpret. This contributes to continued injuries and fatalities. The US Fire Administration reported 72 firefighter duty deaths in 2024, with 42 linked to stress or overexertion, and fatality numbers have fluctuated little over the past decade (ranging from 65 in 2019 to 141 in 2021) (USFA, 2024). In the UK, 677 on-duty injuries were recorded in 2024-2025, including 18 classified as major according to the RIDDOR specification (MHCLG, 2024). These figures underline the need for better situational awareness and more informed risk assessment during incidents.

Information systems have long been used in the fire safety domain and can be broadly grouped into: systems for fire safety equipment inspection and management (e.g., Almatared et al., 2023); systems designed to support occupant evacuation (e.g., Kim et al., 2024); and systems targeting firefighters directly. The latter include GIS-based systems (Tashakkori et al., 2015), sensor-driven and simulation-coupled systems (Han et al., 2010), BIM and IoT integration approaches (Rezaeifam et al., 2023), Digital Twin-based systems (Zhang et al., 2022), and immersive training environments (Chen et al., 2021). The standards NFPA 950 and 951 distinguish software used by firefighters into two main clusters: (1) incident command and situational awareness software and (2) analytical and decision support software. The standards also specify that software should be provided with an API or other standardised means of data exchange to enable integration with discrete systems (NFPA, 2020, 2022).

Research on firefighter information requirements to inform system development has led to several additional classifications. One of the earliest was a NIST workshop that identified approximately 100 information items needed during building emergencies, broadly divided into static (pre-incident building data) and dynamic (real-time sensor data) categories (Jones et al., 2005). Later, Guyo et al. (2023) distinguished between building and environmental data within each category. Tashakkori et al. (2015) grouped requirements into indoor, outdoor, and dynamic building information. Across these studies, the consistent finding is that fire response requires the integration of indoor and outdoor information from multiple sources, with information needs evolving across the phases of an incident and operational roles.

Emergency management activities are broadly categorised into four phases: preparedness, mitigation, response, and recovery (Larsson, 2008). Within fire response, Jones et al. (2005) identified three operational time periods: from dispatch to arrival, initial on-site assessment, and active mitigation. On receiving an alert, the fire team is provided with basic incident information (type, address, and dispatched units) and consults pre-incident plans en route to gain initial familiarity with the building layout and likely occupancy. On arrival, the first task is to size up the situation, covering life hazards and rescue requirements, fire accessibility, and the equipment needed. From that point, roles diverge. Frontline firefighters focus on search, rescue and fire attack, requiring information on occupancy, building hazards, and on-scene conditions. The Incident Commander, responsible for overall coordination, resource

deployment, and crew safety, additionally requires information on fire progression, resource status and tracking, personnel accountability, and inter-agency communication (Li et al., 2014; NIST, 2015).

To develop information systems for fire response operations, it is therefore necessary to identify what information matters most, when it is needed, and how it should be presented in relation to incident phases and operational roles. Existing research often relies on qualitative data gathered from interviews with firefighters, which limits the ability to prioritise information for system design (Guyo et al., 2023; Rezaeifam et al., 2023). This study addresses this limitation by conducting a structured survey that captures firefighters' perspectives on the types and priority of information, relevant data sources, Digital Twin scale, and required system features. It also collects information about users' digital skills and familiarity with relevant technologies as a proxy to assess the acceptable complexity of the future system.

The directly comparable prior work is the survey by Li et al. (2014), which examined firefighter information needs in the context of situational awareness. However, it was conducted more than a decade ago and was not oriented toward any specific technology. Similarly, the NIST workshop by Jones et al. (2005), which provided one of the first structured lists of firefighter information needs, predates the widespread adoption of digital tools in the fire service. The present survey revisits many of these information categories and frames them in relation to Digital Twin capabilities. It aims to define and prioritise the information requirements for integrating Digital Twins into fire response operations. The findings will support the specification of functional and nonfunctional system requirements and inform the design of the system architecture.

Methodology

The respondents were recruited through email invitations sent to the fire authorities in Ireland and the Dublin Fire Brigade. Eligible participants included individuals who had served as professional firefighters, regardless of their organisational role or rank. Data were collected over seven months, from May to December 2025. The survey received ethical approval from the Kaunas University of Technology Research Ethics Commission on 22 May 2025 (Approval No. M6-2025-15).

Survey design and structure

Some of the survey themes were informed by previous studies, including Jones et al. (2005), Li et al. (2014), Guyo et al. (2023), and Rezaeifam et al. (2023). Jones et al. (2005) documented the outcomes of a workshop with 25 experts, mostly at the strategic level, producing the lists of information items needed by firefighters. Li et al. (2014) conducted a USA-wide survey in 2012 with 197 responses, predominantly from command-level officers (69%), analysing information needs in the context of situational awareness. Guyo et al. (2023) conducted interviews with four experts with different operational roles from Finland, Germany, and Norway to validate an ontology of firefighter data requirements. Rezaeifam et al. (2023) conducted interviews with 10 command-level experts in Turkey to identify information requirements for situational awareness during fire response.

The survey was organised into four thematic sections:

1. Demographics (user profile) - to capture respondents' background and digital skills.

2. Information type - to assess the perceived importance of different types of information for firefighting operations. In this section, pre-arrival information items were derived from static building data categories in Jones et al. (2005), Li et al. (2014), and Guyo et al. (2023). On-scene information items were adapted from Li et al. (2014), Guyo et al. (2023) and Rezaeifam et al. (2023).

3. Information source - to identify which sources firefighters currently use or would like to have available during operations. In this section, source categories were derived from Li et al. (2014), Rezaeifam et al. (2023), Jones et al. (2005) and NIST (2015).

4. Digital Twin capabilities - to assess firefighters' expectations of Digital Twin deployment (level of support, scale, and preferred formats of information delivery). This section was informed by Li et al. (2014), Jones et al. (2005), NIST (2015) and NFPA 950.

The survey primarily used multiple-choice checklists (e.g., identifying each information source as "In Use", "Desired" or "Not Relevant") and 5-point Likert-type scales (e.g., rating importance from "Not desired" to "Most preferred"). Open-ended questions were included only in the demographic section; all other items were fixed responses. The fixed-response format was adopted for three reasons: to enable direct quantitative comparison with the closest prior study (Li et al., 2014); to produce quantifiable results that allow information items to be prioritised; and to minimise the cognitive and time burden on survey participants.

Data preparation and cleaning

Initial cleaning involved removing non-data fields (e.g., consent confirmations). As the survey did not require the responses to proceed to the next question, all records were reviewed for missing values. A small number of missing responses were found, primarily in the optional "Advanced digital skills" sub-section of demographics. These were excluded from subsequent statistical analysis.

Categorical labels were coded for quantitative analysis (e.g., "Not important" to "Critically important" coded as 1-5). Job titles were harmonised into broader role clusters: strategic level, command level, and frontline level, based on the organisational structure provided in the Fire & Emergency Operations Plan 2023-2028 (Dublin City Council, 2023), considering that all participants were Ireland-based.

Descriptive statistical analysis

For categorical variables (e.g., gender), frequency distribution was calculated to characterise the sample. For the job clusters, the average years of professional

experience were also calculated to illustrate differences between the organisational levels.

Given the small sample size (n=10), the analysis focused on descriptive measures rather than inferential statistics for job clusters. For all sections using Likert-type scales, measures of central tendency (mean and mode) and variability (standard deviation) were calculated for each item. For non-Likert items with three categorical options (e.g., "In Use", "Desired", "Not Relevant"), mode agreement (the proportion of respondents selecting the most frequent category, %) is reported.

Validation

Several quality control strategies were implemented to ensure the validity of the results. First, all questionable or incomplete entries identified during data cleaning were cross-checked against the raw survey responses. Second, quantitative findings (e.g., high importance ratings for specific information types) were compared with established domain knowledge to assess plausibility. In particular, the NIST workshop (Jones et al., 2005) and the NIST Research Roadmap for Smart Fire Fighting (NIST, 2015) were used, as they reflect information needs validated with fire service practitioners. NFPA 950 and 951 provided a normative basis, as both standards address data creation, utilisation, and exchange within the fire service. EuroFSA statistics were used to validate data on vulnerable occupants and high-risk buildings. Finally, the survey by Li et al. (2014) was used as the closest comparable study to determine where the findings align with or contradict earlier results.

Results Analysis and Discussion

Respondent demographics

The respondents were experienced first responders with between 10 and 39 years of professional experience (Table 1). Most of the respondents (70%) were male. The sample is dominated by respondents at strategic and command levels, with only one frontline respondent. However, when classified by organisational branch rather than rank, seven of the ten participants belong to the operations branch directly involved in firefighting (Dublin City Council, 2023).

Table 1: Participants by gender and experience

Job cluster	Gender	Avg. experience
Strategic level	Male = 2 Prefer not to say = 1	35 years
Command level	Female = 2 Male = 4	21 years
Frontline level	Male=1	10 years

Participants reported moderate self-assessed technical skills (mean=3.5, SD=0.8), showing the highest familiarity with data acquisition equipment and the lowest with programming languages (Table 2). All participants indicated at least moderate familiarity with digital technologies, reflected in regular everyday use (mean=3.7, SD=0.9), and working knowledge of Digital Twins (mean=3.5, SD=1.0). However, organisational readiness was perceived as limited, with respondents rating their organisations' digitalisation strategy and past experience with new technology adoption relatively low (mean=2.7, SD=1.0, and mean=1.9, SD=0.8, respectively).

Table 2: Participants' digital familiarity and skills

Statement	Mean*	SD	Mode
Regular digital usage	3.7	0.9	4
Digital Twin familiarity	3.5	1.0	4
Overall technical skills	3.5	0.8	3
Troubleshooting experience	3.1	1.0	3

Modeling	2.9	0.9	3
Databases	3.0	1.1	2
Simulation	2.1	0.6	2
AI/ML	2.0	0.5	2
Programming languages	1.6	1.0	1

*Likert scale: 1=low to 5=high

Information type

Respondents rated information on building occupancy and the presence of hazardous materials as critically important before arriving on scene (mean=4.7, SD=0.5 and mean=4.6, SD=0.5, respectively) as shown in Table 3. Similarly, data on nearby water sources, the location and size of the fire based on sensor alarms, building type (e.g., residential, commercial), technical systems (e.g., HVAC), specialised sensors (e.g., chemical detectors), and evacuation elevators were generally considered "Very" to "Critically important". In contrast, peripheral data, such as information on important objects to be saved, neighbourhood maps and underground utilities, and building parking areas, were rated as less critical ("Slightly" to "Moderately important").

Table 3: Importance of information before arrival at the emergency site

Type of information	Mean*	SD	Mode
Occupancy	4.7	0.5	5
Hazardous materials	4.6	0.5	5
Water sources	4.4	0.8	5
Fire location (sensors)	4.4	0.5	4
Building type	4.3	0.6	4
Technical systems	4.2	0.6	4
Specialized sensors	4.2	0.6	4
Evacuation lifts	4.1	0.7	4
Building layout and site plan	4.0	0.6	4
Access routes	3.7	0.8	4
Owner contacts	3.6	0.7	4
Traffic data	3.4	0.8	4
Security system	3.3	0.9	3
Restricted zones	3.1	0.9	3
Neighbourhood and utilities map	2.9	0.7	3
Priority assets	2.9	0.7	3
Parking area	2.8	1.2	3

*Likert scale: 1=Not important to 5= Critically important

These results are consistent with the findings of previous studies. Li et al. (2014) also identified building occupancy, hazards, and water sources as key information before arriving at the emergency site. However, their

study highlighted traffic data (route information) and priority assets as highly important, while in the present survey, these factors were rated lower ("Moderately" to "Very important"). Similarly, Guyo et al. (2023) reported that hazard locations, parking, and restricted areas within buildings were important to firefighters, although in this survey, such elements were viewed as only "Moderately" important. The importance of building type is further supported by the European Fire Safety Action Plan 2020-2023 (EuroFSA, 2020), which identified priority premises for fire safety improvements as collective housing (37%), high-rise buildings (18%), buildings accommodating less self-reliant individuals (17%), individual housing (13%) and buildings where large groups of people gather (10%).

Once on scene, the respondents identified the location of the occupants, trapped individuals, and warnings of structural collapse as critically important information (mean=5.0, SD=0.0 for both), as shown in Table 4. This information was rated as maximally important across all job clusters. Information on fire growth dynamics (location, size, duration), the number of vulnerable persons (elderly, children and persons with special needs) and the current building condition (e.g., unsafe entry, structural instability) was also rated among the most critical. Overall, nearly 70% of the information items in this section were rated between "Very" and "Critically" important.

Peripheral data, such as the location and condition of deployed or standby units, hazard perimeter, contacts of other emergency agencies, occupancy of nearby buildings, and local weather conditions and forecasts, were rated slightly lower, ranging from "Moderately" to "Very" important, with weather-related information receiving the lowest average score (mean = 3.1, SD = 0.7). Some differences were observed in communication-related items, with strategic level respondents rating contact information for other emergency agencies higher (mean=4.00) than command level (mean=3.50).

Table 4: Importance of information at the emergency site

Type of information	Mean*	SD	Mode
Occupant locations	5.0	0	5
Collapse warnings	5.0	0	5
Vulnerable persons	4.8	0.4	5
Fire dynamics	4.8	0.4	5
Building condition	4.7	0.6	5
Smoke status	4.5	0.5	5
Access openings	4.4	0.7	5
Refuge and assembly areas	4.3	0.6	4
Sprinkler status	4.1	0.7	4
Sprinkler coverage	4.1	0.7	4
Ventilation status	4.1	0.7	4
Hazard zone	3.8	0.6	4
Standing-by responding units	3.8	0.9	4
Other emergency agencies	3.7	0.6	4
Nearby occupancy	3.5	0.7	3
Weather data	3.1	0.7	3

*Likert scale: 1=Not important to 5= Critically important

Previous surveys have reported similar findings. Li et al. (2014) identified occupancy information, fire dynamics (location, growth rate, and spread of the fire), and smoke status as key informational needs. Likewise, Guyo et al. (2023) emphasised the importance of factors such as the building year of construction (as an indicator of structural resilience and risk of collapse) and operational smoke ventilation systems. They also noted the relevance of the occupancy of nearby buildings, which in this survey was rated as "Moderately" to "Very" important. The importance of information on vulnerable occupants is further supported by data from the EuroFSA (2020), which shows that more than half of residential fire fatalities occur among people 65 or older. EuroFSA (2020) also identified key vulnerable groups that need targeted fire safety improvements: elderly people (38%), children (36%), adults with reduced independence (6%), and socially disadvantaged populations (6%).

Information source

For predefined and location-based information sources (Table 5), all respondents reported using and having access to emergency preplans (100% "In use"). There was also strong interest in expanding access to more advanced predefined data, with 90% of respondents expressing a desire for 3D building models and 80% indicating a need for improved on-scene positioning and navigation systems. The occupancy schedules were reported as "In use" by 60% of the respondents. Geoinformation systems, digital maps, and open data sources available via the Internet were each cited by 50% as currently in use.

Table 5: Predefined and location-based information sources

Source of information	Mode*	Mode agreement (%)
Building 3D models	3	90
Positioning and navigation	3	80
GIS	2	50
Occupancy schedules	2	60
Open data	2	50
Emergency plans	2	100

*Multiple-choice: 1=Not Relevant, 2=In Use, 3=Desired

A previous survey by Li et al. (2014) similarly highlighted the widespread use of emergency preplans (approximately 95% of respondents). However, the present study indicates a higher use of occupancy schedules (60% compared to 25% in the survey by Li et al.(2014)). The difference may be explained by the increased digitalisation of building records and wider use of occupancy management systems, with such data now more routinely available to fire services.

The demand for 3D building models and improved positioning and navigation also remains strong, comparable to Li et al. (2014), where 80% and 77% of respondents, respectively, expressed such needs. These findings are further supported by interviews conducted by Chou et al. (2019), which emphasised firefighters' demand for improved navigation and path planning capabilities during operations.

For building systems specifications as an information source (Table 6), the level of agreement on the data currently "In use" was slightly lower. The fire protection and water supply systems were each identified as "In use" by 70% of the respondents, while the electrical system

was reported by 50%. Most of the information sources in this category were classified as "Desired" (i.e., systems respondents would like to have available). These included building automation and control systems, security and access control systems (each 70%), as well as HVAC, lighting, and elevator systems (each 60%).

Table 6: Building systems specifications

Source of information	Mode*	Mode agreement (%)
Building automation and control	3	70
Security and access control	3	70
HVAC	3	60
Lighting	3	60
Elevators	3	60
Electrical	2	50
Water supply	2	70
Fire protection	2	70

*Multiple-choice: 1=Not Relevant, 2=In Use, 3=Desired

These results are consistent with previous studies. Li et al. (2014) similarly reported high usage of fire protection systems and a strong desire for access to HVAC, elevator, security, and lighting systems, with response levels of approximately 50%. Comparable findings were also reported in interviews conducted by Rezaeifam et al. (2023), which highlighted the frequent use of fire protection, water supply and electrical systems in firefighting operations.

For the real-time data sources (Table 7), all items were classified as "Desired" by the respondents, generally showing high levels of agreement. Occupancy and movement tracking were identified as the most desired data sources, with 100% agreement among the respondents. Air quality sensors, water pressure and sprinkler activation data, CCTV and thermal imaging camera feeds, and electrical system monitoring were closely followed with 90% agreement. Real-time data from temperature sensors, HVAC system (e.g., airflow, smoke control), lighting control system, and security system alerts (e.g., door locks, access changes) were also highly desired, each with 80% agreement. Specialised sensor data (e.g., chemical or radiation detection) and fire detection and alarm system data were rated slightly lower, with 80% and 50% agreement, respectively.

Table 7: Real-time data sources

Source of information	Mode*	Mode agreement (%)
Occupancy	3	100
Electrical	3	90
Water pressure and sprinklers	3	90
CCTV	3	90
Lighting	3	80
Air quality	3	90
HVAC	3	80
Temperature	3	80
Security	3	80
Specialized sensors	3	80
Fire alarm	3	50

*Multiple-choice: 1=Not Relevant, 2=In Use, 3=Desired

Strong interest in using real-time data for fire emergency operations is reinforced by domain research, including the Research Roadmap for Smart Fire Fighting (NIST, 2015) and the earlier Workshop to Define Information Needed by Emergency Responders During Building Emergencies (Jones et al., 2005). Both highlight that integrating real-time building data can significantly improve preparedness and situational awareness during incidents. In particular, data from HVAC systems, fire alarms, sprinklers, and occupant sensors were envisioned to be integrated into Smart Firefighting systems.

The cognitive and experiential information sources (Table 8) were identified as highly used by the respondents, indicating strong reliance on personal judgment and experience during operations. On-site observations showed the highest mode agreement (90%), followed by memory and experience from previous incidents (80%), highlighting their central role in decision-making on scene. However, 60% of the respondents identified the need for improvement in live communications and reporting during operations. Memory and experience from past incidents were reported as "In Use" across all clusters (strategic-67%, command-83%, frontline-100%). However, given the small sample and its heavy weighting toward strategic and command roles, these results cannot be generalised.

Table 8: Cognitive and experiential information sources

Source of information	Mode*	Mode agreement (%)
Live communications and reports	3	60
Memory and experience	2	80
On-site observations	2	90

*Multiple-choice: 1=Not Relevant, 2=In Use, 3=Desired

A strong reliance on prior experience and on-site observation aligns with the findings of Li et al. (2014), where 82% of respondents cited memory and experience, and 72% cited observations as their primary information sources. The survey also revealed that 81% of the respondents wanted improvements in live communication and reporting during incidents.

Digital Twin capabilities

Digital Twin functionality in this section can be divided into two clusters: general information management and support for operational activities (Table 9). Among information management functions, respondents identified information collection ("accessing and gathering all required information, including real-time data") as the area where Digital Twins could most effectively support daily operations (mean=4.5, SD=0.5). The prediction of information ("anticipating potential trends, such as fire spread or structural collapse based on real-time data") was rated as the second most important function (mean=4.5, SD=0.7). Among functions supporting operational activities, communication and coordination ("ensuring communication among firefighters, the command centre, and other emergency services") received the highest rating (mean=4.4,

SD=0.7), consistent with the previously expressed need to improve live communications and reporting.

Information integration ("combining data from multiple sources into a unified operational picture") was the fourth most desired function (mean=4.3, SD=0.6). Other key functionalities such as information interpretation ("extracting useful insights from available data"), resource allocation ("optimising the deployment of personnel, equipment, and support services"), information revision ("detecting and correcting data inconsistencies and errors"), post-incident analysis ("recording and analysing emergency response actions to improve future preparedness"), and information representation ("presenting and visualising data in an accessible format"), were all identified as areas where "Significant support" is required. Navigation and evacuation assistance ("providing dynamic routes and safe passage recommendations") was the only function rated slightly lower (mean=3.7, SD=1.0), indicating a perceived need for moderate rather than critical support.

Table 9: Required type of support expected from Digital Twin deployment

Type of support	Mean*	SD	Mode
Information collection	4.6	0.5	5
Information prediction	4.5	0.7	5
Information interpretation	4.3	1.0	5
Information integration	4.3	0.6	4
Information revision	4.2	0.9	4
Information representation	4.1	0.8	5
Communication and coordination	4.4	0.7	5
Resource allocation	4.2	0.9	4
Post-incident analysis	4.1	0.9	4
Navigation and evacuation assistance	3.7	1.0	4

*Likert scale: 1=No support needed to 5= Essential support required

Similarly, the study by Li et al. (2014) identified information collection (87%), prediction (72%), and reasoning (64%) as the most needed types of assistance where firefighters sought support. These preferences were also found to correlate with participants' years of experience and job position.

Regarding the operational scale at which a Digital Twin should function to be most useful to firefighters (Table 10), respondents identified the building level as the most important (mean=4.5, SD=0.7). This was followed by the floor level of the building (mean=4.4, SD=0.7) and the emergency site level (mean=4.2, SD=0.4). The building component level received the lowest rating (mean=3.9, SD=0.7), although it was still considered "Moderately" to "Very important" by the respondents.

Table 10: Digital Twin operating scale

Scale	Mean*	SD	Mode
Building	4.5	0.7	5
Building floor	4.4	0.7	5
Emergency site	4.2	0.4	4
Urban	4.0	0.8	4
Building component	3.9	0.7	4

*Likert scale: 1=Not important to 5= Critically important

Regarding the preferred scale, Li et al. (2014) survey found that the building floor level was most desired (75%), followed by the room level and building level. The component level ranked lowest (27%), which is consistent with the results of our survey. The urban scale was not included in the study by Li et al. (2014).

When evaluating preferred formats for information representation (Table 11), respondents expressed a strong preference for 3D models (mean=4.5, SD=0.8). Other formats, such as 2D graphical representations (e.g., drawings, schematics), augmented reality overlays, colour-coded indicators (e.g., heat maps or highlighted danger zones), and virtual simulations were also rated between "Strongly desired" and "Most preferred."

In contrast, numerical data (e.g., tabular or sensor readings), textual information (e.g., reports or instructions), and haptic feedback (e.g., vibration alerts) were viewed as "Slightly" to "Moderately" desirable. Audio and phonetic cues (e.g., spoken instructions or sound-based alerts) were the least preferred format (mean=2.6, SD=0.8).

Table 11: Preferred formats of information representation

Format	Mean*	SD	Mode
3D models	4.5	0.8	5
2D graphics	4.2	0.7	4
AR overlay	4.1	0.5	4
Virtual simulation	4.0	0.6	4
Colour-coded indicators	4.0	0.6	4
Numeric data	3.2	0.7	4
Text data	3.1	1.3	4
Haptic feedback	3.0	1.1	4
Audio cues	2.6	0.8	3

*Likert scale: 1=Not desired to 5= Most preferred

These findings are also consistent with the earlier research by Li et al. (2014), where graphical representation was identified as the most preferred format (64%), followed by 3D visualisation (50%), virtual reality (38%), and augmented reality (33%). Phonetic representation ranked lowest among the options. The NIST workshop similarly identified a preference for 3D building display as easier to use and interpret (Jones et al., 2005).

The survey did not explicitly address the preferred level of detail of 3D models. However, respondents' preferences for building-, floor-, and emergency-site-level information suggest that geometric resolution should reflect operational need rather than technical capability. In practice, photogrammetry-based 3D models are already used by firefighters for high-risk premises as part of Predetermined Attendance strategies (O'Neill, 2025). Regarding BIM, while it is the most commonly proposed source of 3D building representation in the fire safety literature, the majority of existing buildings predate it and have no such model available.

In summary, survey results show that firefighters consistently rely heavily on available emergency preplans and cognitive sources, such as personal observations and prior experience, during operations. Critical information includes occupancy data (including vulnerable occupants), building hazards and structural integrity, fire

dynamics, and the location of water sources, all of which are considered highly important both from dispatch to arrival and during fire attack. Regarding information visualisation, 3D models and 2D graphic representations of buildings and floor layouts are the most preferred, indicating a strong demand for better spatial awareness. The respondents also expressed a high need for improved general information collection, trend forecasting, and communication support during operations. Real-time data utilisation is highly demanded, particularly in terms of occupancy, water systems, and air quality. However, the survey showed moderate self-rated digital skills and low confidence in organisational digital strategy and prior experience with new technologies. This suggests potential challenges in deploying highly complex digital systems.

Implications and Limitations

The survey results help identify functional and non-functional requirements for system architecture development. A practical next step is to prioritise information needs based on response mode agreement (high, medium, low) and mapping each category to existing or required data sources. For example, occupancy information is already used based on occupancy schedules, while real-time occupancy tracking would require additional sensor data.

Interest in real-time sensing is high, yet many buildings lack the necessary infrastructure. This points out that two scenarios should be considered: (1) buildings without sensors or without real-time data access, where firefighters rely on preincident plans, 3D models, and GIS; and (2) buildings with sensor networks whose data is accessible to firefighters. Another tension appears between the strong demand for real-time information and the low preference for numerical or textual formats. Respondents lean toward visual representations (e.g., 3D models, 2D graphics), suggesting the need for dashboards and data abstractions.

Although building- and floor-level information was rated most useful, the preferred granularity of data remains unclear. Higher resolution data does not necessarily lead to better decisions. Component-level information may overload users and was less preferred, yet structural collapse risk was marked as highly important on the scene.

The reliance on several information sources suggests that federated integration is more realistic than centralisation. Data may stay within native systems where suitable, but should be interoperable through shared schemas and interfaces. In addition to the functional aspects, several non-functional requirements also emerge. Alongside common considerations such as performance, usability, scalability, and security, semantic and technical interoperability will be particularly critical. Firefighting systems must work under uncertainty, shifting resource availability, and dynamic coordination, closer to distributed defence systems than standard enterprise software.

The respondents reported moderate digital skills but low organisational readiness, indicating likely adoption challenges. Incremental deployment is therefore more feasible: new functionalities should extend current workflows and practices rather than replace them. Solutions that require heavy onboarding or major workflow changes may struggle to gain acceptance (Carlson et al., 2025).

This study has several limitations. (1) The survey sample was small and limited to first responders in Ireland, which may reduce the generalisability of the findings to other national contexts. (2) The small sample size and its skew toward strategic and command levels prevented meaningful comparisons across job clusters, and reduced the representativeness of operational firefighter information needs. (3) The survey did not account for building type, treating the operational process as uniform. Information needs may differ for high-risk facilities, although such incidents are considerably less frequent than typical dwelling fires (Dublin City Council, 2024). (4) Preferences for information presentation were assessed through text-based questions without interface mockups, which may have influenced responses; the preferred level of detail and granularity of data representations were also not explored. However, user interface design falls outside the scope of this study. (5) Finally, advanced Digital Twin capabilities such as LLM-based interaction or AI-driven prediction were not explicitly addressed. While functions such as information prediction and interpretation indirectly assume data-driven approaches, these were not explored in depth.

Conclusions

This study examined firefighters' information needs, data usage and expectations for Digital Twin capabilities in fire response. The findings confirm a persistent gap between the available digital technologies and their practical use during incidents. Under conditions of uncertainty and time pressure, decision-making continues to rely primarily on experience and direct observation, despite the recognised value of data-driven support.

The results identify occupancy and structural integrity as the most critical information categories, aligning with the core operational priorities: protecting occupants and ensuring crew safety. While some of this information can be obtained from pre-incident data, its real-time availability and prioritised delivery become critical during active operations. A Digital Twin theoretically can support these needs by linking data collection, analytics, and representation, but its practical implementation requires careful phasing. Not all information should be streamed continuously; prioritizations and timing of data will determine usability in real situations.

The main contribution of this study lies in providing quantitative evidence on firefighter information requirements, enabling explicit prioritisation of information types for system design. In addition, the study delivers a quantitative evaluation of Digital Twin functionality, which provides a basis for defining functional system requirements and aligning system

development with actual operational demand. The findings also update and extend earlier surveys, which are now partially outdated due to the increasing digitalisation of buildings and emergency response systems.

Acknowledgments

The authors express their sincere appreciation to all anonymous participants who took the time to complete the survey. We also thank the Dublin Fire Brigade for their consultation and assistance with the dissemination of the survey. We also thank Bentley Systems Inc. for supporting the collaboration between Kaunas University of Technology and Dublin City University.

TOWARDS A SEMANTIC ONTOLOGY FOR OCCUPANT-CENTRIC BUILDING CONTROL

Saif Alramahi[1], Mohammad Mayouf[1], Elham Del Zendeh[1], and Khalid Ismail[2]
[1]Department of Architecture and the Built Environment, Birmingham City University, 4 Cardigan Street, Birmingham B4 7BD, United Kingdom
[2]Department of Computer Science, Birmingham City University, 4 Cardigan Street, Birmingham B4 7RQ, United Kingdom

Abstract

Occupant-centric control (OCC) balances energy efficiency and occupant comfort in buildings, yet methodological fragmentation hinders cumulative progress. This paper presents the Occupant-Centric Control Ontology (OCCO), a semantic framework that extends W3C/ETSI vocabularies with constructs for comfort metrics, control strategies, feedback provenance, and performance evaluation. Developed using the Linked Open Terms methodology with competency questions derived from OCC literature, OCCO unifies subjective occupant feedback with objective sensor data. Structural verification via SPARQL confirms query capability, with automated evaluation returning no remaining critical pitfalls and 88.2% FAIR compliance. OCCO provides a semantic foundation for comparable, reproducible OCC evaluation.

Introduction

Occupant-centric control (OCC) embeds real-time user information into building control logic to jointly optimise comfort and energy efficiency (Nagy *et al.*, 2023; Yuan *et al.*, 2024). Despite growing research activity, the field lacks standardised evaluation metrics, and findings remain difficult to compare across implementations (Nagy *et al.*, 2023). Studies employ inconsistent comfort metrics, varied energy baselines, and frequently exclude occupants from evaluation altogether (Shafavi *et al.*, 2020). The consequence is that effective strategies cannot be distinguished from ineffective ones, evidence cannot accumulate into generalisable knowledge, and real-world deployment of adaptive building controls remains limited to isolated case studies.

A key barrier to addressing this fragmentation is the absence of a shared semantic foundation for describing and evaluating OCC systems. Existing ontologies address adjacent concerns (sensing, building devices, occupant feedback) but lack the integration of quantitative and qualitative evaluation metrics within a unified framework. This paper addresses this gap by presenting the Occupant-Centric Control Ontology (OCCO). OCCO extends W3C and ETSI vocabularies with integrated OCC evaluation constructs for comfort-energy assessment, control strategy representation, and feedback provenance, enabling comparable evaluation of how well OCC implementations balance measured environmental conditions with reported occupant experience. The framework is demonstrated through visual comfort in commercial lighting, a domain where the gap between objective standards compliance and subjective occupant satisfaction is particularly apparent.

Background and related work

While OCC lighting has attracted considerable research attention (Haq *et al.*, 2014; Nagy, Yong and Schlueter, 2016; Park *et al.*, 2019; Colaco *et al.*, 2023), the field still faces persistent challenges that hinder cumulative progress (Shafavi *et al.*, 2020). Energy and comfort outcomes receive unequal treatment. For instance, daylight harvesting implementations often measure power consumption rigorously but rely only on Workplane illuminance as a comfort proxy (Yu *et al.*, 2017; Lee, Song and Cho, 2018). Conversely, studies emphasising comfort through glare indices such as Daylight Glare Probability (DGP) or Unified Glare Rating (UGR) sometimes lack well-defined energy baselines for comparison (Motamed, Deschamps and Scartezzini, 2017; Papinutto *et al.*, 2022). Many implementations exclude users from evaluation entirely, relying exclusively on sensor data (Yin and Keoh, 2016; Kumar *et al.*, 2017; Lee *et al.*, 2017), despite evidence that override rates reach 88% for automatic blinds (Reinhart and Voss, 2003) and 78% permanent system disabling due to dissatisfaction (Meerbeek *et al.*, 2014). Energy baselines vary from manual control (Aghemo, Blaso and Pellegrino, 2014), to fixed illuminance setpoints (Kandasamy *et al.*, 2018), or go completely unspecified (Kumar *et al.*, 2017). A reported "40% energy savings" carries different meaning from study to study. Visual comfort metrics range from EN 12464-1:2021 (CEN, 2021) or ISO/CIE 8995-1:2025 (ISO/CIE, 2025) illuminance thresholds, to DGP, UGR, and custom indices (Gunay *et al.*, 2017; Park *et al.*, 2019), with a lack of consensus equivalent to the PMV/PPD models established for thermal comfort (ISO, 2025).

Addressing this gap requires a shared conceptual foundation for describing OCC systems and their outcomes. Semantic ontologies offer a potential solution by providing machine-readable vocabularies with formal relationships enabling consistent data description and cross-system integration. However, existing approaches address only parts of the problem. SOSA/SSN (Janowicz *et al.*, 2019) provides measurement provenance patterns

but lacks comfort semantics. SAREF4BLDG (Poveda-Villalón and García-Castro, 2018) offers device and spatial vocabulary but omits occupant modelling. OFO (Donkers, de Vries and Yang, 2024) captures subjective feedback but excludes control strategies and performance evaluation. Brick (Balaji *et al.*, 2016) provides building metadata without comfort semantics, while the DNAs framework (Hong *et al.*, 2015) formalised occupant behaviour for simulation rather than operational control. Recent holistic performance ontologies (Mahdavi, Taheri and Wolosiuk, 2019; Chung *et al.*, 2023) focus on design-phase assessment or thermal comfort without constructs for integrated OCC evaluation that unify objective measurements with subjective occupant responses. The most closely related effort is WOMO (Bruttini *et al.*, 2022), a linked-data ontology that integrates objective sensor observations with subjective occupant feedback for workplace management. However, WOMO targets facility management decision-making rather than OCC evaluation and does not model control strategies, energy performance, or standards compliance. OCCO addresses these gaps by providing constructs that unify comfort-energy assessment with feedback provenance within a single evaluation framework.

Based on the literature, there are limited semantic efforts that integrate both objective sensor data and subjective occupant feedback for OCC evaluation. OCCO proposes to address this gap through a standards-aligned framework that extends SOSA/SSN, SAREF4BLDG, and OFO with constructs for comfort-energy assessment, control strategy representation, and feedback provenance, demonstrated here through the visual comfort domain.

Methodology

OCCO was developed following the Linked Open Terms (LOT) methodology, an industrial-oriented ontology engineering framework that promotes FAIR (Findable, Accessible, Interoperable, Reusable) principles (Poveda-Villalón *et al.*, 2022). LOT was selected over traditional methodologies such as METHONTOLOGY and NeOn for three reasons: (1) its explicit emphasis on reusing standardised vocabularies rather than creating redundant terms; (2) its iterative, sprint-based development model suited to evolving requirements; and (3) its alignment with Linked Data publication best practices.

Ontology requirements specification

Ontology requirements were formalised using the Ontology Requirements Specification Document (ORSD) template from the LOT methodology (Poveda-Villalón *et al.*, 2022). Competency questions (CQs) help convey ontology requirements, core elements, and their relationships, thereby defining the ontology vocabulary. These questions are used to test requirements satisfiability through axiom checking and answer verification (Ren *et al.*, 2014), and should be evaluated using different use-cases. Ten competency questions (Table 1) were derived from the gaps identified in Section 2. These questions address control automation, preference modelling, performance evaluation, and cross-domain integration of comfort with energy metrics.

Table 1: Competency questions for the developed ontology

ID	Competency Question
CQ-01	What control actions were taken in response to detected occupancy in each building space during working hours?
CQ-02	Which building spaces received visual discomfort feedback, and what were the corresponding glare or illuminance levels?
CQ-03	Which control strategy resulted in the highest combined comfort scores and lowest energy consumption over the evaluation period?
CQ-04	What are the preferred illuminance and CCT levels for occupants performing specific visual tasks (e.g., reading, screen work)?
CQ-05	How does an occupant's preference profile evolve over time in response to feedback events?
CQ-06	Which building spaces have circadian-friendly lighting control strategies applied, based on occupant chronotype?
CQ-07	Which building spaces meet the applicable comfort standard while also receiving negative comfort feedback from occupants?
CQ-08	What proportion of illuminance observations fall within the range recommended by the applicable comfort standard?
CQ-09	Which occupants most frequently override automated controls, and in which building spaces do overrides occur?
CQ-10	Which control strategy achieves the best balance of energy efficiency, occupant satisfaction, and compliance with comfort standards?

Ontology implementation

The LOT methodology structures implementation through four sub-activities: conceptualisation, ontology reuse, encoding, and evaluation (Poveda-Villalón *et al.*, 2022). Conceptualisation transformed the ORSD requirements into a structured ontology model. Domain knowledge was organised into five thematic modules (detailed in Section 4). Visual representation followed the Chowlk notation (Chávez-Feria, García-Castro and Poveda-Villalón, 2022), a UML-based specification for representing classes, properties, and restrictions in ontology diagrams.

Ontology reuse adopted a standards-first approach, prioritising W3C Recommendations and ETSI Technical Specifications over domain-specific vocabularies. Term extraction drew from the competency questions and OCC literature, identifying core concepts (e.g., illuminance, glare, occupant feedback, control action) and their relationships. Candidate ontologies were evaluated against selection criteria including standardisation status, maintenance activity, and semantic coverage. Section 4 details the reused ontologies and their integration rationale.

Encoding translated the conceptual diagrams into OWL 2 DL. Diagrams were exported as XML files and uploaded to the Chowlk web converter, which parses the visual notation and generates OWL code serialised in both Turtle and RDF/XML formats (Chávez-Feria, García-Castro and Poveda-Villalón, 2021). The Turtle file was then imported into Protégé (Musen, 2015), an open-source ontology editor, for manual refinement including axiom adjustments, import statement configuration, and consistency checking with the HermiT reasoner.

Evaluation comprises two distinct phases. Verification assesses structural correctness, confirming the ontology is free from syntactic, modelling, and semantic errors and can answer the specified competency questions. Validation assesses domain accuracy, confirming the ontology captures real-world practice and meets end-user requirements. This phase, comprising domain and ontology expert review, is planned as future work and falls outside the scope of this paper.

Verification process

Synthetic instance data was generated iteratively using a large language model (Claude Sonnet 4.6, Anthropic). For each competency question, the model was prompted with the ontology schema in Turtle format and the specific CQ requirements, producing tailored RDF instances for that test scenario. This approach aligns with emerging research exploring LLM assistance in ontology engineering tasks (Lippolis *et al.*, 2025). Generated instances represented realistic OCC scenarios, including occupancy observations, illuminance measurements, user feedback events, control actuations, and performance outcomes. All instances were manually reviewed for logical and domain correctness.

Each of the ten competency questions was translated into one or more SPARQL 1.1 queries and executed using rdflib 7.6.0 (Python) against the synthetic ABox instances loaded alongside the OCCO TBox. Protégé (Musen, 2015) and the HermiT reasoner were used separately for OWL 2 DL consistency checking. Queries tested core capabilities including temporal filtering, spatial correlation, aggregation, and provenance tracking. Structural quality was additionally assessed using OOPS! (Poveda-Villalón, Gómez-Pérez and Suárez-Figueroa, 2014) and FAIR compliance evaluated using FOOPS! (Garijo, Corcho and Poveda-Villalon, 2021). Detailed results are presented in Section 5.

OCCO framework

OCCO is designed around two guiding principles. First, standards alignment: rather than defining custom vocabulary, OCCO reuses established W3C and ETSI ontologies wherever possible, extending them only where domain-specific concepts are required. This positions the ontology for integration with systems already using these standards. Second, modularity: the ontology is organised into cohesive, loosely coupled modules that can evolve independently as the field matures. The following subsections present the architecture, reused standards, key classes, and competency question coverage.

Architecture overview

OCCO organises its classes into five thematic modules, each addressing a distinct aspect of OCC, demonstrated here through the visual comfort domain. This modular structure supports selective reuse and facilitates alignment with existing domain ontologies. Table 2 summarises the modules, their representative classes, and the standards from which they derive.

The **Physical Context** module describes the built environment: zones, rooms, lamps, and sensing/actuation devices. Classes are drawn primarily from SAREF4BLDG for building topology and SOSA for sensor/actuator abstractions. The **Occupants & Preferences** module captures individual characteristics relevant to visual comfort, including task type (e.g., screen-based work, paper reading) and chronotype (circadian preference). These classes extend the Occupant Feedback Ontology (OFO). The **Feedback & Interaction** module represents both objective sensor observations and subjective occupant feedback, including manual override events. This dual representation directly addresses the exclusion of occupants from evaluation noted in Section 2. The **Control & Automation** module defines control strategies (e.g., daylight harvesting, occupancy-based dimming) and the actuations they produce. Provenance relations from PROV-O link actions to their triggering observations. The **Evaluation & Outcomes** module enables performance assessment against standards such as EN 12464-1:2021. It captures both comfort outcomes (e.g., satisfaction ratings, glare reports) and energy metrics, supporting the balanced comfort-energy evaluation identified as a gap in Section 2.

Table 2: OCCO modular architecture

Module	Representative Classes	Primary Standards
Physical Context	BuildingSpace, Lamp, Sensor, Actuator	SAREF4BLDG, SOSA
Occupants & Preferences	Person, VisualTask, Chronotype, Preference	OFO, OCCO
Feedback & Interaction	Feedback, OverrideEvent, Observation	OFO, SOSA
Control & Automation	ControlStrategy, Controller, Actuation	PROV-O, SOSA
Evaluation & Outcomes	PerformanceOutcome, Standard, Illuminance, GlareIndex	OCCO, QUDT, dcterms

Ontology reuse strategy

OCCO adopts a standards-first reuse strategy, prioritising W3C Recommendations and ETSI Technical Specifications, supplemented by established domain vocabularies where domain-specific coverage is required. The following ontologies are reused:

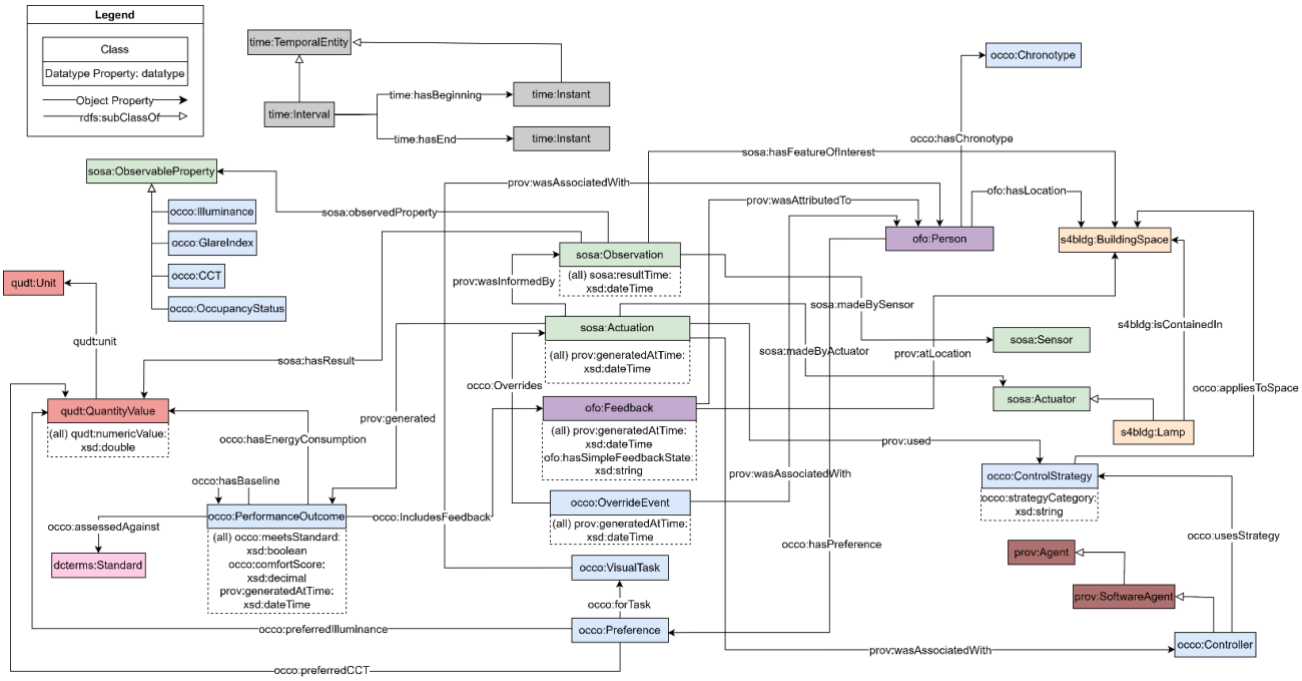

Figure 1: OCCO ontology classes, object properties, and data properties in Chowlk notation

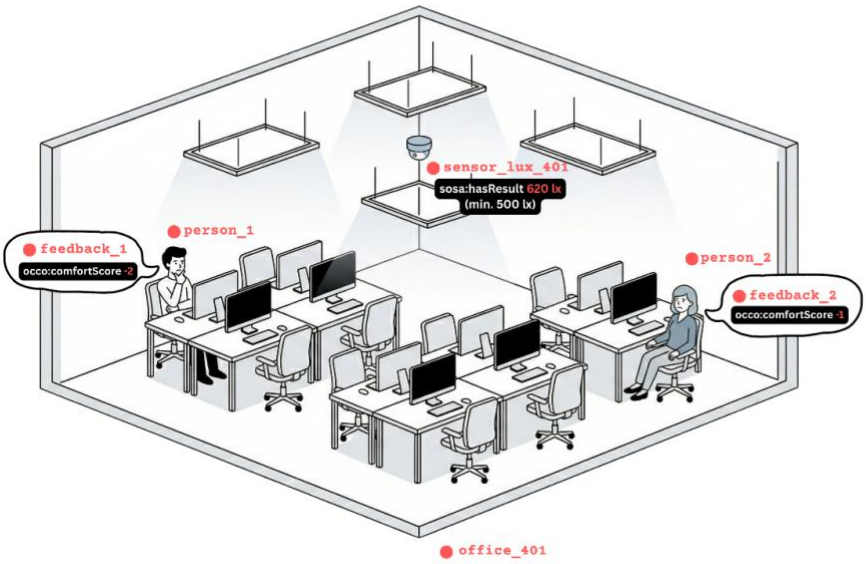

- **SOSA/SSN** (Janowicz *et al.*, 2019): a semantic sensor network ontology for describing sensors, observations, actuators, and actuations. Used in OCCO to model light sensors, occupancy detectors, and dimming actions.
- **SAREF4BLDG** (Poveda-Villalón and García-Castro, 2018): a smart appliances extension for building devices and spaces. Used to represent rooms, zones, and lamps within building topology.
- **OFO** (Donkers, de Vries and Yang, 2024): the Occupant Feedback Ontology for capturing subjective comfort reports and preferences. Used to model occupant feedback, override events, and individual lighting preferences.
- **PROV-O** (Lebo, Sahoo and McGuinness, 2013)**:** a provenance ontology for describing entities, activities, and agents. Used to trace which observations triggered which control actions and attribute feedback to occupants.
- **QUDT** (Hodgson, 2025): a vocabulary for quantities, units, and dimensions. Used to ensure measurement comparability (lux, kWh, UGR, DGP values) across datasets.
- **OWL-Time** (Cox and Little, 2022): a temporal ontology for instants and intervals. Used to represent evaluation periods, schedules, and timestamps for observations and actions.
- **dcterms** (DCMI, 2020): Dublin Core metadata terms. Used to reference lighting and comfort standards (EN 12464-1:2021, ISO/CIE 8995-1:2025) with structured metadata.

Table 3 summarises the namespace prefixes used throughout OCCO. Beyond these reused terms, novel classes in OCCO address concepts absent from existing standards: visual comfort metrics (Illuminance, GlareIndex, CCT), OCC strategies, and performance outcomes integrating subjective feedback with objective measurements.

Key classes and relationships

Figure 1 illustrates OCCO's class hierarchy and principal object properties in Chowlk notation (Chávez-Feria, García-Castro and Poveda-Villalón, 2022). Rather than listing all elements, this section highlights relations that demonstrate the ontology's core capability: linking occupant feedback to control actions and enabling unified performance evaluation.

Feedback-Control linkage. When an occupant reports discomfort, the `ofo:Feedback` instance is linked to the occupant via `prov:wasAttributedTo` and to the affected space via `prov:atLocation`. Control actions (`sosa:Actuation`) reference triggering observations through `prov:wasInformedBy`, enabling queries that trace which sensor readings prompted which responses. Manual overrides (`occo:OverrideEvent`) link to the actuation they supersede via `occo:overrides`, preserving the full decision trail.

Performance evaluation. The `occo:PerformanceOutcome` class aggregates both comfort and energy results for a given evaluation period. It connects to subjective data via `occo:includesFeedback` and to objective measurements via `sosa:hasResult`. Compliance with lighting standards is captured through `occo:assessedAgainst`, linking outcomes to `dcterms:Standard` instances representing EN 12464-1:2021 or ISO/CIE 8995-1:2025 standards for example.

Demonstration and verification

Verification was conducted across three complementary methods as outlined in Section 3.3. All evaluation artefacts, including SPARQL queries, result sets, OOPS! and FOOPS! results, are published alongside the ontology documentation at w3id.org/occo.

To illustrate OCCO in operation, Figure 2 presents an ABox excerpt addressing CQ-07: *"Which building spaces meet the applicable comfort standard while also receiving negative comfort* feedback *from occupants?"* The scenario depicts an open-plan office (`office_401`) where a ceiling-mounted lux sensor (`sensor_lux_401`) records an illuminance of 620 lx – compliant with the EN 12464-1:2021 minimum of 500 lx. Two occupants submit `ofo:Feedback` records spatially anchored to the space via `prov:atLocation`, reporting comfort scores of −2 and −1. The resulting `occo:PerformanceOutcome` aggregates both feedback records and asserts `meetsStandard = true` against EN 12464-1:2021. Although the space satisfies the illuminance standard, occupants remain dissatisfied, a discrepancy that quantitative compliance metrics alone would not reveal.

All ten CQs (Table 1) were executed as SPARQL 1.1 queries using rdflib 7.6.0 against the synthetic ABox, returning between 1 and 6 results per query and confirming complete structural coverage. Boundary conditions were verified explicitly across multiple CQs: out-of-hours actuations were correctly excluded (CQ-01), the occupancy-actuation linkage via `prov:wasInformedBy` was confirmed (CQ-01), standards-compliant periods that still generated negative comfort scores were isolated (CQ-07), and zero-override occupants were correctly absent from grouped results (CQ-09).

Automated structural quality evaluation using OOPS! (Poveda-Villalón, Gómez-Pérez and Suárez-Figueroa, 2014) identified one critical pitfall in v0.1.0 (multiple

`rdfs:domain` declarations on `prov:wasAssociatedWith`, resolved in v0.1.1) alongside four minor pitfalls, all addressed prior to publication. FAIRness compliance assessed using FOOPS! (Garijo, Corcho and Poveda-Villalon, 2021), achieved a score of 88.2% (19 of 22 checks passed); remaining failures relate to LOV registry registration and DOI assignment pending acceptance.

Discussion

The ontology proposed in this paper formalises subjective occupant feedback alongside objective sensor measurements, offers constructs for integrated comfort-energy assessment, and provides a shared vocabulary for consistent and reproducible comparisons across OCC implementations. Where existing ontologies (Poveda-Villalón and García-Castro, 2018; Janowicz *et al.*, 2019; Donkers, de Vries and Yang, 2024) each address only part of this landscape, OCCO uniquely combines all four dimensions: visual comfort metrics (illuminance, UGR, DGP, CCT), control strategies, feedback provenance, and performance evaluation within a single, standards-aligned framework.

Whilst former research (Donkers, de Vries and Yang, 2024) provide practical application and value for OCC systems, the holistic integration of objective and subjective metrics presented in the proposed ontology offers wider value for various stakeholders. For instance, researchers gain a shared vocabulary enabling comparable evaluations and meta-analyses across studies. System vendors can implement transparent control logic with standards-aligned interfaces to existing building management systems and digital twins. Facility managers can query comfort-energy trade-offs to support evidence-based and holistic post-occupancy decisions.

Beyond immediate stakeholder applications, OCCO proposes to address a fundamental methodological gap in visual comfort research. Thermal comfort research benefits from established evaluation foundations such as PMV/PPD models codified in ISO 7730 (ISO, 2025), enabling robust cross-study comparison and cumulative knowledge building. Visual comfort research currently lacks an equivalent foundation. By providing standardised constructs for comfort metrics, control strategies, and performance outcomes, OCCO offers a comparable semantic foundation for the lighting domain. The ontology's ability to correlate standards compliance with subjective measures (as demonstrated in CQ-07) enables systematic investigation of cases where normative thresholds fail to predict occupant satisfaction, a recognised but under-studied phenomenon. Furthermore, the explicit representation of override events supports analysis of user intervention patterns, addressing the high override rates documented in the literature. These capabilities position OCCO not merely as a data integration tool, but as an enabler of the holistic, comparable evaluations that the field currently lacks.

Conclusion

This paper presented OCCO, a standards-aligned semantic ontology that integrates visual comfort metrics, control strategies, feedback provenance, and performance evaluation within a unified framework. By extending W3C and ETSI vocabularies alongside established domain ontologies, OCCO provides interoperability with existing building automation systems while offering a semantic foundation for comparable, reproducible OCC evaluation. Structural verification confirmed that all ten competency questions can be answered through SPARQL queries, with automated quality evaluation returning no remaining critical pitfalls (OOPS!) and 88.2% FAIR compliance (FOOPS!).

Future work will address operational challenges within smart buildings and validate the ontology through domain and ontology expert review, as well as applied use cases involving Internet-of-Things (IoT) systems and Digital Twins. The ontology is published as Linked Data with LOT-compliant documentation at the permanent URI w3id.org/occo, supporting community adoption and extension.

ONTOLOGY-BASED SEMANTIC MANAGEMENT OF BRIDGE DRAWINGS

Xiaoli Song[1], Mengyan Peng[1], Steffen Marx[1], and Chongjie Kang[1]
[1]TUD Dresden University of Technology, Dresden, Germany

Abstract

As one of the primary information carriers throughout the bridge lifecycle, drawings contain rich semantic information. Traditional file-based management does not support efficient organization and retrieval. In this work, an ontology-based semantic management method for bridge drawings is proposed, leveraging information extracted by artificial intelligence (AI) models. After processing, AI outputs are transformed into structured semantic entities and relationships defined in the ontology. The resulting knowledge graph enables semantic search and helps engineers trace how structural components appear and evolve across drawings. It enhances the accessibility and reusability of bridge drawings and provides a practical foundation for intelligent asset management.

Introduction

Throughout the lifecycle of bridge engineering projects, a large number of heterogeneous files are generated (Kang et al., 2025). As a key part of this technical documentation, bridge drawings support all major stages, including design, construction, and maintenance. They carry essential engineering knowledge and form the basis for design decisions, construction guidance, and maintenance management.

As bridge projects continue to grow in scale and increase in complexity, a single project can generate a massive volume of drawings (Yang et al., 2022). However, traditional file-system-based drawing management treats each drawing as an independent file and organizes them through folder hierarchies and naming conventions. Although this approach is simple and intuitive, it has clear limitations when applied to large, heterogeneous drawing collections. Drawings from different project stages are sometimes stored in separate locations, even when they depict the same component at different points in time. As a result, engineers cannot efficiently track a component across views and stages, and the drawing content remains fragmented, lacking a systematic and explicit representation.

In recent years, AI has made significant progress in extracting information from engineering drawings (Moreno-García et al., 2018). AI models can identify component outlines, text, and symbols, providing a solid foundation for drawing digitization. However, most current approaches process individual drawings in isolation and cannot structure data across multiple project phases in a systematic manner. This limitation is particularly relevant in bridge engineering, where drawings are continuously produced throughout design, construction, and maintenance stages. Enabling cross-phase component traceability can therefore improve drawing reuse, inspection documentation, and lifecycle-oriented infrastructure management.

An ontology-based semantic management approach for bridge drawings can help address this gap and support the digitalization of bridge engineering. It enables semantic, content-based retrieval without relying on file names or folder paths, thereby improving accessibility. Explicitly modeling relationships enables the system to track the appearance of components across drawings from different project stages, thereby enhancing traceability for inspection and maintenance. Moreover, it can benefit Building Information Modeling (BIM) by supporting the reconstruction of BIM models from drawings, and by enabling model-to-drawing trace-back and collaborative viewing, thereby increasing the reuse value of drawing files.

Overall, this paper introduces a semantic pipeline that organizes bridge drawing information in a unified way. It further provides a new way of storing and organizing drawing content from the perspective of views. A case study is conducted to demonstrate how this pipeline can enhance the retrieval and traceability of drawing information. This work lays a foundation for ontology-based digital management and reuse of bridge engineering file assets.

Related Work

AI-based information extraction from engineering drawings

To support the digitalization of engineering drawings, various information extraction methods have been proposed, which can broadly be divided into traditional image processing approaches and deep learning–based methods. Early studies focused on text extraction and symbol recognition using techniques such as connected component analysis, Hough transforms, and rule-based databases (Fletcher and Kasturi, 2002; Or et al., 2005). These methods were later applied to interpret 2D drawings for 3D model generation, for example, through line detection and connectivity rules (Lewis and Séquin, 1998). In such approaches, geometric primitives extracted from 2D drawings are mapped to 3D elements based on predefined reconstruction rules, which often require strong assumptions about drawing con-

ventions and completeness.

With the advent of deep learning, automatic feature learning has significantly improved the robustness and scalability of drawing interpretation. Recent studies have applied convolutional neural networks and related models for object detection, symbol classification, scene text detection, and OCR in technical drawings (Elyan et al., 2018; Vilgertshofer et al., 2020; Nguyen et al., 2021). These techniques enable the extraction of both geometric features and high-level semantic cues from 2D drawings, which are essential for bridging the gap between 2D representations and 3D models. Consequently, AI-based extraction is increasingly deployed to facilitate downstream applications, such as BIM and IFC-based bridge modeling. In these workflows, detected components, annotations, and spatial relationships serve as critical inputs for semi-automatic or rule-based 3D reconstruction (Lu et al., 2020; Akanbi and Zhang, 2022; Feist et al., 2024).

However, most existing studies focus on extracting information within individual drawings, while the organization and semantic management of extracted results across multiple drawings remain insufficiently addressed.

Semantic Management of Engineering Information

To manage the massive, fragmented data generated by modern projects, the concept of semantic file systems provides a crucial theoretical foundation (Gifford et al., 1991). Rather than treating files merely as "items stored under a rigid path," subsequent semantic file systems incorporated ontologies to model files as explicit objects with semantic metadata, enabling concept-based associative retrieval and reasoning (Ngo et al., 2007; Mashwani and Khusro, 2018). This ontology-driven paradigm is essential for organizing heterogeneous files.

Product Lifecycle Management (PLM) and Product Data Management (PDM) systems are used in mechanical engineering to manage data across the entire lifecycle of standardized, mass-produced items (Ji and Abdoli, 2023). However, they cannot be directly applied to bridge engineering because construction projects are unique, site-specific, and non-standardized, whereas manufacturing typically involves standardized products (Zhang et al., 2024). In the Architecture, Engineering, and Construction (AEC) industry, ontologies are more extensively deployed as a unified semantic layer (Noy et al., 2001; Elshani et al., 2025). Specifically, they are utilized to enhance information integration (Wu et al., 2021) and achieve interoperability across different systems (Hagedorn et al., 2023; Lorvão Antunes et al., 2024). These are particularly beneficial for the growing adoption of infrastructure digital twins (DT) (Zinke et al., 2023; Ramonell et al., 2023).

However, these macro-level approaches often treat engineering drawings as "black-box" attachments. By focusing on physical assets and broad business processes, they overlook the rich geometric and spatial semantics embedded within the drawings. To address this, specialized ontologies have emerged. Early work explored semantic drawing classification (Lu et al., 2008), and recently, Schönfelder and König (2025) proposed an ontology to standardize AI-extracted visual information, successfully introducing a semantic layer for individual drawings.

While such drawing-specific ontologies enhance the queryability of standalone files, they still lack the relational mechanisms required for complex, multi-drawing projects. Specifically, existing research cannot differentiate view types or trace identical components across drawings. To bridge this gap, this paper proposes a semantic management ontology for bridge engineering drawings that supports unified view representation and cross-view component tracking in multi-phase projects.

Methodology

Semantic Processing Pipeline

As shown in Figure 1, the overall pipeline can be divided into three main parts.

First, a set of bridge drawings is processed by trained AI models to extract basic information. The models produce segmented subviews for each drawing and JSON files containing OCR text and other detected elements. These outputs serve as the input for subsequent semantic processing.

Second, a Bridge Engineering Drawing Ontology (BEDO) is constructed. It defines the classes and relationships needed to represent drawing semantics. Where possible, existing domain ontologies are reused to avoid redefining common concepts and to maintain compatibility with established standards. In parallel, a semantic encoding module processes the AI-generated outputs and organizes information such as view types, components, and scales into a better structured encoding JSON file. This file is then used to automatically populate the ABox of the ontology via scripts. On top of these assertions, a set of rules is applied to further enrich the semantics. Since AI models extract unstructured text without understanding project-specific organizational logic, users can define custom rules tailored to specific naming conventions and operational needs. Applying these rules on top of the initial assertions further enriches the semantics and explicitly expands the relational structure of the final knowledge graph.

Finally, in the query stage, the pipeline supports semantic retrieval and visual localization. Users can issue queries based on components, view types, scales, and their relationships, and the system retrieves related drawings and views from the drawing collection folder. For selected results, the corresponding subviews are highlighted directly on the original full drawing to support positioning. In this way, the pipeline turns semi-structured AI outputs into computable knowledge and visualizable query results.

AI-Based Extraction of Drawing Information

2D engineering drawings contain both geometric and non-geometric information, including graphical representations of structural views as well as textual annotations and title blocks. In this work, information extraction follows an

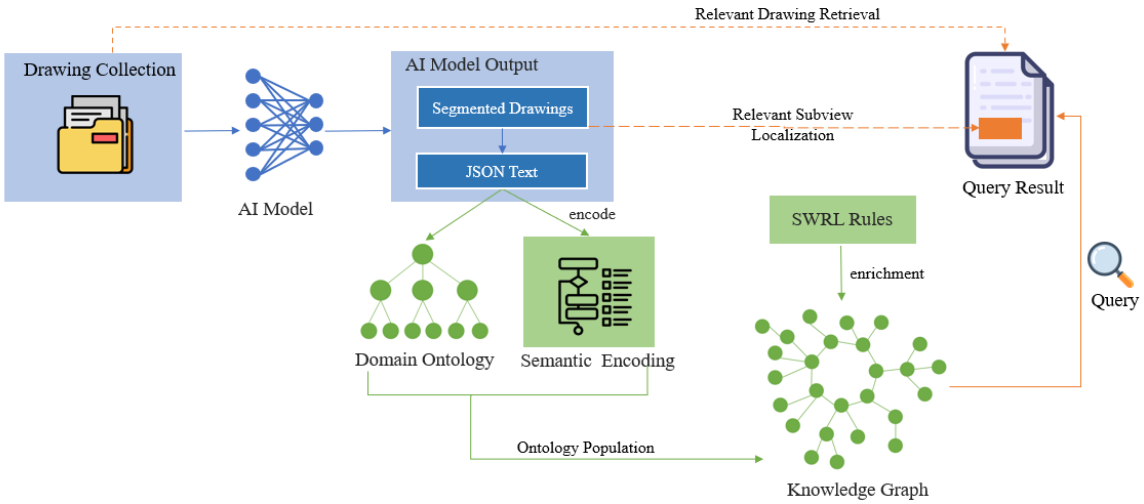

Figure 1: Overall Pipeline: from AI output to ontology-based query and visualization

integrated workflow that combines view localization, text recognition, and semantic post-processing, largely building upon the methodology proposed by Peng et al. (2025). This workflow enables the structured extraction of heterogeneous information from engineering drawings as a foundation for subsequent semantic modeling.

Graphical views in engineering drawings are localized using an AI-based object detection model. In this step, YOLOv7 is applied to identify view regions such as top and side views, providing bounding boxes that describe the spatial extent of each view. These localized view regions establish the geometric reference framework for organizing and associating extracted information. Textual information is obtained through OCR, which detects and recognizes text elements from annotations and title blocks. The OCR outputs include recognized text strings and precise bounding box coordinates, enabling spatial alignment between textual elements and graphical views within the drawings.

To transform the raw outputs of object detection and OCR into semantically meaningful information, post-processing is applied, including title-block metadata extraction, font-size-based view-title identification, and spatial matching between titles and detected views (Peng et al., 2025, 2026). In the current prototype, title-block metadata are extracted using an interactive semi-automatic workflow in which a reference region defined on the first sheet is transferred to subsequent drawings. The results are further filtered using clustering-based analysis and heuristic rules, while uncertain cases are retained for manual verification.

Furthermore, engineering drawings produced by different companies across various project phases exhibit heterogeneous layouts, terminology, varying scales, and geometric distortions from scanning. To handle these inconsistencies, the proposed workflow completely avoids fixed templates and absolute geometric dimensions. Instead, view localization relies on AI-based object detection using normalized bounding-box coordinates, which naturally mitigates the effects of geometric distortion. Similarly, text recognition and view-title identification are driven by relative font-size clustering and spatial relationships rather than predefined title-block positions or fixed pixel thresholds. Finally, explicitly stated scale information is extracted independently and encoded as a semantic attribute. This relative, feature-driven approach ensures that the extraction pipeline remains robust across highly diverse drawing collections.

However, the extracted outputs at this stage still lack a unified relational structure, necessitating further semantic encoding to align with the core ontology concepts.

Semantic Encoding

To transform the semi-structured AI outputs into ontology representations, a semantic encoding module is introduced. Based on the JSON files produced in the information extraction stage, the module identifies and normalizes elements such as view types, components, and scales. The result is an encoding JSON file that is ready for automatic ABox population in the subsequent step.

Figure 2 shows the encoding workflow. To enhance the robustness of the encoding method, the script implements three layers of matching. The matching conditions are progressively relaxed across these layers, so that exact matches are used whenever possible, while fuzzy matches can still be obtained when the available information is incomplete or noisy.

The first layer is exact matching, which uses direct string comparison with word-boundary checks and is suitable for standardized, error-free text. The second layer is substring matching, which relies on substring inclusion to handle compound words (e.g., German compound words). The third layer is fuzzy matching, which compensates for OCR and image segmentation errors, such as missing initial characters or spelling mistakes, by applying a similarity threshold (set to 90% by default).

These three layers are applied on top of the encoding keyword lists, ensuring that semantically relevant terms can still be detected even when the textual inputs deviate from

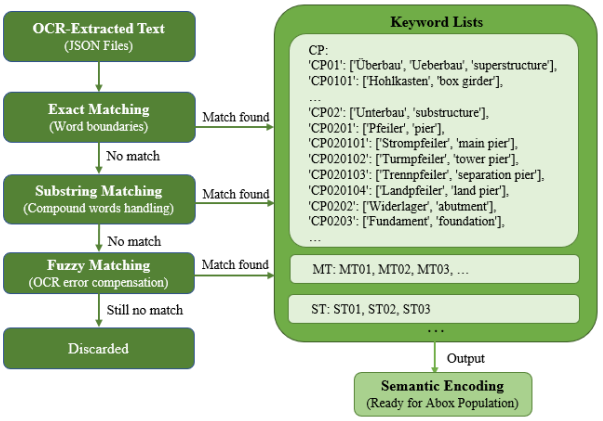

Figure 2: Semantic encoding workflow for OCR-extracted text

their canonical forms. Building on this, the script iterates through seven predefined keyword categories to generate semantic encodings for the extracted text: Bridge Type (BT), Component (CP), Document (DC), View (VW), Material (MT), Lifecycle Stage (ST), and Others (OT).

The keywords used in these categories were developed based on existing domain ontologies reused in BEDO, which are described in detail later in this paper. For each category code, the associated keyword lists include terms in multiple languages, such as German and English, allowing multilingual matching of textual outputs. Figure 2 shows an example encoding keyword list for the Component (CP) category. The design of the encoding keyword lists is extensible. By appending additional language variants to the keywords, the same encoding logic can be directly applied to drawings in new languages. Furthermore, new semantic categories can be added to the keyword lists as AI models become capable of extracting richer information from drawings. In this way, the semantic encoding can be incrementally extended while reusing the same overall pipeline.

Ontology Design

Figure 3 shows the overall structure of the proposed BEDO ontology. The ontology design consists of three main parts: classes, object properties, and data properties.

Classes

To describe engineering drawings, several core classes were designed. The `bedo:Drawing` class, which is a subclass of the `bedo:Document` class, represents technical drawings. `bedo:DrawingView` represents the corresponding views within a drawing. To ensure the defined ontology remains simple and practically applicable, established international standards DIN EN ISO 10209 (2022) and DIN EN ISO 128-3 (2022) were explicitly taken into account when defining the basic nomenclature of drawing views. However, because the definitions in these standards include many view types rarely encountered in the bridge domain, the view classes were selectively filtered and structured to incorporate only those practically utilized in bridge engineering. Additionally, the `bedo:DrawingSeries` class enables higher-level abstraction and organization of drawings when semantic information is more abundant.

The `bedo:Stage` class defines different phases of bridge engineering projects. Throughout a bridge's lifecycle, various types of drawings are produced at different stages, including design drawings, construction drawings, and maintenance drawings. These are represented by the `bedo:Design`, `bedo:Construction`, and `bedo:Maintenance` classes, respectively.

Object Properties

The object properties define the key relationships between classes. The `bedo:hasDrawingView` property links a drawing to its different views, as a single drawing can

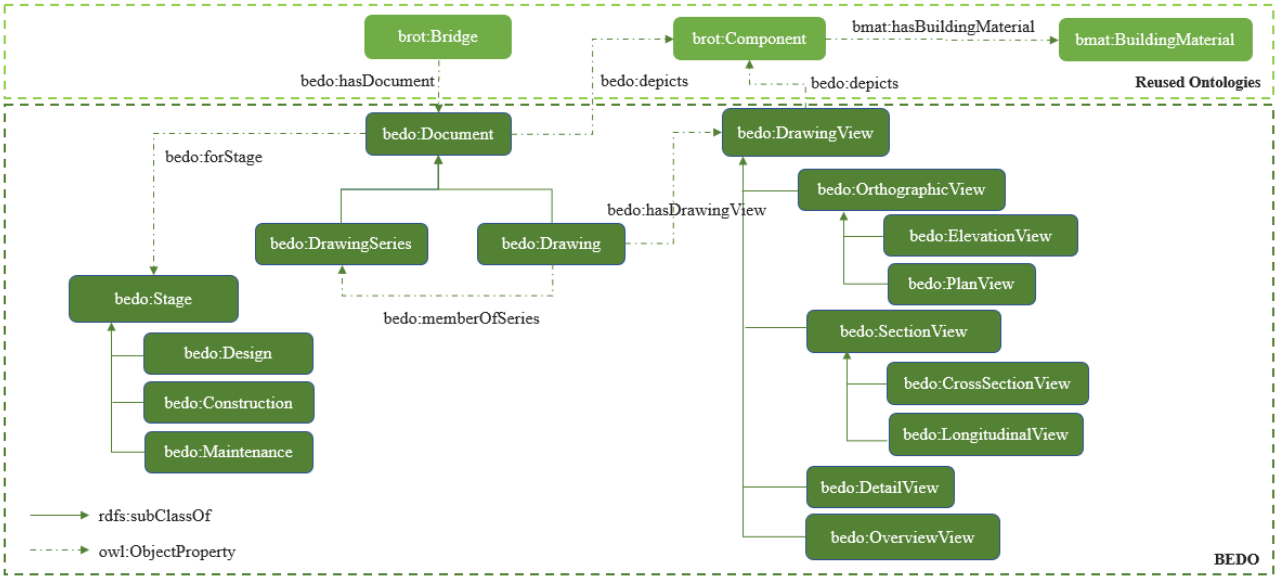

Figure 3: Bridge Engineering Drawing Ontology

contain multiple views. The `bedo:forStage` property describes which engineering stage a bridge document belongs to. The `bedo:memberOfSeries` property indicates that a drawing belongs to a specific drawing series. A single drawing can be included in multiple series based on different classification criteria. The corresponding inverse properties are also defined but are omitted here for brevity.

Data Properties

The data properties primarily capture attribute information from drawing files and processed model outputs. For drawing files, `bedo:drawingFilePath` specifies the file path location within the system, while `bedo:drawingTitle` stores the title from the drawing title block. For subviews generated after AI processing, `bedo:boundingBox` records the bounding box parameters used during AI-based object detection, which can be utilized for reverse view localization during queries. The `bedo:drawingViewTitle` property captures the titles of subviews and thus helps determine the semantic information of each view. Additionally, `bedo:viewFilePath` stores the file path of AI-generated view files. The `bedo:viewJsonFilePath` property records the file path of the OCR output JSON files. Other data properties include `bedo:scale` for scale information and `bedo:seriesType` for classifying drawing series types.

Reusing Existing Bridge Domain Ontologies

To improve interoperability and reusability, some existing bridge domain ontologies were reused. These include the Bridge Topology Ontology (brot), the Bridge Component Ontology (brcomp), and the Bridge Material Ontology (bmat) (Hamdan and Scherer, 2020). While BEDO models drawing- and view-level semantics, it relies on these external ontologies to represent the physical assets depicted in the drawings. Extracted components and materials are mapped directly to classes in `brcomp` and `bmat`, respectively, while topological relationships among components are aligned with `brot`. The reused ontologies and their IRIs are summarized in Table 1.

Table 1: Reused Ontologies in BEDO

Prefix	URI
brot	https://w3id.org/brot#
bmat	https://w3id.org/bmat#
brcomp	https://w3id.org/brcomp#

Application and Results

A case study was conducted using a set of inspection drawings of the Nibelungen Bridge. The Nibelungen Bridge is a historic prestressed concrete bridge in Worms, Germany, constructed in 1953 (Kang et al., 2024).

Ontology Population

The drawing dataset consists of 22 drawing files and was first processed using the model proposed by Peng et al. (2025). Note that the drawings used in this case study are not included in the original training dataset of that model. After semantic encoding and ABox population, a knowledge graph representing this drawing set was generated.

Rule-based Semantic Enrichment

Before being used for downstream tasks, the knowledge graph was further semantically enriched by applying a set of rules. As introduced in the methodology, these rules capture project-specific organizational logic. As shown in Figure 4, the inferred series instances, such as *Drawingseries_003* and *Drawingseries_Hessen*, are automatically linked to their corresponding member drawings, forming a more structured semantic network. Two illustrative examples are as follows:

- Rule 1 (Series by filename): Any drawing whose filename starts with ”003.” is assigned to the drawing series *Drawingseries_003*, where the *seriesType* is set to ”filename”.
- Rule 2 (Series by region): Any drawing whose drawing title contains the word ”Hessen” is assigned to the drawing series *Drawingseries_Hessen*, where the *seriesType* is set to ”region”.

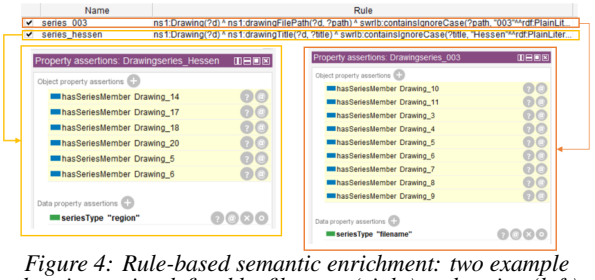

Figure 4: Rule-based semantic enrichment: two example drawing series defined by filename (right) and region (left)

Semantic Retrieval and Visualization

With the knowledge graph, users can perform semantic queries at different levels of granularity. For example, based on the aforementioned enrichment rules, users can directly retrieve all documents belonging to the *Drawingseries_Hessen*. Moreover, the system supports fine-grained, component-level queries, such as requesting all views related to ”pier” components. As shown in Figure 5, when querying for pier components, the system retrieves a list of matching subviews on the left panel, accompanied by their view titles. For each result, its exact location within the original drawing can be further visualized. In this specific example, the red mask effectively highlights the bounding box of the queried pier view.

Figure 6 shows the underlying knowledge graph of the drawing in Figure 5. The graph explicitly represents nine distinct drawing views and their containment relationships. By comparing the two figures, the mapping between visual representations and semantic instances be-

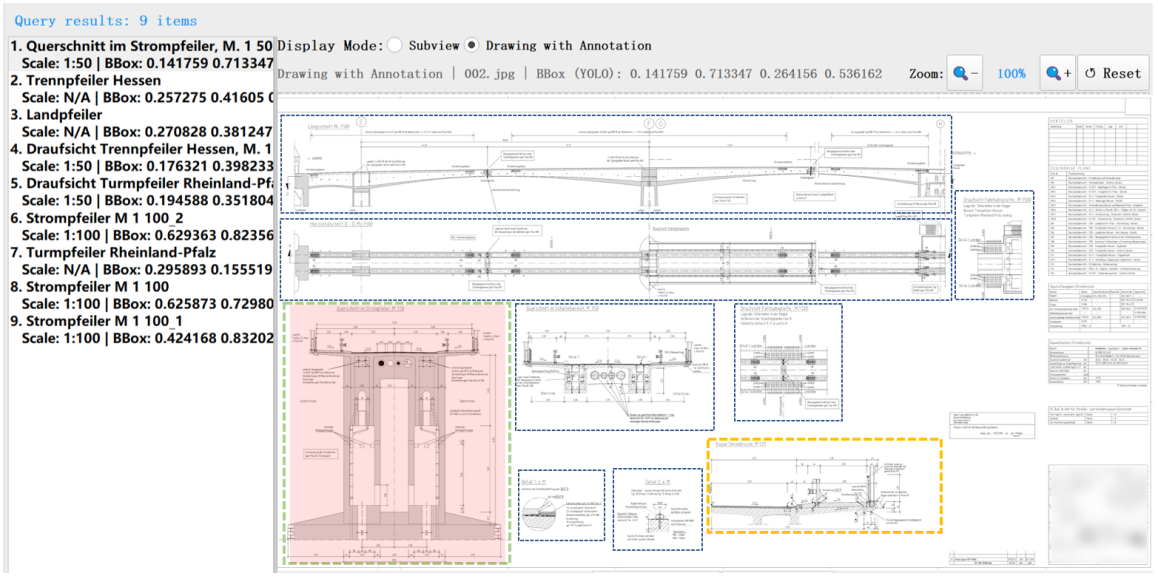

Figure 5: Query and localization of a pier subview within the original drawing

comes transparent. For example, the pier view enclosed in the green dashed box in Figure 5 corresponds to the *DrawingView_23* node. As highlighted by the green dashed box in Figure 6, this node is explicitly marked as a *CrossSectionView* depicting a *Pier* component. Similarly, the view enclosed in the yellow dashed box in the bottom right of Figure 5 maps to *DrawingView_18*, which depicts a *Cap* component. This direct linkage demonstrates how unstructured visual layouts are successfully transformed into a highly organized and queryable semantic network.

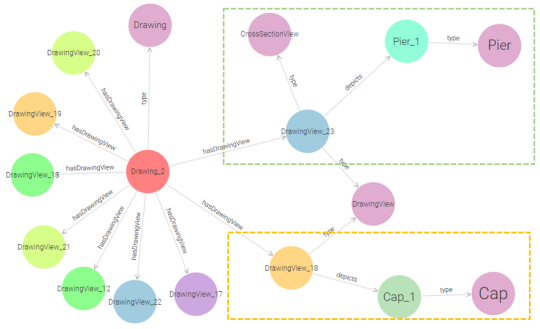

Figure 6: Queried drawing represented in the knowledge graph

Discussion

In the previous section, the proposed pipeline was demonstrated on a set of inspection drawings of the Nibelungen Bridge. The results show that, based on the semantics parsed from subview titles, components can be successfully traced back to their corresponding view locations in the original drawings. As long as the relevant information is explicitly encoded in the drawings, it can be recognized and linked through the ontology, enabling consistent cross-view and cross-stage traceability.

Although the case study uses German bridge drawings, the proposed semantic management approach is not limited to a specific national context. Since the ontology captures generic relationships among drawings, views, components, and project stages rather than country-specific regulations, it can be adapted to drawing collections produced under different standards and documentation conventions. Its applicability is also not constrained by bridge span size. Since BEDO operates at the semantic level of drawings, views, and component occurrences rather than on structural dimensions, it can in principle be applied to bridges with small, medium, or large spans, provided that the relevant information is represented in the drawings. Additionally, the pipeline shows potential for scalability, although this has not yet been validated on a large-scale dataset. Because the AI extraction processes individual drawings independently, the workload can be parallelized to handle much larger numbers of files. Furthermore, the generated semantic data consists of lightweight RDF triples, which modern graph databases can generally manage efficiently at large scale.

However, some limitations remain. In situations where view headings are missing due to overlapping elements, or where titles provide little semantic information on their own (e.g., “Schnitt A - A, M. 1:25”), the current pipeline struggles to assign complete semantics. In these cases, additional context from other parts of the drawing is required to interpret the meaning of the view, which is not yet systematically captured. Consequently, the semantic representation for such views remains incomplete. To further improve the richness of semantic information, additional extraction strategies are needed. These may include exploiting more diverse textual annotations, leveraging layout and graphical context, or incorporating prior domain knowledge to infer missing semantics beyond what is explicitly stated in the view titles. Furthermore, since a manually labeled benchmark dataset for systematically validating metadata extraction is currently unavailable, es-

tablishing one remains an important direction for future work.

Another limitation of the proposed pipeline is that the semantic accuracy of the populated ABox depends on the performance of the upstream AI models used for view detection and OCR. In practical bridge engineering projects, many drawings exist only as scanned documents with heterogeneous quality. Although the pipeline can be applied to such data, low resolution or incomplete scans may reduce extraction accuracy and lead to missing or incorrect semantic assertions. Nevertheless, the ontology-based representation itself remains independent of drawing format once sufficient information has been extracted.

The proposed approach is positioned not as an isolated solution for 2D document processing, but as a complementary mechanism for bridging unstructured legacy drawing data with modern BIM ecosystems. While new infrastructures are increasingly designed natively in 3D, existing assets still rely on vast archives of 2D engineering drawings. To ensure the proposed approach remains highly relevant in a BIM-dominated future, a critical avenue for future work is the direct integration of the proposed ontology with BIM frameworks. This can be achieved by establishing explicit semantic mappings between BEDO and IFC-based bridge models, such as IFCBridge. This integration would enable the transfer and alignment of information between legacy 2D drawings and 3D BIM models. Such a connection would support more comprehensive analyses across multiple data sources and facilitate downstream tasks such as lifecycle management, structural assessment, and digital-twin applications.

Conclusions

This paper presented BEDO, an ontology for representing bridge engineering drawings, together with a pipeline for automatically populating the ontology from the fragmented data produced by AI-based processing of the drawings. By parsing textual information and encoding it as ontology concepts, the approach links drawing content to a formal semantic model. Based on the instantiated ABox assertions, it then enables semantic querying of drawings at the view level. The case study on the Nibelungen Bridge demonstrated that, whenever sufficient semantic cues are explicitly encoded in the drawings, the proposed method can reliably trace component-related views back to their locations in the original documents. At the same time, several limitations remain, such as the incomplete extraction of relationships between views and the dependence on the quality of upstream AI components. Future work will address these limitations and further link BEDO with BIM models to support richer cross-modal analyses and more integrated lifecycle management of bridge infrastructures.

Declaration of generative AI and AI-assisted technologies in the writing process

During the preparation of this work, the authors used Claude 4.5 and DeepL in order to improve the readability and language of the work. After using these services, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication.

ENABELING COMPREHENSIVE QUERYING OF ENVIRONMENTAL CONTEXT AND ROAD INFRASTRUCTURE DATA USING A GRAPH-BASED APPROACH

Ina Heise, André Borrmann
Chair of Computing in Civil and Building Engineering, TUM Georg Nemetschek Institute,
Technical University Munich, Germany

Abstract

Enabling predictive maintenance (PM) of road infrastructure by understanding condition developments requires accounting for internal and external influences. However, the corresponding data are highly heterogeneous and distributed, limiting comprehensive large-scale analysis. To bridge this gap, an existing Digital Twin (DT) approach is enhanced with environmental context data. Knowledge graphs enable scalable querying across heterogeneous subsystems, while a federated database addresses data distribution. The framework is validated using real-world data from Germany. Linking historical climate records with bridge condition development demonstrates comprehensive querying. By enabling scalable cross-system data association, the proposed DT framework enhances the practical applicability of existing PM methods.

Introduction

PM is crucial for ensuring the resilience and sustainability of road infrastructure. Its practical implementation is facilitated by informed decision-making, which requires not only a comprehensive understanding of the current state of the system but also an understanding of trends and tendencies in future conditions.

The challenge of comprehensive state representation arises from the system's complexity, driven by its size, heterogeneity, and the various relationships that span multiple scales. Furthermore, when analyzing trends and predicting the development of conditions, considering the system's interactions with its environmental context becomes crucial, as it allows integration of the climate conditions to which the system was exposed. When dealing with complex real-world systems, the DT concept depicts a recognized method. Applying DTs involves using a digital representation of the physical system, along with its various states, to apply computer-based methods. However, the complexity of road infrastructure and its environmental context is also apparent in the existing data, which is distributed across distinct systems managed and updated independently by different institutions and reflects heterogeneity in its underlying data structures. Thus, creating a database suitable for investigating the development of road infrastructure conditions in conjunction with external influences, such as climate, requires associating data with considerable manual effort, which strongly conflicts with the size of the system under consideration. A comprehensive DT that, in a scalable manner, captures road infrastructure alongside its climate exposures and relationships and facilitates automated data association, overcomes this limitation.

Contributions

Studies examining environmental impacts on road infrastructure deterioration primarily rely on a research database that already provides condition and climate data in an integrated manner. While these studies demonstrate the importance of considering environmental context, they neglect the data heterogeneity and distribution prevalent in road infrastructure management practice. Integration of heterogeneous maintenance data, particularly sensor data, is a key topic in research on road infrastructure DTs. Previous work presents frameworks that address the data-integration challenge using graph-based approaches. However, existing approaches focus on individual assets and neglect scalability to entire road infrastructure systems, which is essential for investigating correlations between environmental data and condition development. Other studies on graph-based DT frameworks focus on scalable capture of road infrastructure and its internal relationships, but neglect the system's interactions with the environmental context. Accordingly, a gap remains between the need for large-scale evaluation of road infrastructure maintenance data alongside its environmental contexts and the existing DT approaches that focus either on time-series data integration or scalability. Accordingly, we build on existing approaches for the scalable representation of road infrastructure with its interactions and enhance them by integrating interface relationships with environmental context data, particularly georeferenced time-series climate data. Thereby, not only is the integration of highly heterogeneous data structures at scale accounted for, but also the effects arising from differences in update cycles, spatial structuring approaches, and data distribution across various systems. Furthermore, scalability factoring requires an efficient approach to automatically establish links between time-series data resources and road infrastructure elements during the DT setup. By leveraging characteristics of road infrastructure, we facilitate inference of these relations, thereby significantly reducing the number of required geospatial calculations. The proposed concepts are validated on complete real-world datasets from Ger-

man road infrastructure management and climate recordings. Thus, the ability to handle real-system sizes while acknowledging the data-inherent heterogeneity and distribution is proven.

Related Works

Environmental Context in Infrastructure Deterioration

Considering climatic influences is crucial when investigating the development of road infrastructure conditions. Providing a broad perspective, Sias et al. (2025) conduct a literature review of the effects of climate change on road infrastructure.

Zhang et al. (2025) examine the effects of rising temperatures on asphalt pavement aging. Focusing on more specific mechanisms, Zhou et al. (2020) analyze the effects of freeze-thaw cycles on concrete pavements, while Chen et al. (2023) examines the pavement roughness' dependency on the influences of temperature, moisture, rainfall, and freeze-thaw cycles. Using a data-driven approach, Piryonesi and El-Diraby (2021) integrate temperature ranges, perspiration, and freeze-thaw cycles in their pavement condition prediction. Lamei et al. (2025) investigate climate predictors for bridge component deterioration. It becomes evident that considering the climatic conditions to which a road infrastructure system is, was, and will be exposed is essential in understanding deterioration. This aligns with the Long-Term Pavement Performance (LTPP) program's (Federal Highway Administration, US Department of Transportation (2017), Schwartz et al. (2015)) goal of supporting research on the deterioration of road infrastructure by providing a comprehensive database. The LTPP database contains data on test road sections and bridges in North America and Canada, including condition records and accumulated climate data per test road section. It is apparent that virtually all studies investigating climate effects on deterioration on a larger scale (such as Zhang et al. (2025), Chen et al. (2023), Piryonesi and El-Diraby (2021), Lamei et al. (2025)) build on data from this LTPP database.

Although the LTPP database is a key resource for developing deterioration models, its static storage of aggregated climate data with fixed assignments to road sections introduces limitations. In particular, the lack of flexibility restricts the development of new deterioration models and the application of models that are not aligned with the accumulated metrics provided. In addition, data maintenance and integration of additional data sources are cumbersome, uncertainty quantification is rendered impossible, and adaptation to nonstationary climate conditions is not feasible. Moreover, this centralized data structure does not reflect real-world asset management practices, where road infrastructure and environmental data are typically maintained by separate institutions using distinct systems, each with heterogeneous underlying data structures.

Integrated Infrastructure DTs

Broo and Schooling (2023) highlights DT's capabilities as an effective tool for improving infrastructure systems maintenance through extensive data analysis, but also outlines existing challenges in integrating complex systems and data.

Knowledge graphs (KG) facilitate the integration of heterogeneous datasets by representing elements as nodes connected by edges that capture their relationships as stated in Hogan et al. (2022). Various graph models exist, including the Resource Description Framework (RDF) and Labeled Property Graph (LPG) model. While RDF benefits from unique identifiers and a clearly defined schema through ontologies, the LPG model offers greater flexibility and a more compact structure by allowing properties to be assigned to nodes and edges. While both approaches have their respective advantages and disadvantages, they are, in principle, suitable, as also reflected in existing works.

Hagedorn et al. (2023) presents a graph-based DT framework that integrates heterogeneous maintenance data for roads and bridges, building on a web-based implementation of the Information Container for Linked Document Delivery (ICDD). In Hagedorn et al. (2024), the focus shifts from maintenance to construction, but the ICDD approach is further refined by integrating dynamic sensor data. Although the ICDD approach enables linking RDF graphs with other time-series datasets, thereby facilitating data integration, its reliance on a file-based architecture requires a centralized data storage system. This centralized architecture contrasts with the distributed data management practices, especially when external data sources, such as weather data, are to be included. Furthermore, the largely static structure not only limits adaptability to changing requirements but also increases maintenance effort and reduces scalability in complex, evolving systems.

Li et al. (2024) examine another area of infrastructure systems with their graph-based DT approach for pipes and tunnels. By using LPGs for implementation, the approach benefits from the flexibility and a more compact graph structure. Li et al. (2024) approach involves considering environmental data in the form of measured ground settlements and, by capturing interactions, their effects on the considered structures. However, the approach explicitly stores interaction-describing relationships and operates on a single graph that represents the entire system. Thus, once again, current infrastructure management practices are neglected, just as the system's ability to adapt for integrating additional subsystems, interactions, or data resources.

Ramonell et al. (2023) integrates IoT data with infrastructure IFC models by proposing an LPG-based microservice architecture for asset maintenance. This approach reveals a limitation that also applies to the approaches proposed by Li et al. (2024), Hagedorn et al. (2023), and Hagedorn et al. (2024): In all cases, the integration of sensor data is examined only for individual assets. The scalability of the proposed DT approaches to an entire infrastructure system, including the associated number of assets and the corresponding number of sensors, remains unexamined. Addi-

tionally, when incorporating environmental data, such as climate data, this information often spans a broad area, making it relevant to multiple assets. As a result, adopting existing methods that rely on data integration via explicit component-level links is highly inefficient. In addition, existing approaches also emphasize streaming sensor data. Although this provides a comprehensive view of a component's actual condition, it neglects large-scale evaluation of historical time series, as compared to, e.g., documented condition changes in the context of correlation analysis. Thus, characteristics of road infrastructure systems, such as size, heterogeneity, and the time spans of interest, are not addressed.

Scalable Road Infrastructure DTs

When it comes to the scalable use of knowledge graphs, Purohit et al. (2020) reports improved scalability for LPGs and suggests mapping RDF graphs onto LPGs to combine the efficiency of LPGs with the knowledge provided by the underlying ontologies of RDF graphs.

Thus, existing DT approaches that address the scalable integration of heterogeneous data build upon LPGs. Heise et al. (2025a) introduce a DT-framework for the scalable evaluation of spatial relationships between heterogeneous road infrastructure elements. Heise et al. (2024) extend this approach to capture spatial relationships at multiple scales, and in Heise et al. (2025b), the framework is further enhanced to capture temporal relationships, enabling the investigation of dependencies between condition developments as time-dependent variables. However, while these works enable data analysis that accounts for internal interactions within road infrastructure, external influences, such as climate, remain unaddressed, although existing research underscores their significant impact on deterioration processes.

A gap remains in DT approaches that can also efficiently and scalably integrate long-term observation data at the corresponding frequency, especially since this data naturally lacks infrastructure-specific characteristics and is most efficiently stored in relational (time-series) databases and maintained independently. Thus, we adopt the DT framework from Heise et al. (2025a) for internal relationships in road infrastructure and enhance it by incorporating interface relationships with environmental context data.

Method

The core of capturing the complex relationships and interactions in road infrastructure lies in applying the System-of-Systems (SoS) concept initially introduced by Ackoff (1971). Relationships within road infrastructure and between road infrastructure elements and the environmental context are treated as distinct subsystems, as illustrated in Figure 1 on the left. Elements represented in multiple subsystems serve as connection points that link the subsystems to an overall SoS.

Reflecting this subdivision of the overall system in the architecture of the digital representation not only accounts for the distributed management and storage of data resulting from the actual distribution of responsibilities but also enables the selection of the most suitable database management system (DBMS) type. The right side of Figure 1 depicts the implementation of the SoS concept in a DT framework, incorporating digital representations of road infrastructure and its relationships as *InfraTwin*, and climate data as a distinct *Climate Twin* in *Layer I*. The cross-system evaluation of the subsystems builds on identifying representations of the same elements across subsystems, and implementation is achieved in *Layer II* via a federated database.

Layer I: Subsystems

The *Climate Twin* is assumed to be an existing external system that provides time-series climate data associated with a georeferenced element (typically the weather station where the data were recorded or the area to which the recorded values apply). It is common practice to use relational DBMSs for time series data. As an example for such a system, we consider the *Climate Data Center (CDC)*[1] maintained by the German Meteorological Service (Deutscher Wetterdienst).

The *InfraTwin* comprises further subsystems and builds on the concept Heise et al. (2025a). These subsystems capture both elements of road infrastructure and their conditions, as well as their internal relationships in the *Internal Relationship Graph*. The framework of Heise et al. (2025a) is enhanced by an additional subsystem comprising interface relationships to external elements in the *Interface Relation Graph*. Each *InfraTwin* subsystem is modelled as a knowledge graph and stored in a distinct graph database instance. The modeling of internal relationships within the *InfraTwin* follows the approach presented in Heise and Borrmann (2024) and exploits linear reference elements as a spatial structuring system. Assets and reference elements, stemming from the road network, are represented as nodes. Modeling their relationships implements the principle of absolute linear referencing. To capture the relationships between road infrastructure elements and the environmental context, this spatial structuring approach is leveraged, as it already accounts for road infrastructure-specific characteristics.

Rather than explicitly linking every asset to its environment, the geospatial context elements are mapped onto the linear reference elements as illustrated in Figure 2. Accordingly, it is explicitly modelled which parts of the road network belong to which environmental context. Environmental contexts are represented as areas on a linear reference element with specific start and end points, defined by distance values. Implementing this absolute linear referencing in the graph structure follows Heise and Borrmann (2024) in a simplified manner: environmental data and linear reference elements are represented as nodes, and the relationship between them is captured by connecting edges, as detailed in Figure 2 on the right.

[1] https://cdc.dwd.de/

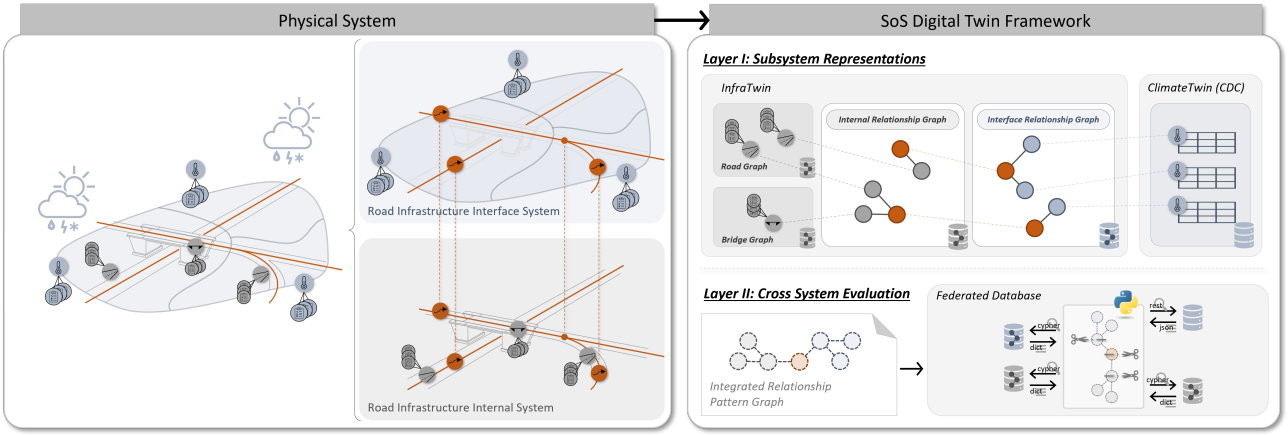

Figure 1: Representing Road Infrastructure with its Environmental Interactions as System-of-Systems Digital Twin Framework

Information on whether a road infrastructure element is located in a specific area can be derived by superimposing its relationships with the common reference element. Therefore, spatial relationships between environmental context and road infrastructure elements can be evaluated with the same precision as those between assets. This includes $n : n$ relationships between areas and assets, which may be important for structures spanning several kilometers, such as noise barrier walls, and their relationships to potentially multiple areas. In summary, the road network serves as the connection point between the two subsystems, which reduces not only the number of cross-system connections but also the number of elements to be represented in the *Interface Relationship Graph*, thereby efficiently reducing its size.

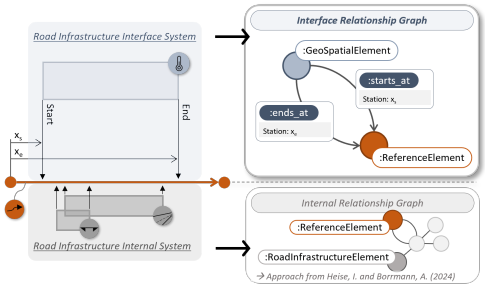

Figure 2: Graph Structures of the Relationship Graphs

Layer II: Comprehensive Evaluation

Applying the SoS principles and the corresponding subdivision into subsystems results in a distribution of information. Thus, elements with their corresponding data and various relationships are spread across several DBMSs. The cross-system relationship can be described as a pattern graph that spans the various subsystem graphs. Thus, identifying elements that exhibit a specific cross-system relationship comes down to a pattern-matching problem, searching for occurrences of this pattern graph in the overall system. The distributed storage of the subsystems turns the problem into a distributed pattern-matching problem, in which each pattern graph fragment corresponds to a single subsystem.

The implementation of distributed pattern matching forms *Layer II* in Figure 1. A federated database connects the distinct DBMSs of the different subsystems without holding any data itself. Instead, for each pattern graph fragment, corresponding queries are sent to the respective subsystem database endpoints. The order (as well as potential parallelization) of this query process is determined by the dependencies defined in the overall pattern graph. Additionally, aligning the query direction with the expected solution set sizes for each subsystem evaluation helps quickly exclude large portions of the system, thereby enhancing overall evaluation efficiency. Implementation of *Layer II* can be achieved through a script, e.g, using Python.

It is worth noting that the query language and the way data is accessed may vary across fragments, as the concept explicitly considers different DBMS types across subsystems. The depiction in *Layer II* of Figure 1 assumes that Neo4j is used as a graph DBMS, and accordingly, interactions involve sending Cypher queries, while the climate time series can be efficiently obtained via a REST API.

Creation of the Interface Relationship Graph

The *Interface Relationship Graph* comprises the relationships between the geospatial environmental context and the road network edges. Since these relationships are not yet present in the data, geospatial calculations are required. Assuming the road network's edge geometries are polylines, this calculation identifies which segments of those polylines fall within specific environmental areas. In principle, this analysis corresponds to geospatial querying already implemented in diverse interfaces and database engines, and it is also applied in existing approaches, such as those presented in the Related Works Section.

Yet, given the specific characteristics of road infrastructure systems, particularly the common sizes of real-world road networks, this poses a fundamental dilemma between geometric analysis accuracy and scalability. In addition, the number of polyline segments of a network edge is often unrelated to its spatial extent. On the contrary, network edges with a small spatial extent, often connecting other main axes, typically have a large number of polyline seg-

ments due to their high curvature. Therefore, considering inherent net characteristics when determining the spatial relationships between the road network and environmental areas, rather than computing them for every road network polyline segment, appears reasonable.

The proposed approach builds on the assumptions that (1) the geometry of the road network is significantly finer-grained than its environmental context areas. Thus, one network edge intersects at most one boundary between environment areas. And (2) only qualitative relationships between the road network and the environmental context areas are to be evaluated, and a tolerance of the geometric calculations of several meters is acceptable.

The approach consists of a two-step process: Firstly, the geospatial relationship between the net nodes and the areas is computed. Based on this information, the network edges themselves are considered second. During the analysis of the network edges, two cases are distinguished, aiming to use inference as far as possible rather than a geometric analysis. Figure 3 illustrates both cases.

In *Case I*, relationships between net edges and areas can be completely inferred by assuming that if two net nodes V_1 and V_2 are within an area A, this also applies to the network edge (and correspondingly the reference element) E connecting V_1 and V_2. Accordingly, the spatial relation required to create the *Interface Relation Graph* is determined using Equation 1. As the environmental area spans the entire reference element, the start station is 0, and the end station is the length of the reference element, respectively.

$$\frac{\mathrm{in}(V_1, A) \quad \mathrm{in}(V_2, A) \quad \mathrm{starts}(V_1, E) \quad \mathrm{ends}(V_2, E)}{\mathrm{in}(E, A)} \tag{1}$$

Case II covers V_1 and V_2 contained in different areas A_1 and A_2 and therefore involves the reference element intersecting a boundary. To localize the boundary P_{Bound} on the reference element, the individual points of the polyline $P_1, ..., P_n$ are checked for their containment in A_1. P_{Bound} corresponds to the first point identified outside A_1, and investigations stop if P_{Bound} is identified. The P_{Bound} station together with the length of the reference element provides the information to model the relationship between the two environmental areas and the reference element, as illustrated in Figure 3.

The result is the *Interface Relation Graph*, which captures the spatial relationships between environmental context areas and linear reference elements, thereby facilitating the comprehensive evaluation of climate and asset data.

Prototypical Real-World Implementation

To validate the practical applicability of the proposed framework, it is applied to a real road infrastructure system. Real-world data from German infrastructure management and publicly available climate data, both structured differently and originating from distinct sources, are used.

Setting Up the DT-Framework

The *InfraTwin* integrates data on bridges and the German road network, while the *ClimateTwin* is represented by the CDC. Bridge data in Germany is maintained in SIB-Bauwerke[2], a proprietary asset management system. SIB-Bauwerke builds on a relational database and supports only file-based data exchange. For the case study, we used a copy of the database for all Bavarian (a state of Germany) assets provided to us as part of a research project. The German road network is centrally managed and publicly provided by the Federal Highway Administration (Bundesanstalt für Straßenwesen (BASt)). For the case study, the data were obtained through the WFS interface[3]. The CDC provides several interfaces, including a REST API and an open file server. Since the REST API interface is still under construction and therefore does not yet provide access to the full data set, the HTTP-based open file server[4] was used, despite the resulting limitations in filtering options. The prototypical implementation of the concept employs Labeled Property Graphs (LPG) and Neo4j, a widely used graph DBMS, for their storage. The federated database is implemented in a Python script.

Internal Relationship Graphs Creation

To facilitate integration of the different legacy data sources, graph representations of the bridge data and the road network were created and stored in distinct graph database instances. Capturing the internal relationships follows the approach presented in Heise et al. (2025a). This involves creating the *Internal Relationship Graph*, which captures the spatial relationships between bridges and reference elements (as referred to in Heise et al. (2025a) as the *InfraNetRelation Graph*). Furthermore, graphs representing the net (*Net Graph*) and the bridge condition recordings (*Bridge Graph*), each stored in a distinct graph database, were generated.

Interface Relationship Graph Creation

In this case study, the *Net Graph* serves as a basis for creating the *Interface Relationship Graph*. According to the concept presented earlier, this involves assigning net nodes to their environmental contexts first. Since the climate data in the CDC is stored associated with weather stations possessing point coordinates, calculating the required information yielded a Voronoi-like decomposition via Euclidean nearest-neighbor assignment. To ensure computational efficiency, the distance calculation was performed using a vectorized approach. For each net node, distances to all weather stations were computed simultaneously, and the minimum value was selected, which avoided the construction of a full distance matrix. Implementation was achieved through a Python script using the NumPy library. The computed assignments of net nodes and weather sta-

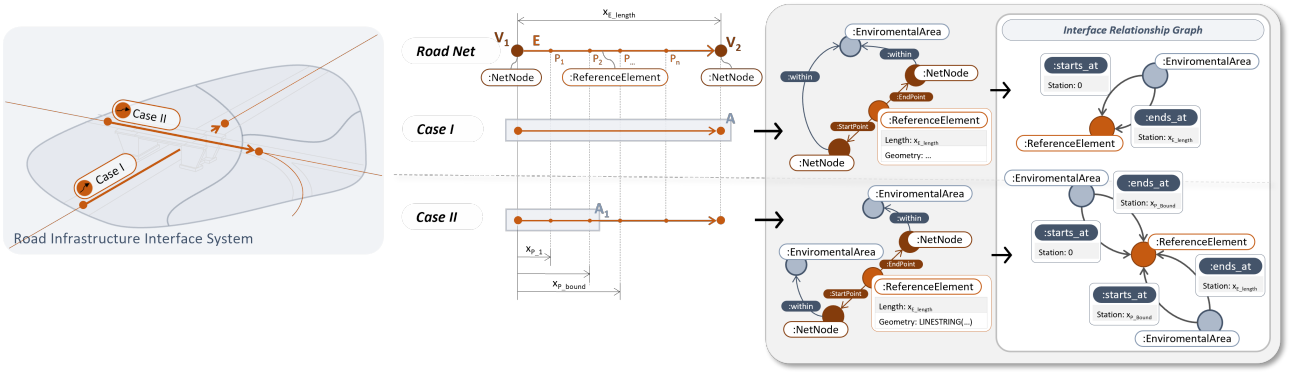

Figure 3: Interface Relationship Graph Creation

tions are fed into the *Net Graph*.

Based on this, the interface relationships between reference elements and weather stations satisfying the conditions of *Case I* could be inferred. The inference is implemented using a CYPHER query, which first extracts the corresponding reference element-weather station pairs (along with the length of the reference element and the respective IDs). Based on the created dictionary, the corresponding nodes and relations in the *Interface Relationship Graph* are generated.

The remaining reference elements fall under *Case II*. To determine x_{P_bound}, a CYPHER query directed to the *Net Graph* identifies the corresponding reference elements with associated weather stations linked to its start and end point. The IDs, along with their geometry (stored as WKT), are given back. The calculation of x_{P_bound} is then implemented in Python using the NumPy and Shapely libraries. The calculation results facilitate the enhancement of the *Interface Relationship Graph* with the remaining relationships between weather stations and reference elements.

The Example Use Case

Associating bridge conditions with frost-thaw cycles derived from daily temperature recordings serves as an example use case. The bridge conditions are contained in the *Bridge Graph* linked to the respective asset. Temperature recordings are provided in different resolutions in the CDC. Automatic association is facilitated by comprehensively evaluating the *Interface Relationships Graph* and *Internal Relationship Graph*, as illustrated in Figure 4. Firstly, the *Internal Relationship Graph* provides all Bridges in the dataset, along with their localization on a reference element. This information is used to subsequently query the *Interface Relationship Graph*. Using the reference elements' IDs, the weather station corresponding to each bridge is determined. The resulting dictionary contains bridge IDs assigned to weather station IDs.

For further querying, the capabilities of the provided interfaces were taken into account. If fetching temperature records for a specific time interval is possible, e.g., via a REST API, continuing the sequential process in which the condition ratings of the bridges were queried first, followed by the temperature data for the covered intervals, is beneficial. However, the CDC interface provides only a single text file containing all historical temperature data for each weather station, prohibiting the preselection of climate data based on bridge data availability. Accordingly, parallel data retrieval was implemented. The first subprocess extends the dictionary of weather station IDs and bridge IDs with a list of available condition grade recordings per bridge by interacting with the *Bridge Graph*. For each weather station ID, historical soil temperature records are retrieved from the CDC. Within the CDC, the ZIP archives corresponding to a specific weather station could be automatically identified and downloaded (via an HTTP request) using the employed naming convention. After downloading the ZIP archives, they are opened in memory, and the text file containing the actual temperature data is extracted and stored, using the corresponding weather station's ID as the file name.

Finally, investigating temporal relationships by implementing the approach presented in Heise et al. (2025b) enables associating frost-thaw cycles with bridge condition recordings, thereby facilitating further data analysis.

Results

The prototypical implementation demonstrated the applicability of the proposed framework to real-world data sets from Germany. The CDC dataset comprised data from 5.311 weather stations. The road network contains 36.565 network edges (and respectively reference elements). The relationship of 87% (31.916) of these reference elements to weather stations could be completely inferred as they fell under *Case I* (Figure 3). Only the remaining 4.649 reference elements required detailed analysis.

The *Internal Relationship Graph* contains 31.309 asset representations. Since we had access to asset data only from a part of Germany (Bavaria), but could use the road network for the entire country, this resulted in fewer assets as reference elements. Nevertheless, the reduction in explicitly modeled relationships by using the net as a connecting element is evident in the average number of assets per reference element, which is 3.3 and is expected to be even higher if road sections are to be integrated.

Implementing automated association of bridge condition

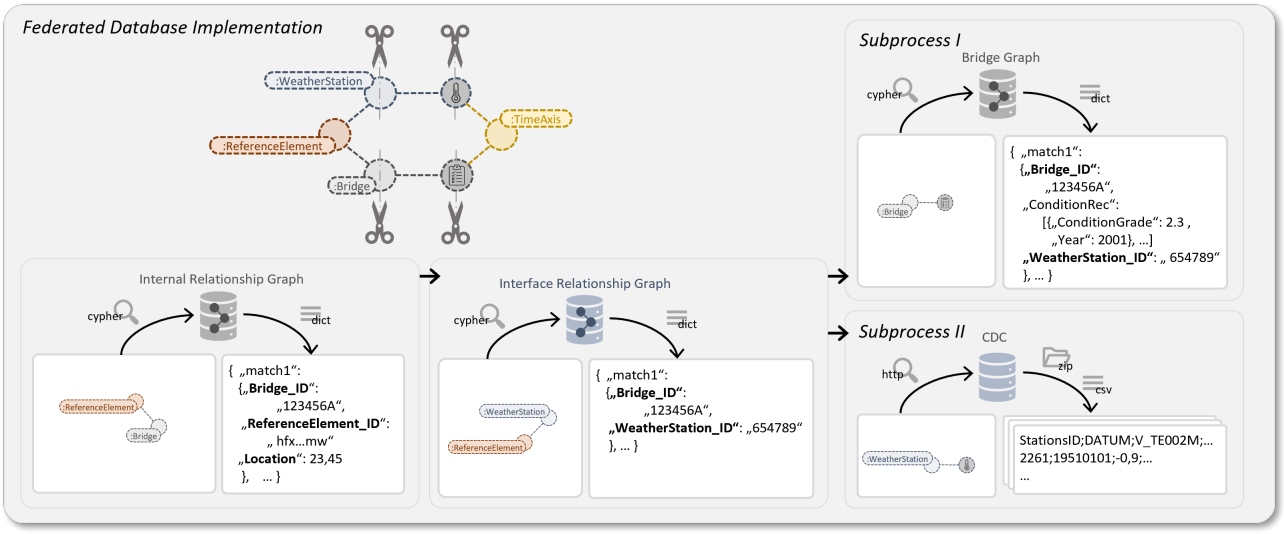

Figure 4: Prototypical Implementation of Layer (II): Federated Database for Comprehensive Evaluation

data with temperature recordings was successful. However, evaluating the temporal relationships proved a bottleneck due to the large number of temperature recordings.

Discussion

The prototypical implementation demonstrates the proposed concept's ability to comprehensively evaluate environmental context and road infrastructure data at a large scale, using temperature and bridge condition records. By considering complete real-world datasets, not only are realistic system sizes accounted for, but also the inherent distributed storage and data maintenance, as well as the significant heterogeneity of data structures involved. This paves the way for applying existing works on multifactorial deterioration models, which currently build on the central, homogenised LTPP data set, to a broader context, including infrastructure management systems currently in use.

By using the road network as a connection point between the two subsystems, a spatial structuring approach accounting for infrastructure-specific characteristics is employed. The approach's effectiveness results from reducing explicitly modeled relationships between road infrastructure and external elements. This minimizes not only the size of the *Interface Relationship Graph*, thereby improving performance during querying and creation, but also the number of cross-system connections that must be considered and maintained.

In addition, mapping environmental context areas to the reference elements enhances the accuracy of spatial relationship evaluation by accounting for the large longitudinal extent of the infrastructure assets. However, due to the very large difference in granularity when mapping climate data to the German road network, only 13% of the reference elements even cross a boundary between two environmental context areas. The effect can therefore be better exploited by examining relationships with environmental data of finer resolution, such as soil data.

The approach faces limitations in ensuring consistency across several subsystems. In particular, this affects changes to the road network or the available weather stations, which require updating the *Interface Relationship Graph* to ensure complete integration of the available data sources. Provided changes are known, the elements' IDs enable efficient updates. However, as the data sources involved are maintained completely independently, this knowledge most likely does not exist. In this case, there is a lack of efficient update strategies that prevent the entire subsystem graph from having to be checked for updates or completely regenerated. Although complete regeneration of the *Interface Relationship Graph* is not the optimal updating strategy, it still benefits from minimizing connection points between subsystems by using the road network instead of individual assets, and from deploying inference to avoid unnecessary geospatial calculations.

Furthermore, the case study revealed the limited effectiveness of the approach of Heise et al. (2025b) for analyzing temporal relationships when the data exhibit a very high degree of heterogeneity in update cycles. Integrating the concept of reference intervals proposed by Allen (1983) appears worth investigating.

Conclusion

The paper presents a comprehensive DT framework that captures road infrastructure and its environmental context. The integration is facilitated by applying SoS principles in the digital representation. A knowledge-graph-based approach addresses scalable semantic integration by capturing contextual relationships and enabling their flexible evaluation despite their inherent heterogeneity. The comprehensive evaluation, accounting for data distribution across heterogeneous DBMS (types), is implemented as a federated database. The applicability of the concept is proven by a prototypical implementation using complete real-world datasets from German infrastructure management and the German meteorological service (Deutscher Wetterdienst, DWD). The achieved data association en-

ables investigating dependencies between condition development and temperature fluctuations. Thus, the presented approach paves the way for PM in infrastructure by leveraging existing data to better understand deterioration.

GREENBIMXELS: A DATA SPACE UNLOCKING ENVIRONMENTAL VALUE FOR PUBLIC FACILITIES IN THE CONSTRUCTION SECTOR

Gordo-Gregorio, Paula[1]; Coloma Picó, Eloi[1]; Martínez Ibañez, Manel[1]; Macarulla Martí, Marcel[1]; Angulo, Cecilio[1]
[1]Polytechnic University of Catalonia, Barcelona,Spain

Abstract

Public administration buildings generate vast operational data, which is rarely used for environmental purposes. GreenBIMxels, a research project led by the Polytechnic University of Catalonia, explores how Data Spaces support environmental assessments in public facilities.

This paper defines environmental services for BIM models within a Data Space named UPCxels. The study addresses the interests of public administrations and private-sector stakeholders, examining how Data Spaces can respond to their needs. Three use cases are designed by combining participatory workshops and a questionnaire survey. The use cases include energy-efficiency, water-consumption optimization and carbon-footprint assessment, each operationalized through KPI sets and BIM/IFC-based properties.

Introduction

Building Information Modeling (BIM) is increasingly used to manage building and infrastructure assets by means of shared digital representations that support decision-making across design, construction and facility management throughout the asset lifecycle. By consolidating geometric, technical and operational information into a single model, BIM improves coordination among stakeholders and provides a data-rich foundation for operation and maintenance activities (Gordo-Gregorio et al., 2025). Despite this potential, BIM is still frequently applied in a construction-centric way, which constrains the systematic reuse of information for environmental performance monitoring or long-term portfolio planning, particularly within public administrations (Akbari et al., 2024; Kivits & Furneaux, 2013).

In parallel, the European data strategy and recent work on Data Spaces propose federated infrastructures where data holders remain sovereign over their assets while enabling controlled sharing and cross-organizational analytics and demand alignment with the international data-space principles (the Data Spaces Support Centre (DSSC), Gaia-X, and the International Data Spaces Association (IDSA)) (Enes, 2025; Valk & Ryan, 2025). Sectoral Data Spaces define common governance, trust and interoperability frameworks so that heterogeneous datasets can be securely combined and analyzed without centralizing sensitive information (Kovach et al., 2026). For the built environment, this paradigm is particularly relevant, because public owners, operators and service providers need to cooperate around services such as energy demand, while respecting contractual constraints, privacy and institutional autonomy (Janev et al., 2021).

At the same time, research in BIM-based sustainability assessment shows the importance of harmonized, object-level data structures to integrate building models with environmental information such as life-cycle assessment (LCA) datasets and operational performance indicators (Klumbyte et al., 2023). Several authors have proposed BIM-centered workflows for energy analysis or water-use evaluation, but these approaches often rely on project-specific schemas, ad hoc integrations or proprietary platforms, which hampers scalability (González et al., 2021; Sameer & Bringezu, 2021). There is therefore a need for an open semantic framework that connects BIM, standardized data dictionaries and environmental datasets within a data-space architecture, so that AI-based services can perform analytics on public facilities.

To demonstrate the practical impact of this approach, GreenBIMxels develops three use cases focused on environmental performance of public facilities (energy, water and carbon footprint). For each case, structured data from BIM models of public facilities are combined with external data bases and IoT data within the Data Space, enabling advanced analytics and AI-based services without exposing raw operational data outside their institutional boundaries. These use cases are defined in this paper to evaluate how a BIM-based Data Space can unlock environmental value from existing BIM datasets of public facilities, support evidence-based decision-making, add value and reduce fragmentation between administrations in the management of building and infrastructure assets.

Methodology

The three use cases were developed with companies and public administrations, within the Catalan context, through a structured, multi-stage Co-Creation Method that combined participatory workshops and a formalized questionnaire-based survey targeting future data consumers. This approach ensured that the selected use cases were not only technically feasible within the GreenBIMxels data-space architecture but also aligned with real market needs, operational practices, and governance expectations. The process started with a series

of dedicated workshops with data providers, aimed at identifying priority environmental challenges, and feasible analytical services that could be realistically deployed within a data-space context. The development of these collaborative workshops is aligned with the guidelines of the DSSC (Data Spaces Support Centre), which define the Co-Creation Method with the aim of ensuring that the evolution process of any Data Space is carried out in an appropriate and structured manner. This process, as shown in the following figure, consists of three stages: the exploratory phase, the preparation phase and the implementation phase (Fauth et al., 2024; Weiss et al., 2025). This paper includes the exploratory and preparatory stages.

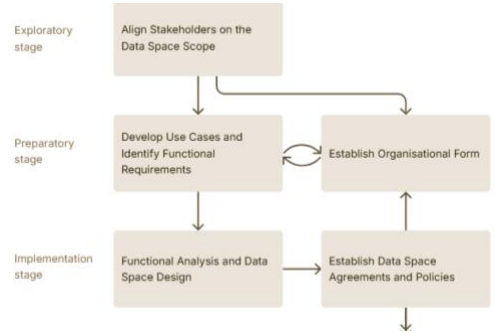

Figure 1 Workflow of the Co-Creation Method. Source: DSSC

A total of ten public administrations participated, including municipalities, regional government departments, public institutes, and public bodies responsible for infrastructure and transport, with technical staff drawn from energy services (end users with in-depth knowledge of operational processes), maintenance representatives (end users with process expertise), and organizational managers and BIM specialists acting as data providers or decision-makers. During these workshops, participants discussed current practices related to energy management, water consumption monitoring, and carbon-footprint assessment, as well as limitations in accessing, sharing, and reusing BIM and operational data across organizational boundaries. The workshops combined exploratory and convergence-oriented activities. First, they gathered information on environmental data services by examining the types of BIM models and IFC datasets currently available, the environmental functionalities that data providers aim to enable through the Data Space, and the key performance indicators (KPIs) used or anticipated for decision-making. Building on these discussions, the workshops converged on three representative, high-impact domains (energy efficiency, water consumption optimization, and life-cycle carbon-footprint assessment) which are common across multiple public administrations and closely aligned with policy-driven sustainability objectives. In parallel, the workshops focused on defining the implementation process, identifying the main barriers that administrations expect to face during the project, and outlining the required technological approach for effective deployment. To complement the qualitative insights with quantitative rigor, workshop contributions from public administrations were analyzed using co-occurrence network analysis and text mining techniques implemented in the R programming language (Amancio et al., 2025).

Furthermore, a structured questionnaire survey was subsequently distributed to prospective data consumers, including architecture and engineering firms, technical consultancies, software providers, and sustainability-oriented service companies. The questionnaire was designed to capture a detailed profile of data consumers, their typical data usage patterns, integration challenges, and required update frequencies. In addition, the survey explored perceived value and priority of different environmental use cases, expectations regarding AI-based analytical services, preferred levels of data processing, and requirements related to data governance, quality and security. This method enables a thorough assessment by integrating multiple data sources, thereby strengthening the reliability of results in applied research contexts (Mayo-Wilson et al., 2018). Consumer surveys provide structured quantitative and qualitative feedback on perceived outcomes, while workshop Post-it notes offer spontaneous, context-rich reflections from providers directly involved in delivery.

The results of the workshops and surveys were jointly analyzed to define the scope, data requirements and KPIs. For each case study, a clear mapping was established between the proposed analytical services, the required data properties and IFC-based data elements, and the KPIs used to assess environmental performance and impact. As part of the preparatory stage, the definition of indicators was carried out by translating the co-created use cases into measurable parameters. This process aimed to operationalize the needs and analytical requirements identified during the workshops into a structured set of indicators suitable for implementation within the data-space architecture.

The development of these indicators followed an iterative approach. First, candidate parameters were derived from workshop discussions, reflecting their data needs and decision-making criteria. Second, these parameters were refined through two complementary activities, an analysis of the digital tools and information systems currently used to ensure alignment with existing data availability and formats and validation through expert consultations and literature review to assess completeness and relevance.

During this process, some parameters initially identified were discarded due to their limited contribution to the proposed services, while additional parameters emerged as necessary to ensure analytical feasibility and robustness. The final set of parameters was then structured into KPIs and mapped to BIMxel properties and IFC-based data elements, forming the basis for the KPI tables presented in the Results section.

As a result, the methodology ensured coherence between stakeholder needs, available and shareable data, and the analytical capabilities supported by the GreenBIMxels infrastructure, thereby increasing both technical robustness and adoption potential.

Results and discussion

The results presented in this section derive from the combined analysis of two complementary empirical sources, a series of structured workshops with public administrations and data providers, and a questionnaire-based survey addressed to prospective data consumers from the construction, engineering, digitalization, and sustainability sectors. This approach simultaneously provided feedback on the project implementation and supported the definition of the three use cases, including their associated KPIs.

On the questionnaire survey most respondents operate as direct data consumers but also express a strong interest in developing data-based services or advisory products, indicating that data consumption and value creation are closely linked in their business models. From a digital readiness perspective, 87% of respondents reported a medium to high level of maturity in managing BIM/IFC data. This finding is consistent with the workshop results, where public administrations demonstrated the availability of IFC models, monitoring systems, and sectorial platforms (such as BMS, SCADA or energy monitoring tools), albeit in a fragmented and heterogeneous manner. Together, these results suggest that both providers and consumers possess a sufficient baseline of digital capabilities to engage with a data-space-based solution, while still facing significant integration challenges.

Project implementation

The findings reflect consumers' perspectives as captured through questionnaire responses and providers' viewpoints as emerging from the workshop discussions. The questionnaire survey was completed by 8 organizations out of 15 invited (response rate ≈ 53%). The questionnaire sample could be acknowledged as modest in absolute terms, yet it can still be considered adequate for the exploratory and descriptive aims of this study. In survey methodology, sample adequacy is not determined solely by size but by its ability to capture the relevant heterogeneity of the target population (Erdogan & Baker, 2002; Fosnacht et al., 2017). From this perspective, the present sample covers micro, small, and medium-sized organizations involved in different stages of the building and infrastructure life cycle, which enhances its structural similarity to the population of interest and supports its analytical representativeness. Post-it notes collected during co-creation workshops were analyzed to identify emerging themes and stakeholder concerns.

As a result, a co-occurrence network (Figure 2) was built based on the content of the post-it notes, which were generated in response to two guiding questions addressing the needs and challenges related to the sustainable management and equipment maintenance of their building assets. Each post-it note was systematically coded to extract key terms. The network was then developed by mapping the frequency with which these terms co-occurred across responses, enabling the identification of the following thematic clusters:

- Need for research: Participants highlighted gaps in applied knowledge on data-space integration for BIM, calling for more pilot studies and evidence on ROI.
- Need for interoperability: Frequent mentions of heterogeneous formats, proprietary tools, and semantic standardization.
- Data and models availability/sharing from administrations: This emerged as the dominant cluster, reflecting frustrations with fragmented access, outdated datasets, and bureaucratic silos.
- Lack of human resources: Capacity constraints, including skilled BIM personnel and training, were recurrent, limiting sustained adoption.

The diagram's visual prominence of the data-sharing cluster signals broader sector challenges like platform fragmentation. Both data consumers and public data providers highlighted that access to operational consumption data (energy and water) and geospatial information remains uneven and often constrained by organizational or technical barriers.

A key convergent result concerns the main barriers to effective data use (Figure 3). Respondents gave greatest importance to practical and structural barriers, especially the cost or time required to obtain data, along with interoperability and incomplete data. In contrast, lack of knowledge was considered less important. This perception mirrors the workshop findings, where public administrations repeatedly emphasize platform fragmentation, dependency on proprietary systems, and difficulties in maintaining up-to-date and consistent datasets across multiple tools and departments.

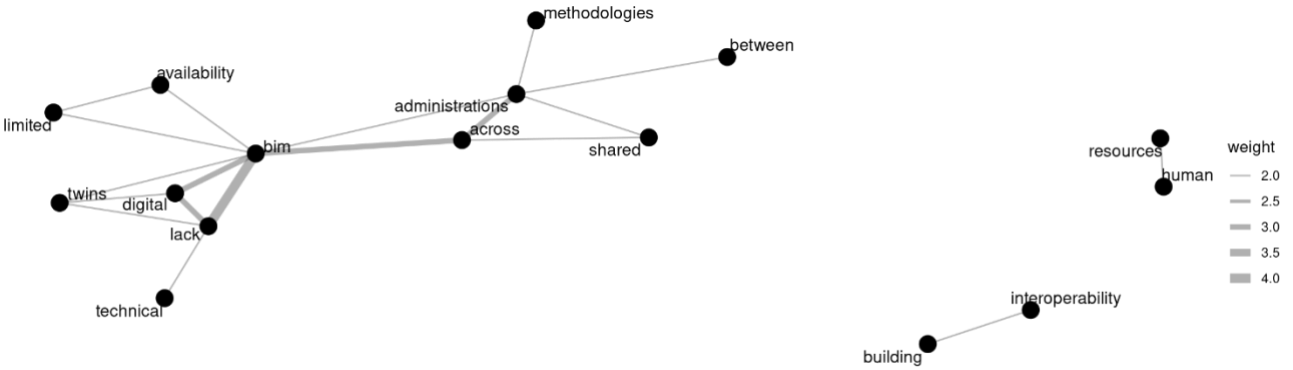

Figure 2 Co-occurrence network of implementation barriers identified in the public administration workshops

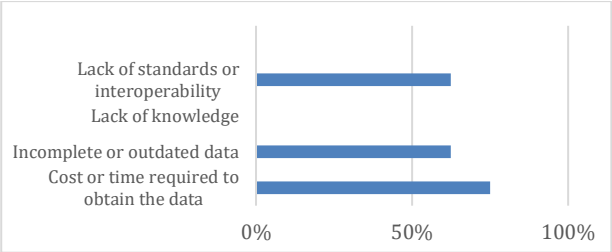

Figure 3 Main difficulties in integrating facility management information into data-consumers workflows (n=8 Companies).

Regarding adoption, consumers emphasized that technical feasibility alone is insufficient, uncertainty about return on investment remains the main barrier (Figure 4). Expected benefits are framed primarily in terms of market differentiation and access to new business opportunities, rather than purely internal efficiency gains (Figure 5).

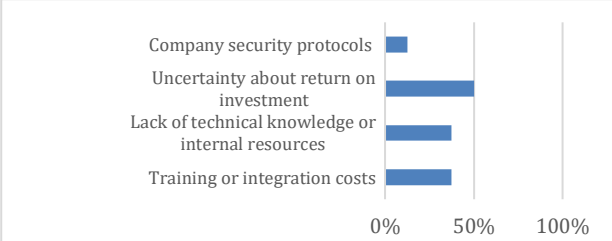

Figure 4 Identified barriers by data-consumers on connecting to the Data Space (n=8 Companies).

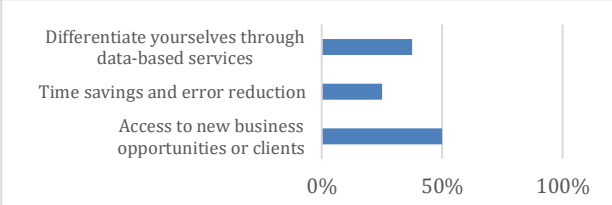

Figure 5 Identified benefits by data-consumers on connecting to the Data Space (n=8 Companies).

Trust-related aspects emerged as critical enablers of participation in the GreenBIMxels Data Space. Data consumers identified confidentiality, secure access, and ease of integration as essential guarantees, with data traceability and clear licensing conditions also playing an important role (Figure 6). These expectations align closely with the governance concerns expressed in the workshops, where compliance with European data-space principles and security requirements was considered a prerequisite for institutional adoption.

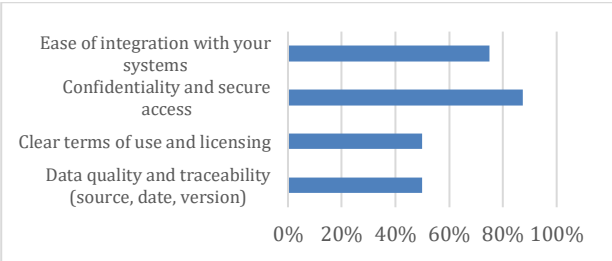

Figure 6 Key guarantees required for data consumers to connect to the Data Space (n=8 Companies).

These results underscore the importance of demonstrating concrete, replicable value through the selected use cases.

Definition of use cases

The network graph in Figure 8 visualizes the thematic clustering of post-it notes from workshops, where node size reflects frequency of mentions, colors denote domains (orange: energy, purple: water, green: carbon, gray/black: transversal), and edges indicate interconnections that directly informed the definition of GreenBIMxels use cases and KPIs.

Gray central nodes dominate the core including "data", "comparison", "monitoring", "consumptions", "IFC", forming a highly repetitive and interconnected hub that underscores these topics as transversal KPIs essential to all three use cases. Their prominence and repetition signal that reliable, standardized access to BIM/IFC models and operational consumption metrics constitutes the primary analytical foundation, enabling portfolio-scale visualization, anomaly detection, and benchmarking across energy, water, and carbon domains.

Energy emerges as the most prominent use case, with the largest orange cluster showing high frequency and dense connections to gray transversals, indicating it as the top stakeholder priority for KPIs like power curves, efficiency patterns, and predictive interventions. This priority is also reflected among consumers in the questionnaire survey (Figure 7). Strong orange-green linkages reveal a tight relationship between energy and carbon footprint, particularly for renovation decisions, material choices, and lifecycle optimizations, positioning combined energy-carbon KPIs (such as CO2eq reductions via efficiency upgrades) as high-impact composites. Water stands apart with fewer blue nodes, mostly peripheral and linked to monitoring, highlighting leak detection and usage patterns (liters) as a more niche but still a relevant use case with lower overall emphasis. The graph's density confirms stakeholder consensus on actionable, data-space-enabled indicators rather than exploratory ones.

With respect to consumers, all proposed functionalities were considered important by the respondents. However, automatic simulations and predictions stood out as the most demanded feature (Figure 7).

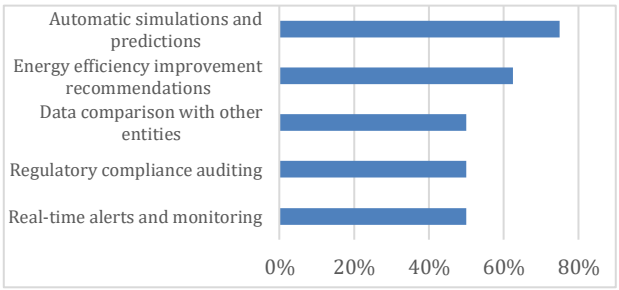

Figure 7 Identified useful domains by data-consumers on connecting to a Data Space (n=8 Companies).

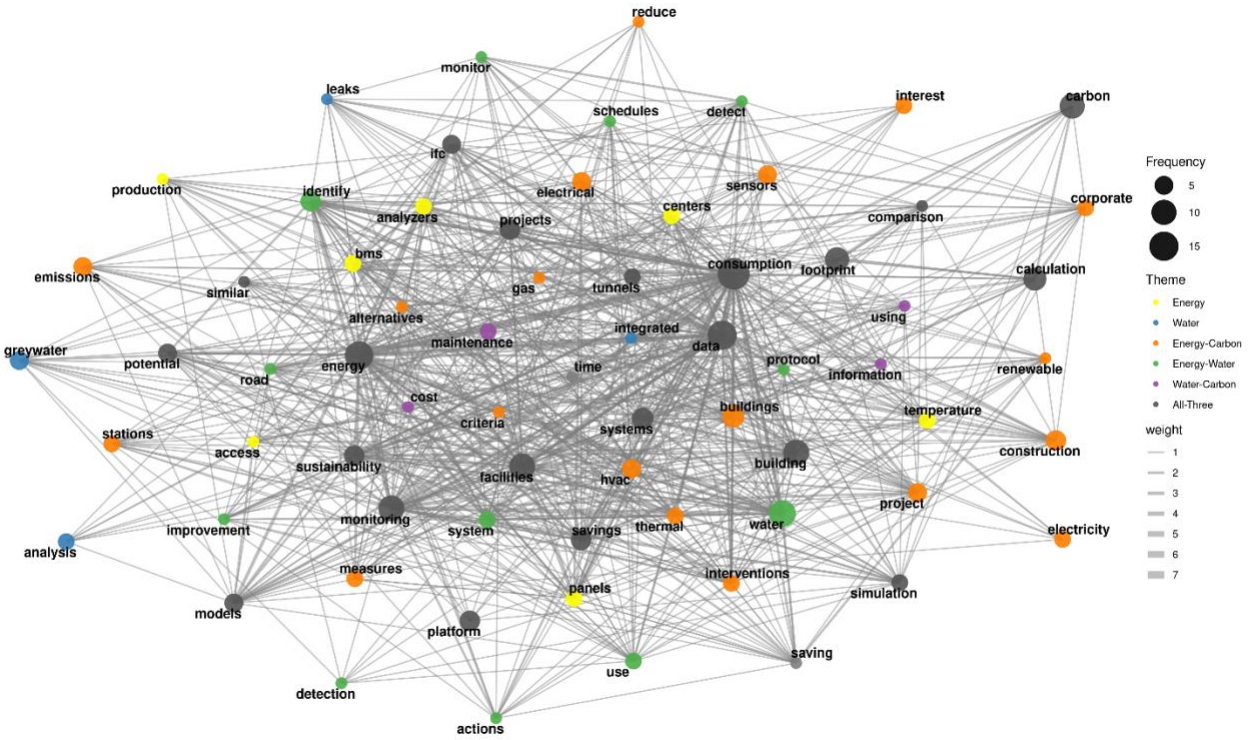

Figure 8 Co-occurrence network of the use cases requirements identified in the public administration workshops

Figure 9 shows that respondents mainly aim to use the Data Space for decision-making in design or planning, followed by developing digital products or services and only a few respondents are uncertain about which data to consume, indicating generally clear expectations.

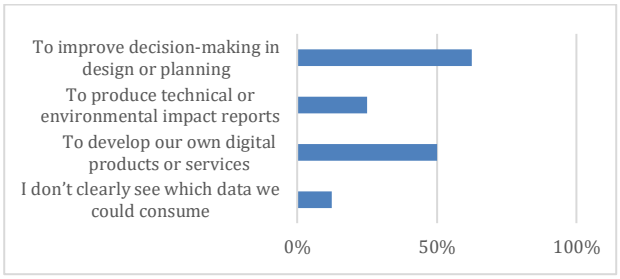

Figure 9 Identified data use by data-consumers on connecting to the Data Space (n=8 Companies).

The results show strong alignment between workshop insights and user expectations. Transversal data elements such as monitoring, comparison and predictions, form the core foundation across all use cases, highlighting the importance of standardized, accessible and interoperable data. Energy emerges as the main priority, closely linked to carbon, while water plays a more secondary role. From the consumer side, the proposed functionalities are well received, with a clear preference for simulations and predictive analytics. Overall, the findings confirm that the Data Space approach is relevant and valued, particularly for decision-making and advanced, actionable insights.

KPIs Definition

The KPI tables presented in this section are the result of the properties-definition process described in the preparatory stage of the methodology. The defined KPIs are directly linked to BIMxel properties that are systematically derived from IFC databases, external reference sources (such as Datadis for consumptions or AEMET for temperatures), and operational data obtained from IoT systems. Detailed KPI tables for each service are provided in Appendix 1[1].

The correlation network built from the workshop post-it notes showed that stakeholders perceive standardized access to BIM/IFC models, asset identification, geometry, space–system mapping and basic consumption metrics as prerequisites for any environmental analysis. The transversal data properties repeated across the KPI tables (IfcBuilding, IfcSpace, asset codes, consumption and anomaly properties) operationalize those clusters by turning the most frequent and central post-it notes topics into reusable, object-level data requirements shared by all three services. Based on the needs from the participants and the existing literature review the KPIs and their properties have been defined as shown in Appendix 1 (Table 1: Energy KPIs, Table 2: Water KPIs and Table 3: Carbon Footprint KPIs).

The correlation graph showed energy as the dominant cluster, the most interconnected, highlighting stakeholder priority for immediate value in monitoring, anomaly detection, and benchmarking. This aligns with

[1] Detailed KPI tables are provided in Appendix 1 and are available in: https://doi.org/10.5281/zenodo.19912259

questionnaire findings favoring AI-driven energy services (simulations, predictions, recommendations). Consequently, the energy KPI (Appendix 1: Table 1) emphasizes portfolio-level and pattern-oriented indicators (including total and seasonal consumption, normalized intensities, PV share, number, frequency and duration of anomalies, and seasonal HVAC efficiency) supported by the transversal data properties needed for pattern analysis (stable IDs, geometry, use, occupancy, meter–asset mapping), directly reflecting the central topics in the correlation network.

Regarding water, surveys and workshop notes pinpoint specific barriers such as uneven access to operational data across municipalities, high costs and time delays for data acquisition, and incomplete datasets lacking historical depth. Therefore, administrations prioritize short-term services like leak detection, consumption anomaly alerts, and basic usage pattern analysis using existing smart meters and sectorization data. This is reflected in the water KPI (Appendix 1: Table 2).which focuses on seasonal consumption, consumption by use type, irrigation and external uses, regenerated water ratio, anomaly counts and resolution times, normalized intensities, monitoring coverage and tank capacity, all grounded on a minimal but coherent set of BIMxel properties (space/use classification, meter linkage, reuse flags, etc.) mirroring the main nodes in the correlation graph.

For carbon footprint, the network shows strong energy-material linkages around renovation and lifecycle impacts, framing it as a composite of operational and embodied decisions rather than standalone. Workshops and surveys reinforce this through emphasis on regulatory compliance, portfolio-scale assessment, and urban context factors like density and street canyons. Accordingly, the carbon KPI (Appendix 1: Table 3). extends the energy and material KPIs to include total and operational CO2eq reductions, PV-related avoided emissions, urbanization interventions, embodied carbon by material, share of low-carbon and circular materials and mobility-related emissions, all parameterized with the same transversal building and consumption data plus additional indicators correspond to the green and transversal nodes in the network. For carbon footprint services, regulatory and taxonomy compliance checks (aligning with frameworks like EPBD, GENERCAT 2023-2027, EU Taxonomy, and DNSH criteria) did appear in stakeholder discussions but will require location-specific development. Thus, they are excluded from the main required properties, though they will be incorporated during implementation by mapping operational/embodied carbon KPIs, and metadata (such as YearOfConstruction, Phase, PrincipalUse) against local regulatory thresholds for automated eligibility screening and portfolio compliance reports.

The three KPI tables specify only those BIMxel properties that can be consistently exposed through a shared object-level layer (IFC entities, classification codes, environmental properties, governance attributes), making it possible to deliver the requested AI-enabled services (anomaly detection, benchmarking, predictive analysis, renovation-support KPIs) through a service-layer architecture where raw BIM and time-series data remain with providers. In this way, the KPIs emerge as a direct translation of the most central and recurrent patterns in the correlation network.

Services definition

Consequently, the AI-based services defined in this work focus on three main families, each leveraging the co-created KPIs and BIMxel properties to deliver actionable environmental analytics within the Data Space.

- Anomaly detection and monitoring services automatically identify abnormal energy and water consumption patterns at both asset and portfolio levels. These services process time-stamped meter data linked to BIM elements (via AssetManagementCode, IfcSpace mappings and Subdiscipline flags) to compute anomaly counts, mean durations and deviation scores against historical baselines or seasonal patterns, enabling early fault detection and prioritized maintenance interventions (Zhang et al., 2023).
- Benchmarking and portfolio comparison services normalize KPIs by floor area (GrossFloorArea), user occupancy or functional use across energy, water and carbon domains. By comparing normalized energy intensity (kWh/m²/year), water intensity (m³/m²/year) or total CO_2eq reductions between comparable public facilities, these services identify efficiency outliers, best practices and intervention priorities at scale (Martínez-Rocamora et al., 2021).
- Predictive performance analytics services forecast future consumption trends, efficiency degradation and carbon trajectories. These integrate KPI time series with BIM-derived context (climate via TerritorialScope/LatitudeLongitude, occupancy patterns, envelope U-values, material properties) and external baselines using time-series models or multivariate learning to simulate intervention impacts and risk profiles (Billanes et al., 2025; Cheng et al., 2020).

These AI-based services collectively address key gaps identified in the workshops (the need for streamlined access to standardized BIM/IFC data, reliable anomaly alerts, cross-asset benchmarking and actionable compliance insights) while respecting data-sovereignty principles through federated processing within the GreenBIMxels Data Space. By operationalizing stakeholder-defined KPIs via BIMxel properties, they enable public administrations to transition from fragmented, project-centric environmental monitoring to scalable, portfolio-wide decision support that aligns with European data-space architectures.

At the current stage of the project, GreenBIMxels is in the implementation phase, where the proposed approach is being developed and tested through pilot deployments. These pilots are being conducted using real-world datasets, BIM models, and operational information from

public buildings, primarily from the Universitat Politècnica de Catalunya and a collaborating municipality. This allows the validation of the approach under realistic conditions, including heterogeneous data availability and existing system constraints.

The three use cases are being implemented through two main development streams. Energy and water management services are being developed within a shared analytical environment, as both rely on similar data sources (such as consumption data from monitoring systems) and analytical logic, particularly anomaly detection and performance monitoring. In parallel, the carbon footprint use case is being developed in a separate tool, currently focused on material-based analysis and comparison, reflecting its different data requirements and methodological approach.

For all three use cases, an initial Minimum Viable Product (MVP) has been defined and is currently under development and testing. This MVP is based on the KPI framework and BIMxel properties defined in this study. However, at this stage, only a subset of the defined properties is being actively used, corresponding to the functionalities implemented in the MVP. The full set of KPIs and properties represents the target model to be progressively integrated as the implementation phase advances. The pilot implementations have already highlighted several practical issues. First, a substantial share of the required BIMxel property values is missing or incomplete in the source BIM models, confirming the relevance of the harmonized property set. Second, energy and water consumption data are currently distributed across heterogeneous platforms (including DEXMA, Datadis and other provider-specific systems), which has motivated the ongoing development of dedicated connectors to federate these sources within the Data Space. Third, temporal and semantic gaps in consumption records have emerged as recurrent, reinforcing the need for analytical services capable of handling incomplete, noisy or inconsistent data. Finally, to address interoperability challenges, a tool for the automated conversion of IFC parameters into BIMxel properties has been developed and integrated into the workflow, reducing manual effort and improving consistency in the preparation of KPI-ready datasets.

Limitations include the focused size and geographical scope of the empirical sample, limiting behavioral insights to the Catalonian context. The paper also concentrates on the exploratory and preparatory stages of data-space implementation, so future work should examine the long-term performance and maintenance effort of the proposed services in operational deployments, thereby improving and complementing the properties set in subsequent steps.

Conclusions

The study concludes that a BIM-based Data Space can effectively unlock underused environmental information from public facility portfolios, enabling administrations and service providers to implement AI-based services for energy, water and carbon management while maintaining data sovereignty. It demonstrates that co-created KPIs, encoded as BIMxel properties and systematically derived from IFC models, external databases and operational data, provide a robust semantic backbone for anomaly detection, benchmarking and predictive analytics. The three use cases prove to be strongly aligned with stakeholder priorities, with energy-related services emerging as the dominant entry point. Results from workshops and surveys indicate that both public administrations and data consumers possess sufficient digital maturity to engage with data-space-based solutions but require harmonized data structures, reduced integration friction and clear governance guarantee to translate this potential into operational value.

This paper confirms the dual-sided value proposition, public data providers in Catalonia gain scalable portfolio insights without data centralization, while engineering firms and sustainability consultants access validated KPIs and analytics foundations to build commercial services. By implementing a service-layer architecture that processes data locally and exposes aggregated indicators via harmonized APIs, GreenBIMxels unlocks environmental value from existing BIM models of public facilities and demonstrates stakeholder's interest in data-space adoption.

Acknowledgments

We thank the public administrations and private stakeholders for their participation, and the Spanish Ministry for Digital Transformation and the Civil Service for funding through the 2024 Call for Demonstrators and Use Cases of Sectoral Data Spaces.

DEEP LEARNING–BASED POINT CLOUD SEGMENTATION AND RELATIONSHIP GRAPH CONSTRUCTION FOR HYDROPOWER DAM DIGITAL TWINS

Alwyn Mathew, Soheila Kookalani, and Ioannis Brilakis
University of Cambridge, England, United Kingdom

Abstract

This paper proposes a deep learning pipeline for generating semantic meshes and relationship graphs from intensity-only laser point clouds of hydropower plants. It segments point clouds into object-level instances using supervised models and derives spatial relationships, including proximity and containment, between components. These are refined into a structured graph, providing a lightweight representation for digital twin applications. Replacing rule-based methods with learning-based segmentation enables automated graph construction for dam infrastructure despite irregular geometries, limited features, and the lack of standardised schemas.

Introduction

Hydropower dams are long-lived, safety-critical assets that underpin electricity supply, water storage, flood control, and regional resilience. Their operation and maintenance increasingly depend on reliable "as-is" information about structural components as well as embedded mechanical and hydraulic equipment. Digital twin (DT) approaches have therefore gained traction to link physical assets to continuously usable digital representations that support inspection planning, performance assessment, anomaly detection, and scenario analysis. Recent large-scale evidence also shows that the DT concept is used inconsistently across the built environment, motivating clearer operational definitions and explicit data requirements for DT implementations as reported by Abdelrahman et al. (2025); Kookalani et al. (2026).

A practical DT for civil infrastructure is not only a geometric model, but an integrated information system that connects geometry, semantics, and relationships to enable querying, automation, and analytics. Construction DT research emphasizes that robust DT pipelines require systematic data capture, semantic structuring, and interoperability-aware information integration across lifecycle workflows as described by Tuhaise et al. (2023).

In this context, terrestrial laser scanning and photogrammetry-derived point clouds have become key modalities for capturing high-fidelity "as-is" geometry. However, translating raw point clouds into usable DT-ready representations remains challenging due to occlusions, clutter, irregular shapes, scale, and the need for detailed semantic labelling as outlined by Yue et al. (2024).

Most scan to building information modelling (BIM) and point-cloud-to-semantic-model workflows have been developed around buildings and industrial facilities, where component taxonomies are mature and standardized schema are relatively well supported as reported in Alavi et al. (2024). For dam infrastructure, the semantic breadth of elements and the heterogeneity between structural and electromechanical subsystems create gaps in standardization and representation. Commonly used exchange standards were originally designed for buildings and do not fully cover dam-specific components and hierarchies, which limits direct "BIM-first" relationship modelling for DT creation. This mismatch motivates DT representations that can be inferred directly from sensed data, especially when a complete parametric BIM is infeasible or uneconomical to create.

A second practical limitation is that many real-world infrastructure point clouds, especially open datasets, do not include rich appearance cues (RGB), and instead provide geometry plus intensity only. This reduces the discriminative signal available to segmentation algorithms and amplifies the need for methods that can learn robust geometric and reflectance patterns from limited features, while also handling the severe class imbalance typical in infrastructure scenes. Domain gaps between synthetic data and real scans further complicate generalization according to Hu et al. (2024).

Finally, DT utility depends heavily on relationships. Even if components are segmented accurately, downstream tasks such as navigation, hierarchical organization, adjacency reasoning, and structured asset inventories require an explicit relationship graph. Prior work in the built environment has shown the value of enriching geometric reconstructions into graph-structured semantic representations, enabling machine-readable links between objects beyond pure geometry as noted by Werbrouck et al. (2020).

To address these challenges, this paper proposes an end-to-end, learning-based framework for deriving digital twin–ready representations directly from intensity-only dam point clouds. The method is evaluated on the Platanovrisi Dam dataset, covering both exterior dam surfaces and interior hydropower plant spaces. The main contributions of this work are summarised as follows:

1. Learning-based segmentation for large-scale dam point clouds: We develop a deep learning pipeline

Figure 1: Platanovrisi dataset: HPP ground level (left) and turbine floor (right).

tailored for non-planar, complex dam surfaces that enables semantic labeling of intensity-only point clouds.

2. Semantic mesh generation and instance relationship extraction: The pipeline converts segmented point clouds into structured semantic meshes and identifies spatial relationships between individual components.
3. Relationship graph construction and connectivity modeling: Semantic predictions are transformed into a connected graph representation that captures adjacency and containment relationships among dam components.
4. End-to-end digital twin workflow from point cloud to UML (Unified Modeling Language): The connected graph can be exported into a generic format and used to generate UML class diagrams, providing a practical scaffold for digital twin modeling and downstream system integration.

Background

DTs in the built environment are commonly positioned as integrated digital representations that can be updated and used to support decision-making across the asset lifecycle. Large-scale bibliometric analyses highlight that the term digital twin is often used ambiguously in built-environment literature, but converges on core characteristics such as representational fidelity, purposeful synchronization and update mechanisms, and actionable use in analysis and operations as described by Abdelrahman et al. (2025). Construction-focused DT reviews in Tuhaise et al. (2023) further emphasize that DT value depends on connecting sensing, data integration, and analytics into an end-to-end workflow, rather than treating the DT as a standalone 3D model. For civil infrastructure, DT research is expanding beyond buildings into bridges, tunnels, and dams, where monitoring and risk assessment are central. For example, recent work in Tian et al. (2025) demonstrates DT approaches for high arch dams by fusing physics-based models with learning-based methods and uncertainty quantification to support real-time state estimation and failure risk assessment. These efforts underscore two recurring bottlenecks for infrastructure DTs: (1) obtaining up-to-date, spatially consistent as-is representations, and (2) structuring heterogeneous information into computable forms that support reasoning and automation. A key implication is that DT-ready representations must encode more than geometry. They must support asset semantics and connectivity or hierarchy, enabling queries such as "which elements belong to the turbine floor?", "what is adjacent to the intake tower?", or "which equipment is connected to which pipes?". Knowledge graph approaches in Tuhaise et al. (2023) explicitly target this integration challenge by using graph-based models to unify multi-source information for built assets, thereby improving cross-system interoperability and downstream analytics.

Laser scanning produces dense 3D point clouds that capture detailed surface geometry, making them attractive for modeling existing assets and enabling downstream DT workflows. However, scan-to-BIM pipelines typically require preprocessing, semantic segmentation and instance grouping, and object reconstruction and relationship modelling. Recent work of Patil and Kalantari (2025) emphasizes how segmentation accuracy can directly influence reconstruction outcomes and highlights practical hybrid workflows that combine deep learning segmentation with geometric fitting for downstream modelling. Across the Architecture, Engineering, and Construction (AEC) domain, deep learning has become the dominant approach for point cloud semantic segmentation because it reduces reliance on handcrafted geometric features and improves robustness across complex scenes as shown by Liu et al. (2025). A recent review in Yue et al. (2024) summarizes how point-cloud deep learning has been increasingly adopted for construction tasks, while also documenting persistent challenges: data scarcity, domain shift, scale variation, computational cost, and class imbalance, issues that are amplified in large infrastructure environments. Seminal architectures such as PointNet and PointNet++ as in Qi et al. (2017a) established the foundational concept of learning directly from unordered point sets, with hierarchical variants capturing local-to-global context for improved segmentation in complex geometries. In the construction and infrastructure domain, prior work reported in Yin et al. (2021) has demonstrated the effectiveness of deep learning-based segmentation for industrial scenes and transportation assets, including ResPointNet++ for industrial point clouds and hierarchical graph-based models for bridge component segmentation. Nevertheless, dam environments introduce additional complexity:

- Feature limitations: Many datasets are intensity-only (no color information), requiring models to separate classes using geometry and reflectance patterns rather than appearance cues.
- Heterogeneous scale and geometry: Dams mix large continuous surfaces with small mechanical compo-

nents and dense equipment layouts, increasing confusion between visually similar elements.

- Domain shift and annotation scarcity: Methods trained on synthetic BIM-derived point clouds often underperform on real scans due to the domain gap. Domain adaptation methods such as DawNet explicitly address this for BIM-to-scan segmentation Hu et al. (2024).
- Class imbalance: Infrastructure point clouds typically have extreme imbalance, motivating loss reweighting, focal losses, and sampling strategies, as also discussed in the proposed pipeline.

Even with accurate semantic segmentation, DT value is limited if the output remains an isolated labelled point cloud. Relationship modelling provides the scaffolding for higher-level reasoning, data integration, and automation. In conventional BIM workflows, relationships are typically defined through schema-specific hierarchies and predefined object types. However, infrastructure DTs often face schema gaps for dams. Standardized BIM schemas may not fully capture dam-specific components and their relationships, motivating alternative graph-first representations inferred directly from data. Two complementary directions in the literature motivate relationship graph construction: (1) Semantic enrichment / scan-to-graph: The scan-to-graph concept integrates scan-to-BIM ideas with semantic network by representing objects and their relationships as a graph, enabling richer queries and greater interoperability than geometry alone as presented in Werbrouck et al. (2020). This approach is particularly relevant when full parametric BIM creation is not feasible, but a computable representation is still required. (2) Connectivity-aware modelling from incomplete data: Infrastructure scans are commonly incomplete due to occlusions and access constraints. Methods that exploit connectivity relationships to improve as-built modelling from incomplete point clouds demonstrate the importance of explicitly reasoning about adjacency and inter-element connections, rather than treating components independently as shown by Kim and Kim (2021). Graph-based asset as outlined by Tuhaise et al. (2023) representations also align naturally with knowledge graph integration approaches for DTs, where nodes or edges support linking geometry-derived entities to metadata, sensor streams, inspection records, and analytical outputs. For dam DTs, this suggests a pragmatic pathway: infer lightweight spatial relations from point cloud instances, progressively enrich those graphs with domain semantics as schema mature and expert knowledge becomes available.

Methodology

Constructing a geometric model of a dam involves several key stages. The point cloud is first segmented into individual components, such as walls, gates, and turbines, breaking down the complex structure into manageable elements. Spatial proximity analysis is then applied to these components to infer their interactions, resulting in a relationship graph that captures spatial and semantic connections. Surface reconstruction techniques are subsequently employed on the segmented point clouds to generate continuous meshes, producing a detailed and coherent geometric representation of the dam.

Semantic mesh

The proposed segmentation network follows the PointNet architecture according to Qi et al. (2017a) for point-wise semantic labeling. It begins with an input transformation module (T-Net) that learns a 3×3 affine matrix to align the raw point cloud, thereby improving invariance to rigid geometric transformations. Feature extraction is performed through a sequence of shared multilayer perceptrons implemented as one-dimensional convolution layers, progressively expanding the channel dimension from the input to 64, 64, 64, 128, and finally 1024. A second transformation network is applied after the early convolution layers to learn a 64×64 feature alignment matrix, enabling canonicalization in the learned feature space. Global context is captured by max pooling across all points to produce a 1024-dimensional global feature vector. For semantic segmentation, the global feature is concatenated with per-point local features to form a fused representation for each point. This combined feature is processed by a segmentation head composed of additional shared multilayer perceptrons with channel dimensions 1088, 512, 256, and 128, followed by a final classification layer that outputs per-point semantic labels for the target number of classes.

Several modifications are introduced relative to the original PointNet to improve robustness and representational power. The network incorporates flexible normalization and dropout strategies, which enhance stability and reduce overfitting, and it can process additional input features beyond spatial coordinates, such as intensity or surface normals, enabling richer point representations. Transformation modules are refined to better align features across points while supporting these enhancements, ensuring more effective learning of both local and global geometric structures. Furthermore, a hierarchical variant inspired by PointNet++ as presented in Qi et al. (2017b) is included to capture local geometric patterns at multiple scales. This extension employs set abstraction and feature propagation modules to encode multi-scale contextual information, significantly improving the network's ability to model complex spatial structures in large-scale infrastructure environments. Strategies for handling class imbalance and tile-based oversampling further enhance segmentation of underrepresented classes, and these are described in detail in the Discussion section. The segmentation method has shown improved accurately as shows in Figure 2 and Table 1.

Surface reconstruction is essential for converting segmented point clouds into continuous, high-fidelity geometric models suitable for digital twin applications. In this study, surface normals computed during segmentation provide local geometric context, guiding the reconstruc-

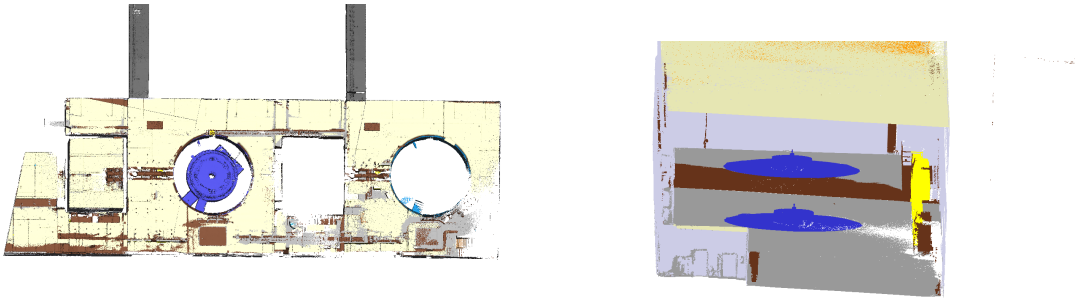

Figure 3: Semantic mesh generated from sematic pointcloud of the Platanovrisi dataset.

tion algorithm to accurately capture the orientation and topology of each component. We employ the Ball Pivoting Algorithm (BPA) Bernardini et al. (1999) to generate triangular meshes, where a virtual ball rolls and pivots across points to form triangles, adapting its radius to handle both smooth and intricate surfaces. This approach is particularly effective for hydropower plants, which combine curved, flat, and angular geometries such as turbine blades, pipes, and structural reinforcements. Challenges such as noise, outliers, occlusions, and irregular geometries are addressed through careful parameter tuning and post-processing techniques, including smoothing, hole filling, and mesh decimation. The resulting semantic meshes provide a coherent and accurate representation that serves as the foundation for visualization, simulation, and downstream tasks, integrating seamlessly with the segmentation and relationship graph pipeline to model complex hydropower infrastructure as shown in Figure 3.

Instance relationships

In traditional BIM workflows, relationship graphs are usually derived from well-defined object hierarchies and standardized schemas. However, for dam infrastructure, the creation of complete BIM models is limited because commonly used exchange formats, such as Industry Foundation

Classes (IFC), were originally developed around building and industrial facility taxonomies Alavi et al. (2024); Zhang et al. (2024) and do not yet provide comprehensive coverage of the heterogeneous structural and electromechanical component hierarchies typical of dam infrastructure.

To address this gap, this study proposes constructing a relationship graph directly from segmented point cloud data. Unlike conventional BIM graphs, this representation is lightweight and inferred, relying on spatial and semantic cues rather than predefined schemas. The graph is generated by establishing "connected" relationships based on spatial adjacency between segmented components. Each node represents a single component, while edges indicate spatial or semantic associations.

A k-dimensional tree (KD-Tree) is employed to efficiently index points and perform radius based searches within the point cloud. For each pair of segments, if any point from one segment lies within a radius of 0.5 m of a point in the other, an adjacency edge is created between their corresponding graph nodes. The KD-Tree is particularly effective in handling the geometric complexity of hydropower plants, which include irregularly shaped components such as turbines, generators, pipes, and reservoirs. Manual identification of such relationships is impractical due to this complexity, making automated inference highly valuable.

Beyond adjacency, components are also associated with higher-level structural abstractions, such as the dam body, ground floor, or turbine floor. If a component is spatially contained within one of these broader regions, a hierarchical "has" relationship is inferred (e.g., the ground floor has a pipe). This introduces an organized semantic structure, though it is limited to spatial and containment logic and does not capture functional or operational dependencies. Capturing these deeper relationships would require domain-specific schemas and expert knowledge, which are currently unavailable for dam infrastructure.

The basic relationships extracted from the point cloud are exported to a generic format, such as puml. This puml file serves as the input to PlantUML, to automatically generate a draft UML diagram. While the generated UML is not complete, it provides an initial framework that can be manually refined, extended, and annotated to include more detailed relationships. Figure 4 shows a preliminary example of the resulting graph, illustrating inferred connectivity and hierarchical groupings among segmented components.

Table 1: Segmentation evaluation result on test split of Platanovrisi dataset

Method	Precision	Recall	F1	IoU
RANSAC	0.5-0.6	0.4-0.5	2 0.5	0.40.4-0.6
Our	0.6813	0.9271	0.7393	0.6253

Dataset

The Platanovrisi Dam is a concrete facility located roughly 7.5 km southeast of the Thesauros Dam in northeastern Greece, has been operational since 1999 (Figure 1). It forms a reservoir capable of storing around 90 million cubic meters of water. Together with the 175-meter-tall earthen Thesauros Dam, among the tallest in Europe, Platanovrisi functions as part of a coordinated hydropower system that maximizes efficiency through water reuse and nighttime pumping between the reservoirs. The combined infrastructure supports a total generation capacity of 500 MW under a Greek-Bulgarian water management agreement. The dataset captures key structural elements of the dam, including the spillway, auxiliary spillway, downstream face, toe still basin, crest, and an intake tower. Interior scans encompass two levels of the hydropower plant: the ground-floor turbine gallery, providing maintenance access, and the lower turbine floor, which houses critical operational components such as the turbine well, piping, tanks, pumps, and control panels.

The dataset comprises approximately 369 million valid points distributed across 33 spatial tiles and annotated with 10 semantic classes: floor, wall, ceiling, stairs, crane, tunnels, electric distributor, turbine well, penstock, and water tank. The class distribution is severely imbalanced, as shown in Table 2, with wall and tunnels together accounting for over 55% of all points while minority classes such as crane and water tank each represent less than 1%. The dataset was partitioned into training, validation, and test splits using an 8:1:1 ratio at the tile level to prevent spatial leakage between splits.

Table 2: Distribution of dominant classes in the Platanovrisi dataset

Classes	#points (in M)	Percentage
Wall	105	28.8
Tunnels	98	27
Floor	73	20.2
Ceiling	49	13.4
Penstock	13	3.7
Electric distributor	9	2.6
Stairs	7	2
Turbine well	3	1.1
Crane	2	0.6
Watertank	2	0.6

Discussion

The integration of semantic mesh generation and relationship graph construction relies critically on accurate deep learning–based segmentation, which forms the foundation of the proposed dam digital twin pipeline. Unlike conventional building structures, dams exhibit highly irregular geometries such as curved spillways, inclined faces, and embedded tunnels that challenge both traditional scan-to-BIM workflows and primitive-fitting approaches such as RANSAC as presented in Mathew et al. (2025) as seen in segmentation evaluation Table 1. Learning-based segmentation is therefore essential for capturing these complex, non-planar surfaces and heterogeneous mechanical components directly from point cloud data.

These geometric difficulties, together with scarce public datasets and inconsistent component definitions across projects, further complicate standardization and modeling. Additional obstacles include incomplete scans, missing hierarchical information, and limited prior knowledge of functional interactions between components. By leveraging deep neural networks to produce semantic predictions that drive surface reconstruction and relationship inference, the proposed pipeline generates compact yet structured representations that can support spatial queries and component-level data integration. This output provides an initial foundation for digital twin applications tailored to dam infrastructure, where the geometric and semantic complexity poses greater challenges than in typical building environments.

Semantic segmentation of large-scale infrastructure point clouds, however, often suffers from severe class imbalance as shown in Table 2. Structural components such as walls and tunnels dominate the point clouds, while smaller elements such as pipes, turbines, or auxiliary equipment contain far fewer points. To mitigate this issue, two complementary strategies were employed during training: loss reweighting and tile-based oversampling. Class loss balancing adjusts the contribution of each category to the training objective in proportion to its prevalence, penalizing misclassifications of underrepresented classes more heavily. Various weighting schemes can be applied, including balanced weighting based on inverse class frequency, simple inverse-frequency weighting, and normalized custom weights. In addition, focal loss is used to down-weight easy examples and focus optimization on hard-to-classify points, while label-smoothed negative log-likelihood further improves generalization by preventing overconfident predictions.

At the data level, tile-based oversampling ensures rare classes are sufficiently represented during training. Point clouds are divided into spatial tiles, and tiles containing rare classes are sampled more frequently based on the rarity of the least common component within the tile, with a maximum oversampling limit to prevent excessive duplication. This increases exposure to underrepresented geometries without artificially inflating individual points. Together, loss reweighting and tile oversampling act at complementary stages of the pipeline, aiming to improve segmentation accuracy for minority classes in complex hydropower environments. Training robust models for dam infrastructure remains challenging due to the limited availability of high-quality, publicly accessible datasets. The Platanovrisi dataset used in this study, while adhering to high-quality standards, still suffers from incomplete scans and inconsistent color mapping. As a result, the model was trained exclusively on laser intensity data, avoiding reliance on potentially unreliable color information to ensure robust generalization. A key limitation of the current study is that the pipeline has been evaluated on a single site (Platanovrisi Dam). While the architectural and geometric diversity within this dataset provides a meaningful testbed, the generalizability of the trained model to other dam structures with different typologies, materials, or scanning conditions has not yet been assessed. Evaluating transferability across multiple dam sites and identifying domain adaptation needs are planned for the follow up journal extension.

The segmentation model receives 4 input channels per point (XYZ coordinates and laser intensity) and was trained with a batch size of 5 using the Adam optimizer with a learning rate of 0.0008, weight decay of 1e-4, and

cosine annealing with a 5 epoch warmup to a minimum learning rate of 1e-6. Group normalization was used for stability with small batches, and gradient clipping with a maximum norm of 1.0 was applied. Training ran for up to 150 epochs with early stopping (patience of 15 epochs). To address the severe class imbalance, balanced inverse frequency weighting was combined with focal loss (alpha = 0.75, gamma = 2.0). As reported in Table 1, the model segments dominant structural categories such as floor, wall, and ceiling with reasonable accuracy. However, minority classes including crane, turbine well, and water tank remain challenging due to their extremely low representation in the dataset (each below 1% of total points, as shown in Table 2). This reflects the inherent difficulty of dam point cloud segmentation compared to building environments, where class distributions tend to be more balanced and component geometries more standardized.

The quality of the relationship graph depends directly on the accuracy of the upstream segmentation. In the proposed pipeline, adjacency (''connected") edges are inferred using a KD-Tree radius search: for each segment pair, if any point from one segment falls within a radius of 0.5 m of a point in the other, an adjacency edge is created between their corresponding nodes. Containment (''has") relationships are assigned when a component lies spatially within a higher level region such as the ground floor or turbine floor. Segmentation errors, particularly oversegmentation of large surfaces such as walls or confusion between adjacent classes, can introduce spurious edges or miss valid connections. For instance, if a wall segment is split into multiple fragments, each fragment generates its own node and edges, inflating the graph with redundant adjacency links. Conversely, if a small component such as a pipe is absorbed into a neighbouring wall segment, the corresponding node and its relationships are lost entirely. Since no ground truth relationship graph currently exists for the Platanovrisi dataset, quantitative evaluation of graph quality (e.g., edge level precision and recall) is not feasible at this stage. Constructing such a reference through expert annotation and conducting sensitivity analysis of the distance threshold are planned for the follow up journal paper.

Conclusion

This paper presented an end-to-end pipeline for constructing relationship graphs from intensity-only laser point clouds of hydropower dams by integrating deep learning based segmentation, surface mesh reconstruction, and instance-level relationship inference. Evaluated on the Platanovrisi Dam dataset across exterior structures and interior hydropower plant spaces, the framework demonstrates the feasibility of producing structured geometric and relational models directly from laser scans without relying on complete parametric BIM schemas. Dam infrastructure poses greater challenges than typical building environments due to irregular geometries, heterogeneous component types, the absence of standardized schemas, and severe class imbalance in point cloud data. Remaining challenges include limited training data, poor performance on minority classes, the lack of a ground truth relationship graph for quantitative evaluation, and the current restriction to spatial relationships. Future work includes multi-site evaluation, construction of an expert annotated reference graph, improved handling of class imbalance, and richer domain informed semantics toward scalable digital twins for hydropower infrastructure.

Abstract

Building Information Modelling provides the geometric and semantic foundation for Digital Twins (DT), but its effectiveness depends on the availability of use-case-specific information. In OpenBIM workflows, Industry Foundation Classes (IFC) models often contain missing or incomplete information, limiting reliable integration with DT platforms. This paper presents an envelope retrofit-oriented data quality control using Information Delivery Specifications (IDS). Minimum requirements were formalized into IDS and validated against an IFC model. Results show that while geometry was generally complete, critical semantics, particularly material and thermal properties, were frequently missing. IDS-based validation enables early detection of data gaps and improves IFC data readiness.

Introduction

The built environment is a major contributor to global energy use and CO_2 emissions (International Energy Agency, 2023), making existing building stock an important target for retrofit interventions aimed at reducing energy use, lowering emissions, and extending operational lifespans.

Digital technologies, particularly Building Information Modelling (BIM) and Digital Twin (DT), offer significant potential to support and optimize retrofit processes (D'Angelo et al., 2022). However, the effectiveness of these technologies is often constrained by persistent interoperability and data exchange challenges.

Building retrofitting aims to enhance energy efficiency (Ma et al., 2025), occupant comfort (Hosamo et al., 2023a), and environmental performance. Traditional retrofit approaches rely primarily on static building properties, historical weather data, and simplified energy models (Feng et al., 2022). Such approaches often fail to capture the true complexity of existing buildings, leading to suboptimal design decisions, unforeseen implementation challenges, and performance outcomes that deviate from predictions, commonly referred to as the energy performance gap (Cuerda et al., 2020).

DTs offer a promising alternative by enabling data-driven retrofit decision-making through continuous monitoring and real-time performance feedback (Ba et al., 2025). By integrating live data streams, DTs can support optimized energy use and improved occupant comfort (Hosamo et al., 2023b). A DT can be defined as a digital replica of a physical asset that integrates data from Internet of Things (IoT) devices with analytics and computational models to represent the state and behavior of the asset across its lifecycle (Agostinelli et al., 2021). DT ecosystems typically consist of a physical asset, its virtual counterpart, and a bidirectional flow of information between them (Hadjidemetriou et al., 2023). Within this context, BIM provides the geometric and semantic foundation of the virtual model, while IoT technologies enable dynamic data acquisition, making BIM and IoT core enablers for DT development in the built environment (Li et al., 2023). BIM models represent the physical and functional characteristics of buildings through both geometric and non-geometric information, providing a structured baseline for simulation, analysis, and decision support (Azhar et al., 2020).

Despite this conceptual synergy, integrating BIM models into DT workflows remains technically challenging due to interoperability limitations (Muchla et al., 2025). Interoperability refers to the ability to exchange and reuse data across heterogeneous software platforms throughout the building lifecycle while minimizing information loss and manual intervention (Agostinelli et al., 2021). In practice, BIM platforms, energy simulation tools, IoT systems, and DT environments often rely on proprietary data structures and inconsistent schemas (Piras et al., 2025). During BIM data exchange, critical semantic information such as thermal properties, material definitions, and equipment specifications may be omitted, misclassified, or improperly mapped due to incomplete information requirements, variations in modelling practices, and IFC export configurations, particularly in workflows using open standards such as IFC and gbXML (Bastos Porsani et al., 2021; Li et al., 2023). These issues hinder the automated linkage of BIM-based static data with dynamic data sources, such as Building Automation Systems (BAS), Building Management Systems (BMS), and IoT sensors, resulting in manual data correction, extended workflows, and unreliable analytics.

While interoperability challenges in BIM–DT integration are well recognized, existing studies predominantly focus on conceptual frameworks or platform-specific implementations. Limited attention has been given to the explicit definition and automated validation of retrofit-oriented information requirements in IFC models prior to DT deployment. As a result, data quality issues are often

identified late in the workflow, reducing scalability and limiting the effectiveness of DT applications for retrofit projects. Accordingly, this study is guided by the following research question: How can minimum, use-case-specific information requirements for envelope retrofit be explicitly defined and automatically validated in IFC models to support DT integration? This paper addresses this gap by proposing a structured approach for defining and validating minimum, use-case-specific information requirements and demonstrates how IDS can be used not only as a checking tool but as a mechanism for improving upstream data definition in envelope retrofit-oriented workflows. The main contributions of this study are:
(1) the definition of a minimum, use-case-specific set of envelope retrofit information requirements, (2) their formalization into machine-interpretable IDS specifications, and
(3) the demonstration of an automated validation workflow to assess IFC data readiness for DT integration.

In this research, the term retrofit refers specifically to building envelope retrofit, focusing on elements that govern heat exchange with the external environment. The proposed approach is demonstrated through a case study on an IFC model. The objective is to improve IFC data readiness and support scalable, openBIM-compliant DT applications for retrofit projects.

Methodology

This study applies a case-study approach to assess IFC data readiness for envelope retrofit-oriented DT integration through requirement definition and IDS-based validation. The methodological workflow consists of five main steps: (1) identification of retrofit-oriented information requirements, (2) formalization of these requirements using IDS, (3) preparation and export of the BIM model to IFC format, (4) validation of IFC models against the defined IDS rules, and (5) analysis of validation results to identify data quality issues.

Figure illustrates the validation workflow used in this study. This workflow represents one stage within a broader process that begins with use-case-based requirement definition, followed by validation (this research), and subsequent model refinement and DT integration in future work.

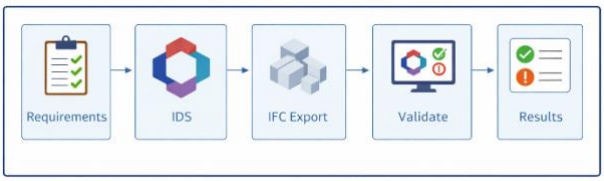

Figure 1: IDS-based validation workflow

The methodology defines information requirements rather than as a general measure of BIM completeness. For the use-case addressed in this study, the minimum set was limited to the static envelope information needed for initial retrofit assessment and subsequent DT use. Requirement selection was based on the information needed for envelope performance evaluation. Although additional information may be available in external sources such as product and material databases or environmental product declarations, these were considered outside the scope of this study. The scope of the IDS was therefore limited to information that could be reliably represented in IFC and automatically validated.

Retrofit-oriented information requirements were identified based on the literature insights, common inputs required for building energy analysis, and domain knowledge relevant to envelope retrofit. The scope was intentionally limited to external envelope elements, including walls, roofs, slabs, windows, and doors, which are central to envelope retrofit assessment. The resulting requirements focus on the presence and correct assignment of envelope-related information, including element identification, material assignment, and the availability of thermal performance properties. Together, these requirements represent a core but non-exhaustive subset of information relevant to the selected use-case. The identified requirements were formalized using buildingSMART IDS (buildingSMART International, 2024), enabling machine-interpretable definition of expected IFC entities, properties, and quantities. In this study, IDS rules were designed to verify information availability and completeness without prescribing how elements must be modelled or requiring specific property values, allowing flexibility across BIM authoring practices. A prototype validation workflow was implemented by exporting a BIM model of an existing building to IFC format and validating it using an IDS-compatible tool.

Case Study and Validation Workflow

Case Study Description

The case study is based on the Future Buildings Laboratory (FBL), a research facility located at Concordia University in Montreal, Quebec. The FBL functions as a living laboratory supporting multidisciplinary research and education in sustainable buildings and infrastructure. The facility provides a controlled environment for testing building technologies and monitoring performance, making it a suitable case study for investigating data readiness in retrofit-oriented DT workflows.

The building is a single-storey structure with approximate plan dimensions of 14.7 m × 7.5 m and an overall height of about 8 m. From a thermal perspective, the facility operates primarily as a single thermal zone; however, it is internally subdivided into four dedicated test cells used for independent experimental studies, along with two mechanical cells. The building is equipped with a compact set of building systems, including an outdoor heat pump unit paired with an indoor air handling unit for heating and cooling, as well as an electric domestic hot water system. These characteristics make the FBL representative of small-scale experimental buildings commonly used in retrofit research and DT development.

BIM Modelling and IFC Export

A three-dimensional BIM model of the FBL was developed using Autodesk Revit to represent the actual building geometry and associated static building information. The model focuses on architectural and envelope components required for retrofit assessment and DT initialization. The BIM model was subsequently exported to the IFC format using IFC 4 and the Reference view MVD to enable open and tool-independent data exchange.

The IFC export was performed without manual post-processing or correction before validation. This approach ensures that the validation results reflect the completeness and correct assignment of information as produced by the BIM authoring and export process, rather than improvements introduced through manual intervention. The exported IFC model served as the sole input for IDS-based validation.

IDS Definition and Scope

To develop the IDS, usBIM.IDSeditor (ACCA software, 2026) was used due to its native support for the buildingSMART IDS standard and its schema-aware environment for defining requirements without manual XML editing. The tool was selected because it is dedicated to requirement authoring rather than model checking, is independent of any specific IFC model, and produces portable IDS definitions accompanied by human-readable documentation. This separation allows IDS validation to be performed independently using an IDS-compatible tool.

Retrofit-Oriented Information Requirements

This section details how retrofit-oriented requirements were selected. The requirements target static building information and should therefore be understood as a minimum information specification for this use-case, rather than as a complete definition of all information that could be relevant to building lifecycle analysis.

These requirements were derived from the information typically needed for envelope performance evaluation. In particular, the selection reflects inputs commonly required by building energy simulation workflows, including geometry and zoning context, material and construction properties, and thermal performance parameters.

The IDS requirements were defined as a core subset that is both (i) retrofit-relevant and (ii) practically checkable in IFC exports across tools. For opaque elements (external walls, roofs, and slabs), requirements emphasize element identification, material assignment, and thermal transmittance properties. For openings (windows and doors), the focus is on thermal transmittance, with quantity information treated as optional.

In the IDS structure, each requirement is defined within a Specification that includes an Applicability definition and a set of Requirements, enabling the translation of these information needs into explicit, machine-interpretable validation rules.

Five envelope element categories were selected as the validation scope of the IDS, and requirements were defined for applicable instances of these categories using standard IFC entity types, property sets, and quantity take-off sets. The detailed requirements are summarized in Table 1.

Table 1: Summary of IDS requirements for envelope elements

Element Type	IFC Entity	Properties
External Walls	IfcWall	Name, IsExternal, LoadBearing, ThermalTransmittance, NetSideArea, NetVolume, Material
Roofs	IfcRoof	IsExternal, ThermalTransmittance, GrossArea, Material
Slabs/Floors	IfcSlab	IsExternal, ThermalTransmittance, Material
Windows	IfcWindow	IsExternal, U-value
Doors	fcDoor	IsExternal, ThermalTransmittance

For external walls (Figure), the IDS defines the most extensive set of checks, reflecting the central role of walls in envelope heat transfer. The specification includes identification and applicability conditions to define which elements are evaluated, together with requirements for thermal, material, and quantity-related properties; however, classification and fire rating remain optional to avoid over-constraining IFC exports.

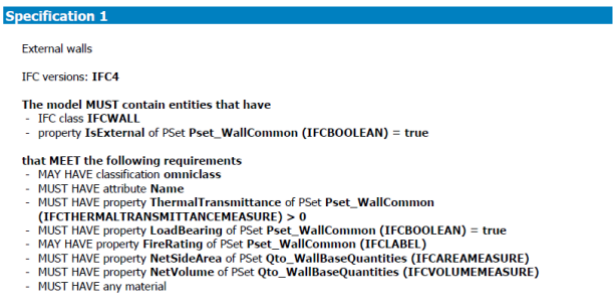

Figure 2: External walls specification

For roofs, the IDS specifies external applicability together with thermal, material, and gross area information. For

slabs and floors, the IDS includes external applicability, material assignment, and thermal transmittance properties, without additional quantity requirements.

For windows, the IDS requires external applicability and thermal transmittance, while area-related quantities are optional. For doors, the external applicability and thermal transmittance were included, without additional quantity requirements.

Requirements related to dynamic operation (e.g., real-time sensor data, control setpoints, or occupancy schedules), performance targets (e.g., prescribed U-value thresholds or regulatory compliance limits), proprietary or tool-specific parameters (e.g., authoring-tool custom fields), detailed construction layering (e.g., full multi-layer wall build-ups with material thicknesses), and non-retrofit lifecycle data (e.g., construction sequencing or maintenance scheduling) were excluded, as they cannot be consistently expressed, validated, or verified as static information within IFC-based IDS workflows.

In addition, some information that is typically maintained in external sources rather than within the IFC model was excluded. This includes manufacturer-specific product data, detailed material properties, and environmental declaration information such as embodied carbon indicators. While such information may be important for broader sustainability or lifecycle analyses, it falls outside the scope of this study, which focuses on validating the minimum IFC-based information required for retrofit-oriented DT initialization. The resulting set supports early, automated IFC data quality assessment for retrofit-oriented DT integration without defining a comprehensive modelling specification.

Validation Workflow

The validation workflow evaluates IFC data readiness through automated, standards-based checks. The IFC4 model was validated against the defined IDS specifications using BIMcollabZoom (BIMcollab, 2026.), as shown in Figure , which assessed each applicable element and generated element-level pass/fail results. For non-compliant elements, the output included requirement-specific messages indicating missing or incomplete information, such as absent thermal properties, missing material assignments, or missing quantity data.

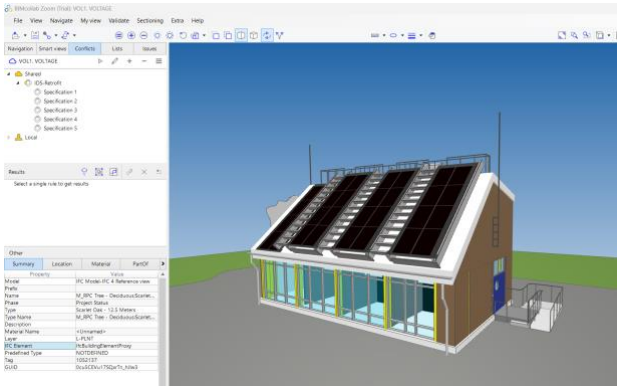

Figure 3: Case study 3D model in BIMcollab

The validation results were then analyzed to identify recurring data gaps across envelope elements and to assess overall IFC data readiness. Non-compliant elements can be traced and corrected in the BIM authoring environment, followed by re-export and re-validation; however, this corrective loop is outside the scope of this study.

Result Analysis and Discussion

Results Analysis

The validation assessed compliance with the retrofit-oriented information requirements defined for envelope elements and showed that a substantial number of applicable elements failed one or more IDS checks. In addition to the pass/fail indicators, the BIMcollabZoom provided detailed Property–Value information for each non-compliant element. These fields are essential for interpreting why elements failed IDS requirements and for distinguishing between geometric completeness and semantic deficiencies. In several cases, elements included correct geometry, dimensions, and basic identifiers, while required attributes such as material assignments, thermal transmittance values, or external applicability flags were undefined or absent. These failures were primarily associated with missing thermal properties and material assignments. This indicates that data gaps are concentrated in the semantic information required for envelope retrofit assessment rather than in geometric representation.

For walls (Figure), the validation output shows repeated failures associated with undefined material assignments and missing thermal transmittance properties, despite the presence of geometric representations and basic element identifiers. It should be noted that the figure primarily shows internal walls. Their inclusion in the validation results indicates that the external applicability condition (e.g., IsExternal) was missing or not correctly assigned, causing these elements to be evaluated against IDS requirements intended for external walls. This highlights the importance of correctly defining applicability attributes in addition to providing required semantic information.

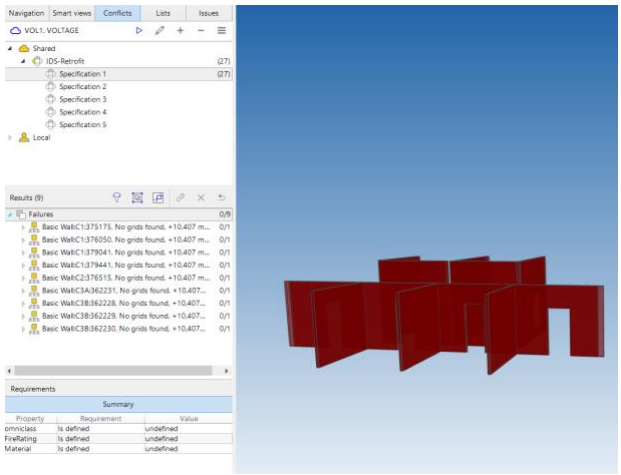

Figure 4: Validation of External Walls

For slabs and floors (Figure), although geometries were present and correctly represented as IfcSlab entities, the absence of material assignments resulted in systematic non-compliance.

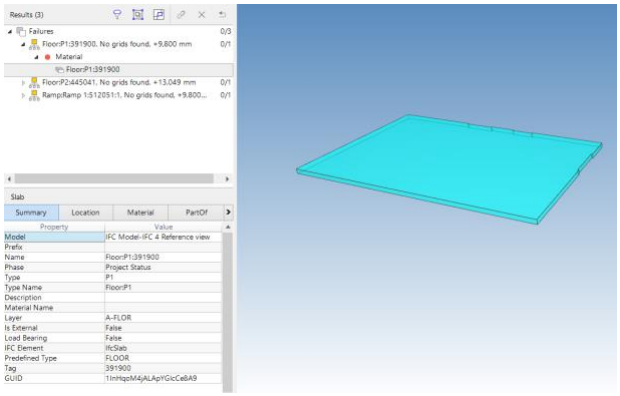

Figure 5: Validation of Slabs/Floors

For windows (Figure), the validation results show that while window geometries and basic dimensional attributes were available, the absence of thermal transmittance properties, particularly U-values prevented compliance with the retrofit-oriented requirements. This suggests that thermal properties were either not defined at the authoring stage or not reliably transferred during IFC export

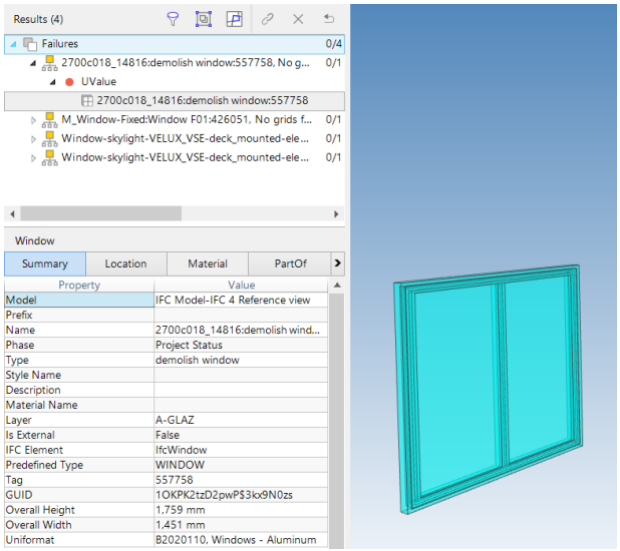

Figure 6: Validation of Windows

For doors (Figure), validation failures were associated with missing thermal transmittance properties and missing or incorrect external applicability information. Even when doors were correctly classified as external and included additional attributes such as fire rating, the lack of thermal performance information resulted in non-compliance with the IDS requirements.

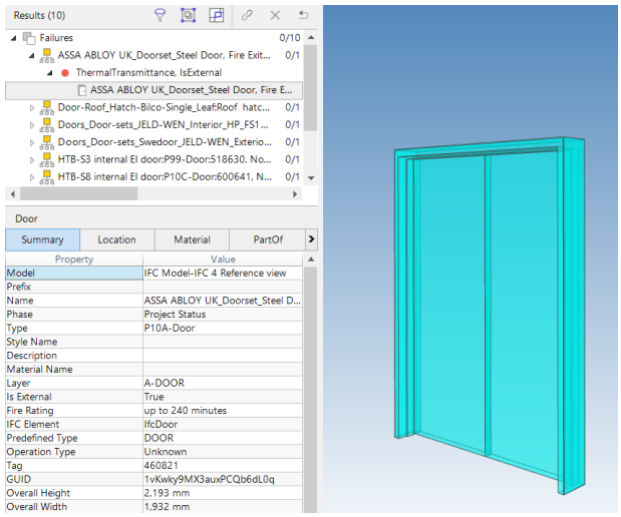

Figure 7: Validation of Doors

Discussion

The validation outcomes highlight a fundamental challenge in using IFC models as a foundation for retrofit-oriented DT workflows: geometric completeness alone does not guarantee data readiness. Although the BIM model provided visually complete representations of envelope elements, the frequent absence of material and thermal properties significantly limits its suitability for retrofit assessment and DT initialization. The findings should be interpreted within the scope of envelope retrofit, as the requirement set does not address system-level or operational retrofit interventions.

The results indicate that IFC data readiness is not solely a technical issue, but also a methodological one related to how information requirements are defined and communicated prior to modelling. In the absence of explicit, use-case-driven requirements, critical attributes such as thermal transmittance and material definitions remain optional, leading to systematic data gaps across the model. This highlights the importance of linking requirement definition to model authoring and export processes rather than relying on implicit assumptions about data availability.

The study also clarifies the role of IDS within the broader process of preparing BIM data for DT use. In this work, IDS was used to validate the minimum set of IFC-embedded information required for the selected use-case. This does not imply that all relevant information must reside within the IFC model. In practice, richer data such as manufacturer-specific product information, material databases, or environmental product declarations may be integrated after the baseline IFC model has been validated. IDS-based validation should therefore be understood as an early quality-control step within a broader workflow that includes model preparation, enrichment, and DT integration. The IDS-based validation approach proved effective in making data deficiencies explicit and traceable. By encoding requirements in a machine-interpretable form, the validation process clearly distinguished between

geometric completeness and semantic readiness, identifying missing or incomplete information at the element level. This supports early detection of data gaps before DT integration, where manual correction would otherwise be required.

Despite its advantages, IDS-based validation has several limitations in the context of envelope retrofit-oriented DT workflows. IDS supports verification of the presence and correct assignment of information, but does not assess the accuracy or physical validity of property values. In addition, IDS operates on static IFC data and does not capture dynamic information such as sensor data or operational conditions. Its effectiveness also depends on how models are authored and exported, meaning that variations in modelling practices and export configurations can influence validation outcomes. IDS should therefore be considered a necessary but not sufficient mechanism for ensuring data readiness.

Overall, the results demonstrate that explicitly defined retrofit-oriented information requirements, when validated through IDS, improve transparency regarding IFC data readiness. This enables earlier and more reliable data quality control and provides a practical mechanism for strengthening interoperability between BIM models and DT workflows.

Beyond demonstrating current IDS usage, the study contributes a structured approach for defining and validating minimum information requirements tailored to a specific envelope retrofit use-case.

Conclusion

This study presented an envelope retrofit-oriented approach to assessing IFC data readiness for DT integration using Information Delivery Specifications (IDS). By explicitly defining use-case-specific information requirements and validating them through an automated, standards-based workflow, the study demonstrated how IDS can be used to identify missing and incomplete information in IFC models before DT deployment.

The case study showed that, while the IFC model provided complete geometric representations of envelope elements, essential semantic information, particularly material definitions and thermal performance properties, was frequently absent or only partially defined. Validation results highlight the limitations of relying on visual completeness alone when evaluating IFC models for retrofit-oriented DT workflows.

The findings further indicate that IDS-based validation enables early and repeatable data quality control in a tool-independent manner. They also show that the primary barrier to IFC data readiness is not the data format itself, but the lack of explicitly defined information requirements. By formalizing these requirements in a machine-interpretable form, IDS supports systematic detection of data gaps and facilitates targeted model improvement, reducing the need for manual data correction during later stages of DT integration. This approach provides a practical basis for improving IFC data readiness and supporting DT integration.

This study has limitations: the requirement set focuses on a core subset of retrofit-relevant information rather than a comprehensive specification, and validation was conducted on a single case-study building. While the workflow supports iterative correction of detected issues through model updates and re-validation, the implementation of model corrections and subsequent validation cycles is outside the scope of this study, which focuses on requirement definition and initial data quality assessment. Nevertheless, the proposed workflow is transferable and provides a solid foundation for extending IDS-based validation to broader retrofit scenarios. Beyond demonstrating a practical application, the study provides analytical insights into common patterns of information deficiency in IFC models and highlights the role of explicit requirement definition in improving data readiness.

Future work will expand the requirement scope to additional building systems, integrate semantic linking through the buildingSMART Data Dictionary(bSDD), and explore the combined use of IDS and Information Delivery Manuals (IDM) to better define roles and responsibilities in retrofit-oriented DT workflows.

Appendix A

Specification 1

External walls

IFC versions: IFC4

The model MUST contain entities that have

- IFC class IFCWALL
- property IsExternal of PSet Pset_WallCommon (IFCBOOLEAN) = true

that MEET the following requirements

- MAY HAVE classification omniclass
- MUST HAVE attribute Name
- MUST HAVE property ThermalTransmittance of PSet Pset_WallCommon (IFCTHERMALTRANSMITTANCEMEASURE) > 0
- MUST HAVE property LoadBearing of PSet Pset_WallCommon (IFCBOOLEAN) = true
- MAY HAVE property FireRating of PSet Pset_WallCommon (IFCLABEL)
- MUST HAVE property NetSideArea of PSet Qto_WallBaseQuantities (IFCAREAMEASURE)
- MUST HAVE property NetVolume of PSet Qto_WallBaseQuantities (IFCVOLUMEMEASURE)
- MUST HAVE any material

Specification 2

Roofs

IFC versions: IFC4

The model MUST contain entities that have

- IFC class IFCROOF
- attribute ObjectType = ROOF

that MEET the following requirements

- MUST HAVE property ThermalTransmittance of PSet Pset_RoofCommon (IFCTHERMALTRANSMITTANCEMEASURE) > 0
- MUST HAVE property IsExternal of PSet Pset_RoofCommon (IFCBOOLEAN) = true
- MUST HAVE property GrossArea of PSet Qto_RoofBaseQuantities (IFCAREAMEASURE)
- MUST HAVE any material

Specification 3

Slabs/Floors

IFC versions: IFC4

The model MUST contain entities that have

- IFC class IFCSLAB
- property IsExternal of PSet Pset_SlabCommon (IFCBOOLEAN) = true

that MEET the following requirements

- MUST HAVE property ThermalTransmittance of PSet Pset_SlabCommon (IFCTHERMALTRANSMITTANCEMEASURE) > 0
- MUST HAVE property IsExternal of PSet Pset_SlabCommon (IFCBOOLEAN) = true
- MUST HAVE any material

Specification 4

Windows

IFC versions: IFC4

The model MUST contain entities that have

- IFC class IFCWINDOW

that MEET the following requirements

- MUST HAVE property UValue of PSet Pset_WindowCommon (IFCLABEL) > 0
- MUST HAVE property IsExternal of PSet Pset_WindowCommon (IFCBOOLEAN) = true
- MAY HAVE property Area of PSet Qto_WindowBaseQuantities (IFCAREAMEASURE)

Specification 5

Doors

IFC versions: IFC4

The model MUST contain entities that have

- IFC class IFCDOOR

that MEET the following requirements

- MUST HAVE property ThermalTransmittance of PSet Pset_DoorCommon (IFCTHERMALTRANSMITTANCEMEASURE) > 0
- MUST HAVE property IsExternal of PSet Pset_DoorCommon (IFCBOOLEAN) = true

INTEROPERABILITY IMPERATIVE: A BUILT ENVIRONMENT MATURITY-BARRIER ANALYSIS FOR DIGITAL TWIN CONVERGENCE WITH BIM AND IOT

Ubongabasi Inyang, Bamidele Adebisi, and Weizhuo Wang
Department of Engineering, Manchester Metropolitan University, Manchester, UK

Abstract

The built environment faces pressure to improve efficiency and sustainability throughout its lifecycle. Digital twins (DT), leveraging BIM, IoT sensor data, and AI, offer significant potential for proactive and intelligent asset management. However, deployment is hindered by the Interoperability Imperative—the need for heterogeneous systems to exchange and interpret data seamlessly. This paper develops a Maturity–Barrier Logic that frames DT evolution as constrained by interoperability-related barriers. It identifies a persistent implementation gap, with applications stagnating at the Digital Shadow and failing to achieve autonomous Cognitive Twins. A diagnostic framework is proposed to support the transition toward federated, system-of-systems DT.

Introduction

The Architecture, Engineering, Construction, and Operations (AECO) industry is undergoing a significant transformation driven by the digitalisation and integration of cyber-physical systems (CPS) (Boje et al., 2020). Central to this transition is the convergence of Building Information Modelling (BIM), the Internet of Things (IoT), and DT technologies, enabling a shift from static representations to dynamic, data-driven systems capable of real-time monitoring, simulation, and predictive analysis. Despite this potential, the realisation of fully functional DTs remains constrained by the interoperability imperative for heterogeneous systems to exchange, interpret, and utilise data without ambiguity. In this study, a Digital Twin is defined as a virtual representation of a physical asset that is continuously updated through automated, bi-directional data exchange, enabling real-time monitoring, prediction, and optimisation (Rasheed et al., 2020; Grieves and Vickers, 2017). This emphasises the distinction between true DTs and lower levels of digital representation, where limited data integration restricts system functionality (Kritzinger et al., 2018). As DT evolves, Artificial Intelligence (AI) is increasingly playing a critical role in enabling advanced capabilities. While BIM provides semantic structure and IoT enables real-time sensing, AI functions as the computational engine that supports pattern recognition, predictive analytics, and autonomous decision-making. This integration enables the emergence of Cognitive Twins at higher maturity levels that are capable of adaptive and self-learning behaviour (Boje et al., 2020; Madni et al., 2019; Yitmen et al., 2021). These capabilities also further intensify interoperability requirements, particularly in relation to semantic integration, data governance, and trust in algorithmic outputs. Despite extensive research on DT technologies and their associated implementation barriers, a critical limitation persists as existing studies either focus on identifying barriers ranging from technical and data-related challenges to organisational constraints (Opoku et al., 2023; Kineber et al., 2023) or on defining Digital Twin Maturity Models (DTMM) that describe system evolution (Deng et al., 2021; Liu et al., 2024). To address this gap, this paper develops a structured analysis that links interoperability barriers to distinct stages of DT maturity. Several DTMMs have been proposed and a referenced classification by Kritzinger et al. (2018) distinguishes between Digital Models, Digital Shadows, and DTs based on the level of data integration and automation. Studies highlight limitations within existing maturity models and Liu et al. (2024) noted that many DTMMs lack clarity in defining capability progression and fail to provide continuous and measurable development pathways thus resulting in models that effectively describe idealised end states. Interoperability is consistently identified as the most critical technical constraint (Naderi and Shojaei, 2023), and challenges arise at both syntactic and semantic levels, reflecting difficulties in data exchange formats as well as inconsistencies in meaning and interpretation across systems. A key issue is the integration of BIM data, typically structured in Industry Foundation Classes(IFC) schemas, with IoT-generated time-series data, which operates on fundamentally different data models (Boje et al., 2020). Machine-readable knowledge representation and integration such as semantic web technologies and ontologies, such as Brick Schema, SOSA/SSN (Sensor, Observation, Sample, and Actuator/Semantic Sensor Network), and ifcOWL(Web Ontology Language representation of the IFC schema), have been proposed to address these challenges (Petrova and Pauwels, 2020; Farghaly et al., 2023), but their adoption remains limited due to implementation complexity and the absence of unified industry standards. In addition, technical, organisational, and governance barriers further impede DT adoption. Concerns related to data security, privacy,

and ownership also complicate collaboration across stakeholders, limiting trust and restricting data sharing (AlBalkhy et al., 2024; Kineber et al., 2023).

Further analysis reveals a fundamental disconnect between two dominant research streams: the study of DTMM and the identification of implementation barriers. While maturity models define the evolutionary trajectory of DT systems (Deng et al., 2021; Liu et al., 2024), and barrier-focused studies classify implementation challenges (Opoku et al., 2023), there is a lack of integration between these perspectives. Existing research does not systematically examine how particular barriers constrain progress between maturity stages. For example, early-stage DT development is often limited by data acquisition and sensor integration challenges, whereas advanced stages require sophisticated semantic interoperability, data governance, and trust in AI-driven decision-making (AlBalkhy et al., 2024; Boje et al., 2020). This lack of alignment results in a practical limitations where stakeholders are unable to identify which barriers must be addressed to achieve specific maturity transitions, as current frameworks do not provide actionable guidance for implementation or strategic planning (Liu et al., 2024). By synthesising technical, semantic, and organisational challenges identified in the literature, this study proposes a Maturity–Barrier Logic that maps barriers, interoperability challenges to DT maturity stages to address this gap and enable a more systematic understanding of transition constraints and supporting more informed decision-making in DT implementation in the built environment. To guide this investigation, the study addresses the following research questions:

- How do interoperability barriers manifest across different DT maturity stages?
- What specific barriers inhibit progression between these maturity stages?
- How can these barriers be mapped to support DT diagnostic framework development?

Methodology

This study adopts a conceptual synthesis approach to systematically identify and analyse interoperability-related barriers and their relationship to DT maturity stages in the built environment. Guided by PRISMA principles, the review was conducted using Scopus as the primary database. Searches, restricted to English-language publications from 2015 onward, using this terms : Core Concept(Federated DTs); Domain & Context (Built Environment, Construction Industry, Asset Lifecycle, Facility Management (O&M)); Tech & Systems (BIM, IoT, Sensors, Cyber-Physical Systems, Data/System Integration); Interoperability (Semantic & Organisational Standards, IFC, Asset Administration Shell, Ontologies); Performance (Predictive/Proactive Maintenance, Energy Optimisation, IEQ, Occupant Comfort); Governance (Data/DT Governance, Ecosystems, Policy, Stakeholder & Tech Readiness); Implementation (Adoption Barriers (Org/Process), Deployment Challenges, Transformation); Maturity (Digital Twin Maturity Models, Technology & Digital Maturity Levels); Methodology (Systematic Literature Reviews, Bibliometric Analysis). To capture interoperability challenges across the full technological spectrum, keywords included not only “digital twin” but also associated enablers such as BIM and IoT. The search process yielded 1,089 records. Following relevance screening, 180 studies were retained. The analysis covered both technical barriers (data integration, semantic alignment, standards fragmentation, legacy systems) and organisational issues (governance, stakeholder readiness, and workflow alignment). The outcome is a structured Maturity–Barrier Mapping that aligns interoperability challenges with DT maturity progression.

Barrier Taxonomy and Distribution

The systematic analysis of the provided literature reveals that the convergence of BIM, IoT, and DT is hindered by a complex matrix of technical and organisational barriers. These barriers confirm the Interoperability Imperative, in which the primary friction lies not merely in the availability of technology but in the capacity to integrate heterogeneous systems and govern them effectively. The Barrier-to-Maturity Mapping Logic was developed by extracting interoperability-related barriers and grouping them into categories and then mapping them to DT maturity stages. Table 1 illustrates the delineation of these challenges, categorised by their impact on the DT.

Interoperability Barriers:

- **Data Capture and Connectivity:** A fundamental technical barrier is the difficulty in establishing real-time synchronisation between the physical asset and the virtual counterpart (Naderi and Shojaei, 2023).
- **Semantic Alignment:** A critical limitation identified is the semantic gap between BIM that relies on static, hierarchical schemas (e.g., IFC), while IoT generates dynamic, time-series data.
- **Visualisation and Integration:** The integration of diverse software tools and the diversity in source systems create fragmented data silos.

Governance and Organisational Barriers:

- **Organisational Inertia:** This poses challenges that are as great as, or greater than, technical limitations. Overcoming the organisational inertia inhibiting DT adoption requires a shift from voluntary adoption to mandated governance frameworks that support a System-of-Systems approach.
- **Fragmentation and Silos:** The industry is characterised by fragmented supply chains and silos between departments, which obstruct the holistic data sharing required for DTs (AlBalkhy et al., 2024;

Table 1: Taxonomy of Barriers to DT-BIM-IoT Convergence

Category	Barrier Sub-Type	Description & Key Citations
Technical/ Semantic	Semantic Interoperability	Inability of systems to interpret data across BIM (static) and IoT (dynamic) domains; lack of unified ontologies.
	Data Integration/Fusion	Difficulty fusing heterogeneous data formats (e.g., geometric vs. time-series); diversity in source systems.
	Connectivity/Latency	Real-time data transmission, bandwidth, and latency issues that disrupt the physical–virtual link.
	Data Quality	Uncertainties with data quality and reliability, including noisy sensor data and lack of accuracy.
Organisational Governance	Readiness & Skills	Skilled professionals shortage, low level of knowledge, resistance to change, and lack of training.
	Structural/Process	Fragmentation of the industry; silos between departments.
	Economic/Financial	High investment costs, uncertain ROI, and lack of financial incentives.
	Trust & Security	Lack of trust in data security, privacy concerns, and unclear data ownership/intellectual property rights.

Opoku et al., 2023).

- **Readiness and Skills:** The pervasive low level of knowledge and lack of competence regarding DT technologies among stakeholders contributes to resistance to change and a preference for traditional workflows (Kineber et al., 2023; Opoku et al., 2023).
- **Cost and Value:** High initial investment costs (CapEx) and an unclear value proposition or unproven Return on Investment (ROI) act as significant deterrents, particularly for Small and Medium Enterprises (SMEs) (AlBalkhy et al., 2024; Kineber et al., 2023).

Exemplars and Benchmarks:

The literature frequently cites specific frameworks as benchmarks for guiding DT implementation:

- **The Gemini Principles:** Proposed by the Centre for Digital Built Britain (CDBB), Purpose, Trust, Function principles are cited as a foundational ethical and functional value-based framework that serves as a benchmark for national-level DT strategy (Al-Sehrawy et al., 2021; Bolton et al., 2018; Chen et al., 2021). It emphasises that a DT must have a clear purpose, must be trustworthy, and must function effectively. Chen et al. (2021) utilised these principles to develop a maturity model for asset management, validating that alignment with these principles correlates with higher DT maturity.
- **Incremental Digital Twin (iDTw) Framework:** A framework, proposed by Calvetti et al. (2025), that breaks down DT implementation into granular levels (Static, Detailed, Sensored, Responsive, Adaptive, Intelligent). It is particularly effective for smart enterprises and construction logistics, offering a phased deployment strategy that lowers the barrier to entry for organisations daunted by the complexity of complete autonomy.
- **BIM-IoT Data Integration (BIM-IoTDI) Architecture:** Developed by Eneyew et al. (2022), this framework explicitly addresses the semantic interoperability gap in smart buildings. By utilising an ontology-based query mediation method, it enables the integration of static BIM data and dynamic IoT data without loss of semantic meaning. It is critical for supporting proactive FM tasks such as predictive maintenance and energy management.
- **CITYSTEPS Maturity Model:** This model assesses governance and technological readiness in urban DTs. It highlights that while many projects achieve visualisation, few progress to real-time decision-making or autonomous stages due to governance and interoperability failures (Masoumi et al., 2023).
- **ISO Standards:** References are made to ISO 19650 for information management and ISO 23247 for automation systems as emerging standards attempting to regulate this space (Calvetti et al., 2025; Palihakkara et al., 2025).

Mapping Maturity Levels and Interoperability Gaps

The analysis identifies a consensus on multi-stage evolutionary pathways for DTs, as presented in Table 2. While terminologies vary, the progression moves from static representation to autonomous interaction. Crucially, specific interoperability gaps act as limitations, preventing progression to higher maturity levels. The strategic roadmap synthesises the technical, semantic, and organisational requirements necessary to navigate the convergence to address the Interoperability Imperative by structuring deployment into maturity phases to overcome specific barrier limitations. To navigate the Interoperability Imperative, stakeholders should adopt a

Table 2: Maturity Mapping and Levels Gaps

Maturity Level	Characteristics and Limitation
Level 1: Descriptive (Digital Model)	Static 3D representation (e.g., BIM) with manual data exchange. **Limitation:** Digitisation Gap. The transition to the next level is blocked by the inability to digitise physical assets and processes effectively.
Level 2: Informative (Digital Shadow)	One-way automatic data flow from physical to digital (monitoring)- real-time visualisation. **Limitation:** Connectivity Gap. Progress is restricted by the lack of robust IoT infrastructure and reliable data transmission protocols.
Level 3: Predictive (Adaptive Twin)	Bi-directional data flow or advanced simulation capabilities. Uses historical data and AI to predict future states. **Limitation:** Semantic Gap. Lack of semantic interoperability (ontologies) prevents the DT from contextualising IoT readings within BIM geometry.
Level 4: Comprehensive/ Intelligent (Cognitive Twin)	Autonomous decision-making, self-learning, and prescriptive analytics. The DT can act on the physical world. **Limitation:** Trust and Governance Gap. Stakeholders lack trust in black box AI algorithms and fear security breaches.
Level 5: Federated (System-of-Systems)	Interconnected DTs interacting to optimise broader systems. **Limitation:** Standardisation Gap. The lack of universal data standards prevents disparate DTs from interacting.

phased approach, as illustrated in Table 3 case studies for overcoming distinct interoperability challenges at each phase to unlock subsequent maturity levels. For Foundational (Static Twin) where the asset exists as a high-fidelity digital model, the primary hurdle data quality and digitisation is the static nature of building data and the lack of accurate as-built geometric information (Opoku et al., 2023). Without resolving the digitisation gap, the twin remains a passive repository. For digital shadow, the one-way automated data flow from physical sensors to the digital platform affects connectivity and integration. Progression requires overcoming the Connectivity Gap by integrating IoT sensors with legacy systems and ensuring low-latency data transmission (Kang and Mo, 2024; Sepasgozar, 2021). This phase establishes the digital shadow. In Autonomous Cognitive Twin where bi-directional data flow with AI helping drive autonomous decision-making, Semantic Alignment Interoperability is required to move from a shadow to a true twin capable of prediction and control. This involves mapping heterogeneous data streams to unified ontologies (e.g., aligning IFC with SSN/SOSA) to enable automated reasoning and simulation (Boje et al., 2020; Huang and Hsieh, 2026). On the Federated System-of-Systems, trust is the key anchor.

Bridging the Gap: From Connectivity to Cognition

The progression through the roadmap is not linear but rather stepwise; specific barriers serve as limitations that must be overcome to advance.

- **Foundational to Integrative (The Connectivity Limitations):** To move from Level 1 (Static) to Level 2/3 (Dynamic), practitioners must resolve data and/or integration barriers. Specifically, the physical-digital disconnect must be bridged by retrofitting assets with IoT sensors and establishing reliable middleware (e.g., Node-RED) to handle the velocity of real-time data (Biagini et al., 2024; Naderi and Shojaei, 2023).
- **Integrative to Autonomous (The Semantic Limitations):** To move from Level 3 (Monitoring) to Level 4/5 (Prediction/Autonomy), the Semantic/Standards Barrier is the primary obstacle. A DT cannot predict if it does not understand the relationship between a temperature reading and the volume of a specific room. This requires resolving semantic silos by mapping BIM data to ontologies (e.g., Brick, SSN), moving beyond simple data transfer to knowledge graph integration (Boje et al., 2020; Eneyew et al., 2022).
- **Autonomous to Federated (The Trust Limitations):** To achieve a true System-of-Systems (Federated DT), the organisational governance barrier must be resolved. Technical connectivity is insufficient if stakeholders do not trust the data security or the AI's decision-making logic. Overcoming this requires adherence to governance frameworks as these legal structures are essential for resolving data sovereignty issues, enabling stakeholders to share proprietary data within federated ecosystems without compromising control, thereby meeting the governance requirements for Level 5 (AlBalkhy et al., 2024; Jørgensen, 2025). Policy-makers must establish a regulatory environment that incentivises interoperability through three core actions. First, public procurement must mandate open standards to ensure that data remain Findable,

Table 3: Maturity Mapping and Interoperability Gaps: Empirical Case Studies and Barrier Resolution

Maturity Phase	Empirical Case Study Evidence
Phase 1: Foundational (Descriptive Twin)	**The Digitisation Gap:** Overcomes data/integration barriers (AlBalkhy et al., 2024). **Case Study:** Northumbria University City Campus (UK) (Boje et al., 2020; Lu et al., 2020) **Digitisation Barrier:** Case study proves that relying on fragmented legacy documents restricts facility management to manual updates. It demonstrates that establishing a unified, standardised 3D semantic model (ISO 19650) is the foundational requirement to break non-machine-readable data
Phase 2: Integrative (Responsive Twin)	**The Connectivity Gap:** Overcomes established data connectivity barriers. (Boje et al., 2020; Jahangir et al., 2024). **Case Study:** University of Florence & UNF Engineering Building (Biagini et al., 2024; Kang and Mo, 2024) **Connectivity Barrier:** The Florence case proves that a middleware layer (Node-RED) is required to overcome protocol mismatches, while the UNF case shows that custom IFC Property Sets (pSets) anchor dynamic data feeds to static BIM elements, enabling a real-time Digital Shadow.
Phase 3: Autonomous (Cognitive Twin)	**The Semantic Gap:** Overcomes AI reasoning barriers (Boje et al., 2020). **Case Study:** Institute for Manufacturing (West Cambridge, UK) (Eneyew et al., 2022) **Semantic Barrier:** Proves an IFCxBrick pipeline is required for semantic interoperability. Mapping IFC to Brick via RDF/OWL achieves machine-understandable context, making automated tasks like Fault Detection and Diagnosis (FDD) feasible.
Phase 4: Federated (System-of-Systems)	**The Trust Gap:** Overcomes multi-owner data barriers (AlBalkhy et al., 2024). **Case Study:** Smart Dublin / Urban DT (Jørgensen, 2025; Masoumi et al., 2023) **Trust & Governance Barrier:** Proves that formal ''Data Spaces'' aligned with the Data Governance Act (DGA) are required for trusted exchange. It demonstrates that technical interoperability alone is insufficient without legally compliant open-data frameworks.

Accessible, Interoperable, and Reusable (FAIR), thereby preventing vendor lock-in (Klar et al., 2024). Second, the adoption of the Smart Readiness Indicator (SRI) should be promoted as a regulatory benchmark for assessing a building's capacity to adapt to needs and demands, serving as a key performance indicator of DT effectiveness. Finally, governance must align with the Data Governance Act (DGA) and Data Act (DA) to establish secure Data Spaces (Jørgensen, 2025).

Digital Shadow to Cognitive Twin Transition:

The most significant limitation identified in the transition from Level 2 (Digital Shadow) to Level 3/4 (Cognitive Twin) is Semantic Interoperability. To resolve this semantic gap and evolve the DT from a passive visualisation tool into a Cognitive Twin, a Diagnostic Implementation Guide (Figure 1) was developed. By synthesising theoretical concepts, maturity models, and empirical case studies from existing literature, this guide was structured to address specific technical constraints. The involved transforming disparate technical data into a cohesive, step-by-step workflow designed to transition a DT from a stalled state to a cognitive capability. Consequently, Figure 1 serves as a diagnostic framework outlining the technical protocols required to overcome this barrier—a critical distinction, as practitioners frequently conflate mere data connectivity (the transmission of bytes) with true data integration (the synthesis of meaning).

Discussion and Implications

DTs as Socio-Technical Systems: Beyond Technical Maturity: As illustrated in Figure 2, DT progression extends beyond static 3D models to real-time monitoring, predictive analytics, and autonomous decision-making, rather than being solely determined by technological capability (Sacks et al., 2020; Yitmen et al., 2021). Instead, it is inherently socio-technical, requiring alignment between technical infrastructure and organisational practices. The transition across maturity levels is systematically constrained by interoperability-related barriers—digitisation, connectivity, semantic, and governance gaps—which reflect both technical limitations and stakeholder misalignment. The evolution to Cognitive and Federated Twins is not simply a matter of deploying more advanced technologies, but of resolving the human, organisational, and institutional constraints embedded in each transition stage. To bridge and resolve the semantic gap between connectivity and cognition, the diagnostic guide in Figure 1 is useful to aid the transformation of the DTs, a prerequisite for envisioned predictive maintenance and energy optimisation (Boje et al., 2020; Liu et al., 2024).

Stakeholder-Specific Implications: Operationalising the Framework: The Maturity–Barrier Logic provides a structured lens for operationalising stakeholder

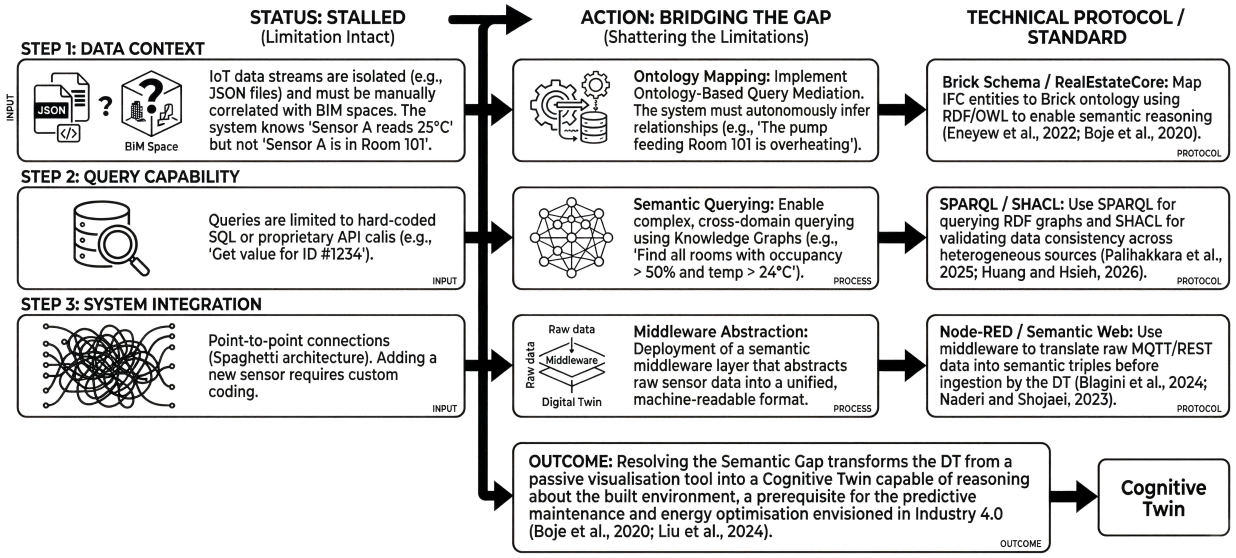

Figure 1: Diagnostic Implementation Guide for Overcoming the Semantic Barrier

responsibilities. Each blockade identified in Figure 2 corresponds to specific actions required by key actors:

- **Asset Owners:** To overcome the barriers at early and intermediate maturity stages of unclear value proposition, asset owners must transition from passive recipients of static BIM deliverables to active drivers of digital continuity. This requires embedding interoperability and semantic data requirements into procurement contracts, ensuring that deliverables support lifecycle integration rather than project completion alone.
- **Technology Providers:** Providers reliance on proprietary systems and closed data architectures inhibits cross-platform integration. To enable progression, providers must adopt open, modular system architectures, supported by middleware solutions (e.g., Node-RED) and semantic technologies (RDF/OWL). Mapping BIM standards such as IFC to ontologies like Brick Schema or RealEstateCore enables machine-readable context, facilitating advanced analytics and automated reasoning capabilities.
- **Policy-Makers and Industry Bodies:** The transition toward higher maturity levels (Levels 4–5) is constrained by trust and governance barriers, where data sharing is limited by legal, ethical, and commercial concerns. Policy-makers need to establish regulatory frameworks and data governance mechanisms to promote secure and standardised data exchange.

Practical and Research Outlook

The proposed Maturity–Barrier Logic serves not only as an analytical model but as a practical diagnostic tool for guiding DT implementation:

- **Industry Practitioners:** Organisations should utilise the framework to assess their current maturity level and identify the specific barriers preventing progression. For firms operating at the Digital Shadow stage, the priority should shift from additional sensor deployment to semantic data integration and architecture development. Implementing ontology-based pipelines (e.g., IFC-to-Brick) and establishing interoperable data environments are critical next steps.
- **Academic Community:** Future research must move beyond conceptual definitions toward empirical validation and implementation strategies. Key priorities should include quantitative evaluation of DT ROI across lifecycle stages, development of automated ontology mapping techniques and investigation of socio-technical governance models addressing data sovereignty, security, and ethics.

Conclusions

This study addressed the challenge of fragmented DT implementation in the AECO industry by developing a structured Maturity–Barrier Logic that links DT evolution to interoperability constraints. A systematic analysis of existing literature, technical standards, and industry practices was conducted to examine the convergence of BIM, IOT, and DT technologies. Through this analysis, DT maturity stages were explicitly mapped against four critical transition barriers—Digitisation, Connectivity, Semantic, and Trust/Governance gaps—thereby reframing DT progression as a sequence of constrained transitions rather than a purely linear technological evolution. The findings reveal a significant disparity between theoretical DT maturity models and real-world implementation. While existing frameworks suggest a clear pathway toward autonomous and federated systems, most practical applications remain constrained at Level 2 (Digital Shadow). This stagnation is primarily driven by a semantic limitation where systems achieve syntactic connectivity but lack the ontology-based interoperability

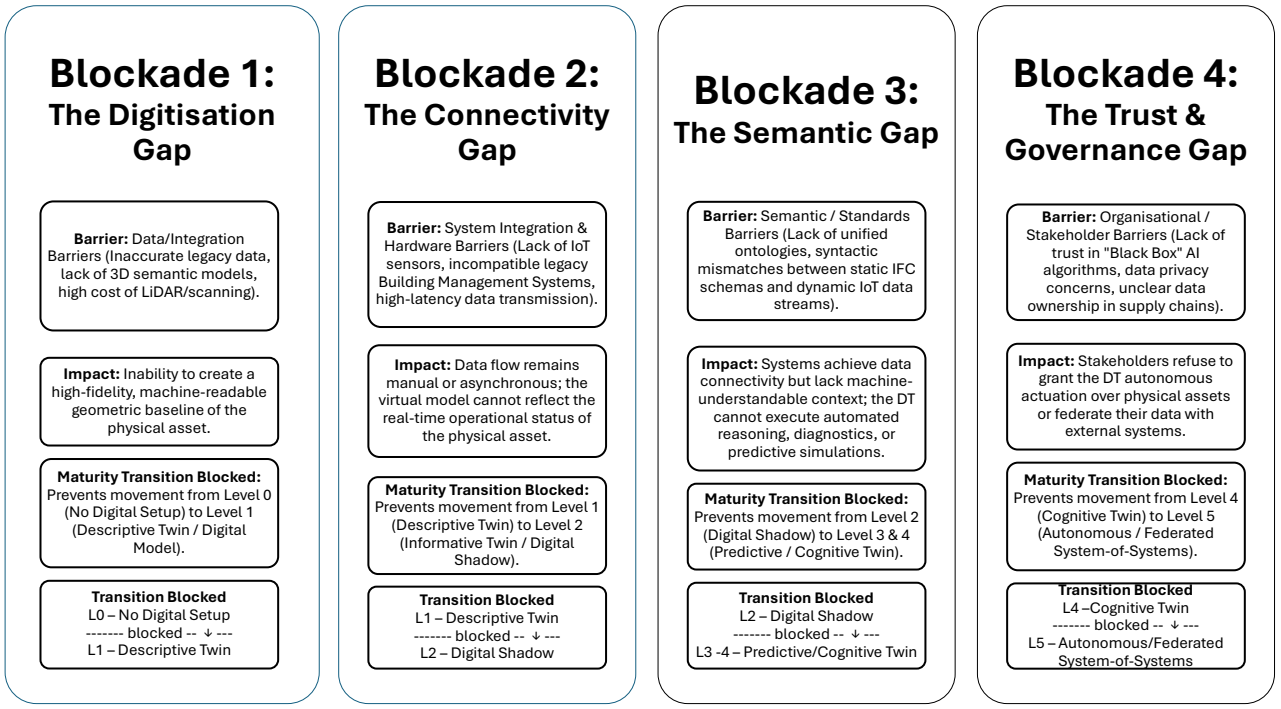

Figure 2: Barrier → Impact → Maturity Transition Diagram

required for machine understanding and AI-driven reasoning. Furthermore, progression to higher maturity levels is inhibited by a trust and governance gap, where organisational, legal, and ethical concerns surrounding data sharing and algorithmic transparency limit the adoption of fully autonomous and federated DT systems. These findings establish interoperability not as a secondary technical issue, but as the central enabling condition for DT maturity. Advancing DTs is less about deploying additional sensing technologies and more about enabling machine-readable, semantically aligned, and governable data ecosystems. Without addressing these barriers, the industry risks remaining confined to isolated, low-value digital implementations. This paper presents diagnostic and decision-support logic for practitioners and researchers alike. This review repositions the future of DTs as an interoperability-driven transformation, where the successful alignment of technology, data, and stakeholders determines the pathway from isolated digital models to fully integrated, intelligent DTs. Achieving this vision requires systematic resolution of the interoperability barriers identified in this study. By addressing these constraints, the industry can transition from fragmented digital implementations to cohesive, intelligent ecosystems that support global sustainability objectives, including Sustainable Development Goal 11.

Abstract

Industry Foundation Classes (IFC) enable interoperability across the AECO sector, yet IFC2x3 and IFC4 remain constrained by monolithic structures, limited external data integration, and weak support for real-time and web-based workflows. This paper applies comparative schema analysis and domain-based evaluation across four lifecycle phases, design, construction, operation, and deconstruction, to critically assess these limitations. Emerging IFC5 concepts are examined against identified requirements, highlighting both improvements and unsolved challenges, including governance complexity and implementation maturity. Results indicate increased flexibility and potential, alongside new dependencies and trade-offs. In conclusion, a forward-looking assessment and early-adoption priorities for IFC5-enabled data-centric workflows are provided.

Introduction

The architecture, engineering, construction, and operation (AECO) sector increasingly relies on Building Information Modeling (BIM) to meet growing demands for coordination, efficiency, and information exchange. Initially used for geometric representation, BIM has expanded to support model-based collaboration and a wide range of domain-specific use cases across the project lifecycle (Wang and Chen, 2023). However, to deliver its full value, such collaboration requires the continuous exchange of structured data among stakeholders (Shelden et al., 2020). Addressing this need, the Industry Foundation Classes (IFC) standard, developed by buildingSMART International (bSI), serves as an open and vendor-neutral data schema to support interoperability. It provides a standardized object-based digital description through entities, attributes, and relationships. This includes the geometry of elements as well as information related to processes and operations from design and construction, through safety, operational, and maintenance, to deconstruction (Li et al., 2025).

As industry requirements evolve, IFC technical committees extend the standard with new domain-specific definitions (Laakso and Kiviniemi, 2012), but formal adoption into official releases depends on lengthy ISO-compliant review processes. Consequently, practitioners and researchers frequently used custom solutions and dedicated IFC extensions, highlighting the need for more flexible data structures and interoperable information exchange (Yu et al., 2023).

With the construction industry becoming increasingly data-intensive and reliant on dynamic, multi-source digital workflows, the limitations of existing IFC versions (IFC2x3 and IFC4) have become more evident. These versions lack native support for real-time data exchange, integration with external data sources, advanced analytics, and modern visualization tools. To address these gaps, bSI started the development of IFC5 as a next-generation schema (Berlo, van et al., 2021).

Currently under development, IFC5 adopts modular and extensible architecture and supports multiple interoperable formats, including XML Schema Definition (XSD), Web Ontology Language (OWL), and JavaScript Object Notation (JSON). Moreover, its integration with visualization technologies, such as Universal Scene Description (USD), combines semantic content with real-time, interactive visualizations.

This paper examines current challenges and future opportunities of IFC5 for heterogeneous data integration and visualization across the project lifecycle. Four lifecycle phases and representative use cases are considered: design (cost and time management), construction site health and safety (H&S) management, operation and maintenance (O&M), and circular deconstruction. Based on a literature review of IFC-based approaches for integrating BIM data, a set of functional requirements that the schema should support in each domain, with emphasis on data representation, exchange, and integration, was identified. These requirements ensure a comparative schema analysis of IFC2x3 and IFC4, highlighting recurring gaps and challenges across phases. The analysis subsequently examines emerging IFC5 concepts to discuss how far they address these limitations and to what extent they can support more flexible and interoperable data environments. Overall, the paper analyses the ongoing evolution of IFC and discusses early adoption, as well as the practical implications of integrating IFC5 into data-centric AECO workflows.

Research questions and methodology

To assess the current limitations and future potential of IFC for data-centric integration and visualization across four representative lifecycle use cases, the following research questions (RQs) were identified:

- RQ1: *Which limitations emerge for data representation, exchange, integration, and visualization in the IFC2x3 and IFC4 versions across key lifecycle phases of the built asset?*
- RQ2: *To what extent do emerging IFC5 concepts address these gaps, and what trade-offs and implications emerge for implementation across the same lifecycle phases?*

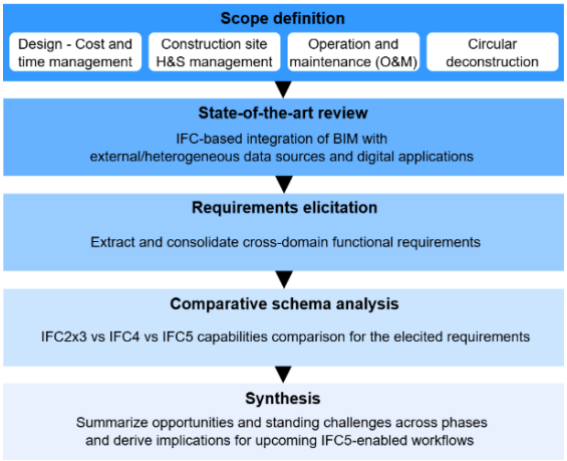

Figure 1: Research methodology

Building on these RQs, the study follows the workflow reported in Figure 1. First, the scope is defined by selecting four lifecycle phases and representative use cases: cost and time management, construction site H&S management, O&M, and circular deconstruction. A state-of-the-art review is then conducted, focusing on IFC-based approaches that integrate data sources and digital applications in these domains. Building on the literature, both specific and cross-domain functional requirements are derived and are intended to capture recurring patterns across lifecycle phases and use cases. These are subsequently used as evaluation criteria in a comparative assessment of IFC versions' capabilities, to determine which address the identified needs and to highlight gaps, trade-offs, and implications for upcoming implementations. Finally, findings are synthesized to summarize key challenges and opportunities.

Background

Since its early releases, IFC has been developed as a vendor-neutral schema to support information exchange across the AECO sector. Its evolution since the late 1990s reflects growing industry requirements alongside data modeling constraints (Laakso and Kiviniemi, 2012).

IFC2x3, standardized as ISO/PAS 16739:2005, remains the most widely implemented version. Based on a monolithic STEP/EXPRESS architecture optimized for file-based exchange, it reliably represents geometry and core building semantics. However, limited extensibility, weak integration of external data, and reduced support for process-oriented information constrain its suitability for data and real-time workflows (Jia et al., 2024).

IFC4 ADD2 TC1, standardized as ISO 16739-1:2018, following a first release in 2013, introduced incremental refinements over IFC2x3, including improved geometric representations, clearer and more extensive property sets (PSets), stronger semantic consistency, and closer alignment with Model View Definitions (MVDs). Complementary Information Delivery Specifications (IDS) and buildingSMART Data Dictionary (bSDD), further support the validation and definition of information requirements. IFC4 also expanded process-related modeling and domain coverage, though it preserved the underlying monolithic exchange paradigm. Subsequent revisions culminated in IFC4.3, released in 2024 as ISO 16739-1:2024, extending the schema to infrastructure assets with the same architectural foundations. As a result, despite a broader scope and richer semantics, persistent structural constraints remain, particularly regarding extensibility, modular evolution, and alignment with web and cloud-native environments (Yu et al., 2023). To address these constraints, IFC5 is under development as a step-change toward a modular, decomposed architecture supporting multiple serializations (e.g., XSD, OWL, JSON). This shift aims to improve interoperability with digital ecosystems and real-time workflows, while introducing new challenges related to governance, migration, and tooling maturity. In parallel, emerging OpenUSD-based pipelines illustrate how IFC semantics can be integrated with high-performance visualization frameworks to support digital twins and interactive applications (Ren et al., 2025).

The following subsections review IFC-based implementations across the selected lifecycle phases, summarizing the state of the art and informing of the functional requirements used in the comparative analysis.

Cost and time management – Design phase

During the design phase, BIM has been increasingly adopted to support cost estimation and scheduling, enabling earlier and more informed decision-making. In this context, 4D and 5D BIM, which integrate time and cost information with 3D geometry, have been widely investigated to improve transparency and control during design (Yang et al., 2022). Prior research has shown that model-based quantity take-off, automated cost calculation, and links to external cost databases can improve accuracy and consistency compared to document-based workflows (Sacks et al., 2018).

Recent studies have revisited the role of IFC in cost estimation and scheduling, demonstrating that cost and time information can be explicitly modeled using entities such as *IfcCostItem*, *IfcCostSchedule*, *IfcTask*, and *IfcWorkSchedule*. For example, Cassandro et al. (2024) propose an IFC-based approach linking cost items directly to geometric elements, enabling semi-automated cost calculation and validation, while comparative results indicate reductions in manual coding and errors relative to traditional 5D BIM software. Similarly, Fürstenberg et al. (2021) show that IFC4-based process models can support data exchange across stakeholders and software.

Despite these advances, cost and scheduling information are still rarely managed directly within IFC in practice. Instead, they are typically handled in external tools using

proprietary formats (Borrmann et al., 2018). Links between geometry, cost, and time are commonly established through key–value mechanisms (e.g., identifiers, classification systems, or WBS codes), rather than through semantically explicit relationships (Boje et al., 2020). Consequently, current IFC-based workflows support data exchange rather than full data integration, leaving cost and time data external to the model and highlighting persistent challenges in modeling effort, tool support, and workflow integration.

Site and safety management – Construction phase

During construction, processes become more dynamic and seamless information exchange becomes crucial. Construction site H&S management is shaped by spatiotemporal complexity, as risk emerges from changing conditions, temporary works, and interactions among workers, equipment, and partially completed assets. Therefore, effective digital support requires situational awareness of what is being built, the sequencing and spatial context of activities, and the evolution of hazards and mitigation measures as the site layout changes (Zhang et al., 2024). IFC-based workflows address these needs by offering a shared, vendor-neutral backbone that anchors H&S information to a consistent spatial and semantic reference (Hu et al., 2024). Safety relevant attributes can be linked to elements and spaces via PSets and classifications, while process constructs (e.g., tasks, schedules) connect activities to affected components, enabling 4D safety reasoning and automated or semi-automated checks (e.g., fall risks) and visual outputs such as hazard maps (Hong and Teizer, 2025). Temporary works and site logistics remain essential yet often under-specified, so many approaches rely on modeling conventions, dedicated libraries, or external datasets linked through IFC identifiers to maintain consistency across revisions (Getuli et al., 2025). Given the document-intensive nature of H&S, exchanges must preserve traceability (e.g., inspection reports or photos) and support heterogeneous, frequently updated data streams (e.g., sensor observations) through linked services or databases rather than embedding volatile data in static files (Amo Larbi et al., 2024). Issue communication and visualization-ready delivery (e.g., dashboards) are also central, with growing attention to AR-assisted compliance checks (Corneli et al., 2025) and integrated VR/AR safety training (Getuli et al., 2020).

Operation and Maintenance – Operational phase

Effective management decisions during the operational phase require timely, accurate information on building components, systems, and their performance over time. IFC-based methodologies have been investigated to support the transition from construction to O&M. Key IFC entities, including MEP element classes, O&M-related PSets, and space-related constructs, provide the semantic linking of physical assets with maintenance data, performance indicators, and lifecycle cost data (Patacas et al., 2016). Several extensions to IFC4 have been proposed to improve the representation of maintenance activities, inspection, and failure modes. In parallel, COBie has become a widely adopted standard for structuring O&M data at handover; however, its implementation continues to face challenges related to data consistency and tool interoperability (Oliveira et al., 2024).

Despite these efforts, interoperability and data quality problems remain significant. O&M systems (such as CAFM and CMMS) rely on proprietary schemas that are incompatible with IFC, often requiring custom integrations that increase complexity and error risk (Farghaly et al., 2018). Operational data, including sensor measurements and work orders, are typically stored in external databases and only referenced in BIM models. Existing PSets frequently fail to meet O&M needs, leading to custom extensions and data loss during data exchanges (Tomczak et al., 2022). Additional barriers include inaccurate as-built models, generic O&M MVD, and organizational limitations such as insufficient BIM expertise and high implementation costs (Otranto et al., 2025). Emerging digital twin approaches aim to address these limitations by integrating real-time Internet of Things (IoT) sensor data with IFC, enabling continuous monitoring and predictive maintenance (Biagini et al., 2024). However, challenges related to data governance, interoperability, and standardized workflows limit large-scale implementation.

Circularity and reuse – Deconstruction phase

Robust reuse outcomes require reliable data: accurate as-built models and maintenance records enable assessment of reuse potential. Requirements for circularity, reuse, and deconstruction are inconsistently defined. Life Cycle Assessment (LCA) is central, but in IFC2x3/IFC4, its integration typically relies on custom PSets (Guntermann et al., 2025). Diverse metrics (e.g., global warming potential, service life, disassemblability) complicate integration. Harmonization efforts, as in the bSDD, are critical for a design for deconstruction (DfD) and for planning with reused components in a closed-loop circular economy. Kim, S. and Kim, S.-A. (2023) developed a graph-based DfD tool for steel construction using *IfcRelConnectsElements,* and Allam and Nik-Bakht (2025) combined knowledge graphs with IFC to automate deconstruction planning, deriving XML-based schedules with 4D simulations from PSets and IFC classes. Representation and extraction of circular information remain challenging. Tomczak et al. (2024) reported difficulties documenting disassembly instructions and element connections in IFC. While *IfcStructuralPointConnection* captures connection types for structural elements, non-structural components (e.g., windows) are more problematic. Mantelatto et al. (2026) used a Python routine based on IfcOpenShell to extract interdependence between structural elements.

IDS validates IFC information requirements. For circularity, limitations stem from IDS v1.0, not IFC: requirements address only individual entities (no cross-entity generalization), and abstract IFC classes cannot be referenced – since *IfcPort* is abstract, non-structural elements cannot be validated this way (Guntermann et al., 2025; Tomczak et al., 2024). Reuse Marketplaces

(Hagedorn et al., 2025) impose further requirements: component separability is critical; workflows require extracting and publishing component-level IFC files, raising feasibility questions around reliable extraction/integration and ID management, especially the fate of GUIDs when components are cut and whether parent IDs can generate child IDs.

Data requirements for IFC standards

This section consolidates five shared, cross-domain requirements for data integration and visualization, identified through analysis of the four lifecycle use cases. Although their relative importance varies across different stages, all requirements recur in multiple domains and therefore constitute shared evaluation criteria for the comparative analysis of IFC2x3, IFC4, and IFC5 concepts presented in the following sections.

Data model extensibility

To support evolving lifecycle needs, a schema is required that can be extended with additional concepts, attributes, and relationships while remaining stable across versions. This is essential for integrating heterogeneous data, such as cost structures, safety rules, operational and deconstruction data, without compromising interoperability, since limited extensibility often leads to proprietary extensions or reliance on external data, weakening standard-based integration.

Integration with external datasets

The capability to reference, align, and synchronize non-IFC data sources with IFC-based models is critical for integrating cost databases, construction schedules, sensor streams, regulatory documents, maintenance records, and environmental data. Beyond simple identifiers or file references, it requires semantically explicit links, version awareness, and support for heterogeneous data models, since authoritative information often resides outside BIM authoring environments across all lifecycle phases.

Time-aware and real-time application support

Representing and managing time-dependent states, events, and changes is essential to support dynamic workflows such as construction sequencing, safety monitoring, asset condition tracking, and lifecycle performance analysis. Time-aware data support includes explicit temporal relationships, event modelling, and the capacity to accommodate incremental updates and streaming observations. Without these capabilities, IFC models remain difficult to use in real-time applications.

Web-friendly data exchange

Suitability for modern web-based and cloud-native toolchains depends on efficient exchange and integration mechanisms, including lightweight serializations, API-based access, partial data retrieval, and reduced parsing overhead. These capabilities are increasingly important for collaborative platforms, digital twins, and distributed applications, where file-based, monolithic transfers introduce performance and scalability bottlenecks.

Performance-oriented geometry representation

Efficient use in high-performance visualization and rendering pipelines – such as real-time viewers, simulation engines, and immersive environments – depends on geometry representations that are performant to parse, stream, and render. While semantic richness remains essential, excessive geometric complexity or tightly coupled semantics can hinder interactive performance. This need is especially relevant for large-scale models, for advanced construction monitoring and XR-enabled interactive applications across the lifecycle.

Comparative analysis of IFC capabilities

This section qualitatively evaluates how IFC2x3, IFC4, and IFC5 support the identified requirements. Using the four use cases as reference scenarios, it focuses on structural capabilities rather than tool implementations.

Data model extensibility

IFC2x3 exhibits limited extensibility due to its monolithic schema and rigid inheritance structure. Concepts beyond the design phase are therefore typically introduced through custom PSets and informal conventions rather than controlled domain evolution, leading to inconsistent semantics and weak validation. In cost and time management, entities such as *IfcCostItem* and *IfcTask* exist but offer limited expressiveness, often prompting ad-hoc extensions. In construction H&S, safety concepts (e.g., hazards) are not first-class entities and are commonly represented via custom PSets and linked documents, reducing interoperability. Similarly, in O&M, *IfcAsset* provides only a basic anchor and lacks the operational structures expected by CAFM/CMMS systems, while deconstruction workflows rely almost entirely on project-specific extensions due to minimal native support for circularity and LCA information.

IFC4 expands semantic coverage and improves conceptual clarity, reducing the need for customization in some areas, while largely preserving the same extensibility mechanisms based on PSets, classifications, and external links. As a result, fragmentation persists in domains that require structured, evolving semantics. Refinements in cost and time entities, standardized risk-related properties for H&S, and the introduction of entities for O&M represent incremental progress. Still, they do not fully support complex workflows such as work-order hierarchies or lifecycle-oriented extensions. Deconstruction-related information still depends heavily on custom PSets and external vocabularies (e.g., bSDD).

IFC5 explicitly addresses these limitations through a modular architecture that separates stable core concepts from domain-specific modules, enabling parallel and governed semantic evolution across lifecycle phases. While this improves the feasibility of dedicated extensions, it also introduces coordination challenges related to versioning and cross-module consistency. Moreover, while increased extensibility facilitates customization, it must be carefully managed to avoid a proliferation of project-specific data that could compromise interoperability.

A comparative overview of IFC extensibility across lifecycle phases is provided in Figure 2.

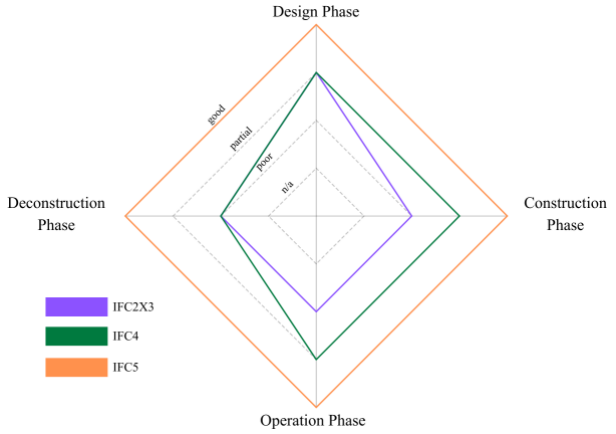

Figure 2: Data model extensibility chart

across data sources. The IFC integration with external datasets across lifecycle phases is provided in Figure 3.

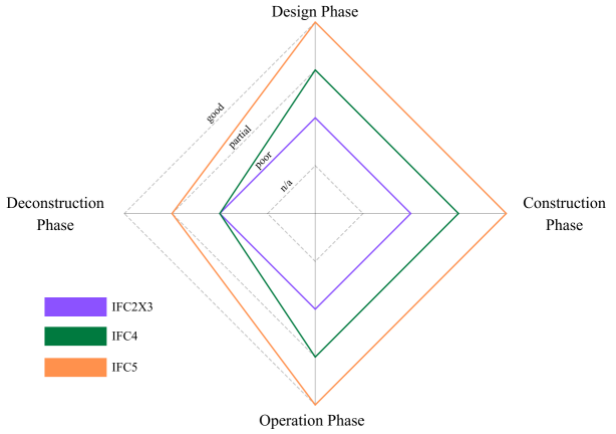

Figure 3: Integration with external datasets chart

Integration with external datasets

In IFC2x3, integration with external datasets is largely implicit and identifier-based, relying on GUID matching, classification codes, and file references, with limited semantic alignment. In cost estimation, this leads to static connections of costs, schedules, and physical elements, pushing 4D/5D workflows to external systems without mechanisms for consistency checking. In construction H&S, safety documentation and site observations remain outside the model and are merely referenced, limiting traceability, automated compliance checks, and reliable synchronization. Similarly, in O&M, basic reference constructs provide insufficient structure to integrate CMMS work orders, IoT streams, or maintenance data. Deconstruction workflows face comparable limitations, as native support for integration with Geographic Information Systems (GIS) and Environmental Product Declaration (EPD) datasets is largely absent.

IFC4 improves reference mechanisms and clarifies process-related semantics, enabling more explicit associations between IFC and external datasets such as cost databases, schedules, H&S checklists, and O&M resources. While this reduces ambiguity compared with IFC2x3, data typically remains external to the IFC model, and integration continues to rely on GUIDs. As a result, bidirectional synchronization with frequently updated sources, such as sensors, KPIs, or H&S issue lifecycles, remains weak and project-specific. Deconstruction scenarios still depend on external tools and additional semantic layers for GIS and EPD integration.

IFC5 explicitly targets heterogeneous integration through decoupled representations and web- and Linked-Data-friendly encodings (e.g., JSON/OWL), improving semantic interoperability with external services across domains. Alignment with OWL/RDF and Linked Data principles can support richer, machine-interpretable integration with ontologies (e.g., CI/SOSA/SSN), compliance repositories, CMMS, and issue-tracking systems. However, effective interoperability will ultimately depend on standardized mappings, governance frameworks, and robust identity and version management

Time-aware and real-time application support

In IFC2x3, support for time-aware and real-time applications is minimal and largely planning-oriented, with no effective constructions for dynamic events or state changes. As a result, cost and time management updates (e.g., schedule changes or actual versus planned values) are typically handled outside IFC, and 4D/5D workflows rely on external tools. In construction H&S, time-stamped safety events and evolving site conditions cannot be natively represented, limiting IFC's role to a static geometric reference. In O&M, *IfcTimeSeries* allows storage of time-dependent values but does not support event-driven transitions or maintenance histories, constraining native performance tracking. Circular planning workflows are similarly unsupported, as IFC2x3 provides no mechanisms for real-time monitoring or incremental change management.

IFC4 enhances scheduling semantics through richer process entities and relationships, enabling more explicit representation of planned timelines and dependencies. This supports improved cost and time planning and structured scheduling of H&S activities, such as inspections. However, the model remains essentially static: event-driven updates, state transitions, and continuous data flows are not natively supported. In O&M, although device entities are introduced, real-time data feeds and dynamic updates still depend on external platforms, reducing IFC4 to a reference role. Limitations also persist in circular planning, where incremental model changes and real-time visualization of evolving variants are not directly supported.

IFC5 introduces a conceptual shift toward time-aware and event-based representations, aligning more closely with digital-twin-oriented workflows. This could enable tighter coupling between schedules and changing quantities or costs, explicit modeling of temporal validity and evolving risk states in construction H&S, and dynamic asset states with predictive triggers in O&M. For deconstruction planning, event-based and incremental-change concepts could support more responsive variant tracking. However, their practical impact will depend on

specification choices, serialization, querying, synchronization, and performance in time-critical applications. Figure 4 summarizes the IFC time-aware and real-time application support across lifecycle phases.

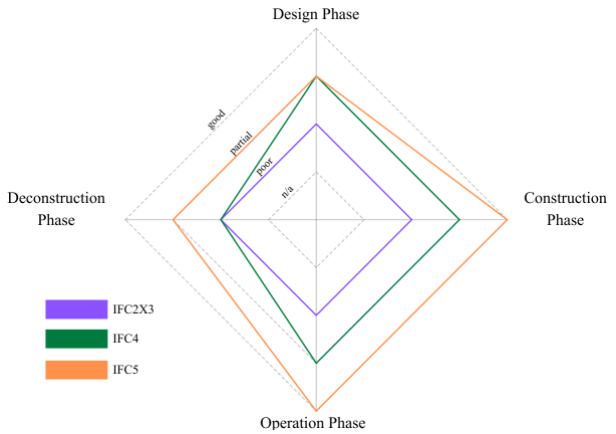

Figure 4: Time-aware and real-time application support chart

components and attributes. The trade-off is greater architectural complexity, requiring standardized interfaces and strong governance across distributed services. The outcomes are summarized in Figure 5.

Figure 5: Web-friendly data exchange chart

Web-friendly data exchange

IFC2x3 is fundamentally based on STEP and file-oriented exchange, resulting in large, monolithic datasets that are poorly suited to web-based workflows. This limits scalable collaboration in cost and time management, where querying, incremental updates, and API-driven interactions are weakly supported, and 4D/5D coordination typically relies on external tools and full-file transfers. In construction H&S, frequent dissemination of updated information requires repeated exchange of complete IFC files and linked documents, creating overhead for mobile and field use and weakening traceability. In O&M, routine cloud or mobile queries require full-file parsing, as spatial containment and relationships cannot be selectively accessed, making web-scale operations inefficient. Similar limitations affect deconstruction scenarios involving distributed stakeholders and reuse-oriented platforms.

IFC4 improves schema consistency and clarifies relationships but does not alter the underlying exchange paradigm. Web-based use cases, therefore, still depend on full file transfers or middleware layers. As a result, just-in-time access to relevant model subsets, such as elements affected by a task, safety issue, or cost update, remains difficult without external services. In O&M, despite clearer spatial constructs, the lack of native API patterns and partial extraction mechanisms continues to constrain cloud dashboards and mobile applications. Deconstruction workflows likewise remain poorly supported by monolithic exchange models.

IFC5 explicitly moves toward web-native exchange through lightweight, language-independent encodings that enable API-based access, partial data exchange, and incremental updates aligned with cloud-native toolchains. These capabilities support specific queries and updates in cost/time, fast publication of H&S changes, and REST-like access to assets and spaces for O&M applications. These capabilities suit distributed reuse and urban-mining workflows needing selective extraction and publication of

Performance-oriented geometry representation

IFC2x3 geometry prioritizes semantic completeness over real-time performance, which limits its suitability for interactive and visualization-intensive applications. In cost and time workflows, complex boundary representations and detailed solids often degrade performance in large models. In construction H&S, these limitations are particularly evident in AR/VR-based coordination and safety training, where low latency and stable frame rates are essential, requiring external conversion and simplification. In O&M, detailed geometric representations are excessive for dashboards, space management, and mobile wayfinding, while standardized lightweight proxies are not natively defined. Similar constraints hinder interactive visualization in deconstruction and reuse-oriented scenarios.

IFC4 improves geometric robustness and introduces tessellated representations, which better align with real-time rendering pipelines. However, performance-oriented geometry remains a secondary concern. Visualization workflows across cost/time analysis, H&S AR/VR applications, and O&M digital twins still depend on external optimization techniques or conversion to alternative formats. A key limitation is the tight coupling between semantics and geometry within product shape structures, which restricts selective extraction of lightweight, visualization-only subsets for streaming, incremental loading, and mobile or immersive use. Circular planning workflows face comparable constraints.

IFC5 explores a clearer separation between authoritative semantics and visualization-optimized geometry, with conceptual alignment to high-performance scene frameworks such as USD. This approach can support responsive model exploration in cost/time management, multiple levels of geometry tailored to AR/VR safety coordination, and simplified operational views for O&M applications consumed directly by web or AR tools. For circular design, it enables interactive evaluation of reuse scenarios. The main challenge lies in preserving semantic-

geometric coherence and traceability, ensuring that optimized visual assets remain reliably linked to authoritative IFC entities for auditing and regulatory purposes. A comparative overview of outcomes is provided in Figure 6.

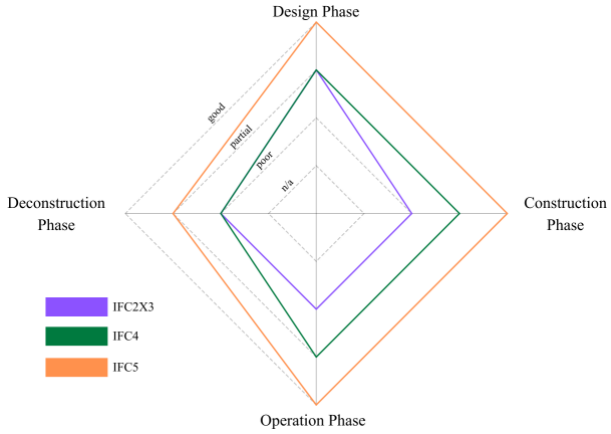

Figure 6: Performance-oriented geometry representation chart

Conclusion

This paper evaluates the current state of IFC2x3 and IFC4 and examines the future potential of IFC5 for data-centric integration across the building lifecycle. The comparative analysis highlights that IFC2x3 and IFC4 remain largely constrained by a monolithic, file-based exchange paradigm. Although IFC4 introduces notable semantic and geometric improvements, persistent limitations affect all lifecycle phases, particularly in operation and deconstruction. These include limited extensibility beyond geometry-centric models, reliance on identifier-based links to external data sources, and insufficient support for time-aware and real-time workflows.

The analysis of IFC5 indicates a strategic shift toward modular, web-aligned architectures, supporting multiple encodings and improved integration with contemporary toolchains. However, these advances redistribute rather than eliminate complexity, introducing new challenges related to governance, tooling maturity, identity management, and semantic consistency across distributed representations. Moreover, while increased extensibility facilitates customization, it must be carefully managed to avoid a proliferation of project-specific data that could undermine interoperability. Several critical capabilities also remain dependent on implementation choices.

The main limitations of the study comprise the lack of quantitative evaluation and empirical validation, as well as limited consideration of context-specific regulatory aspects and management implications. Future work will address these issues through quantitative metrics, real-world validation, and further investigation of governance and coordination aspects.

In conclusion, while IFC4 represents an essential evolution beyond IFC2x3, it does not fully address interoperability constraints. IFC5 offers a promising reorientation toward integration-oriented workflows, whose success will depend on robust governance frameworks, mature tooling, and standardized integration patterns beyond traditional file-based exchange.

Abstract

Automated symbol recognition in Piping and Instrumentation Diagrams (P&IDs) is challenging due to varying standards and complex structures where text, lines, and symbols are intermingled. This study proposes a non-learning-based framework applying extended template matching using the symbol legend. The framework extracts the Region of Interest (RoI) masks via the Convex Hull algorithm and performs matching using Intersection over Union (IoU) as a similarity metric to reflect spatial similarity. Subsequently, Intersection over Minimum (IoM)-based Non-Maximum Suppression (NMS) is introduced to suppress duplicate detections. Experiments on real-world industrial P&IDs achieved an F1 Score of 0.992, demonstrating its applicability to P&ID digitization.

Introduction

Piping and Instrumentation Diagrams (P&IDs) are fundamental engineering drawings in the plant industry, illustrating equipment, piping, and control systems along with their functional relationships. Serving as essential reference materials throughout the project lifecycle from design to operation, P&IDs utilize standardized symbols to represent critical information regarding process flow, control logic, and safety mechanisms (Kim et al., 2025).

P&ID reviews are conducted iteratively to ensure design accuracy, safety, and consistency. Although P&IDs are generated using Computer-Aided Design (CAD) tools where symbols are managed as blocks, design attributes are often not fully embedded within the drawing. Consequently, detailed specifications are managed in external documents rather than being intrinsically linked to the P&ID, creating challenges in reviewing and linking data (Kang et al., 2019; Koziolek and Koziolek, 2024).

In this environment, digitizing P&IDs for integration into downstream systems requires the preliminary process of manually identifying instruments, equipment, piping elements, and their interconnections. For instance, symbol label information must be matched with external documents such as equipment lists and datasheets. Most of these tasks rely on manual work by skilled engineers, rendering the process time-consuming and labor-intensive. Furthermore, this approach often leads to errors, omissions, and data inconsistencies, highlighting the necessity for automated symbol recognition (Li et al., 2025; Shteriyanov et al., 2025a).

However, the automation of P&ID symbol recognition faces several challenges. First, when CAD drawings are distributed as static images, block-based structures are lost, leaving symbols as a collection of simple geometric primitives without object-level semantics (Su et al., 2024). Second, as illustrated in Fig. 1, symbol geometries and labeling conventions vary significantly depending on the project, client, and design standards. General rule-based approaches or models trained on fixed datasets often fail to generalize across these diverse project-specific variations (Gupta et al., 2024).

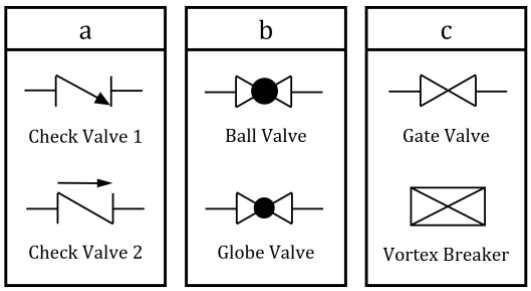

Figure 1: Examples of variations in P&ID symbol and labeling conventions: a) Different symbol geometries with identical labels; b) Identical symbol geometries with different labels; c) Similar symbol geometries with different labels.

To address this challenge, this study exploits symbol legend included in P&IDs. The symbol legend systematically defines the symbols, names, and codes used in a specific project, clearly presenting the project-specific symbol standards applied throughout the drawing set. In this study, symbols defined in the legend are constructed as symbol templates to serve as references for automated recognition. Based on this, we propose a template matching approach utilizing the Intersection over Union (IoU) metric.

First, symbol templates are constructed through preprocessing, and the Region of Interest (RoI) for the symbol is extracted using the Convex Hull algorithm. Subsequently, the symbol template is overlaid on the P&ID using a sliding window method to systematically scan the drawing. The similarity between the symbol template and the symbol candidate area (P&ID patch) is quantitatively evaluated using the IoU metric. If the similarity exceeds a predefined threshold, the instance is stored as a symbol candidate. Thereafter, to resolve the issue of duplicate detections, an Intersection over

Minimum (IoM)-based Non-Maximum Suppression (NMS) technique is applied to ensure a single, unambiguous detection result for each symbol instance.

This approach enables accurate symbol recognition in image-format drawings without requiring additional training data, while simultaneously allowing for the reflection of project-specific symbol standards. The main contributions of this study are summarized as follows:

- An IoU-based template matching framework is proposed to evaluate spatial similarity instead of pixel intensity, demonstrating superior performance in binary P&ID environments.
- The Convex Hull algorithm is utilized to extract precise RoI masks, thereby ensuring matching reliability against background noise.
- An IoM-based NMS is adopted to strictly and effectively filter duplicate detections in symbol-dense areas.

Background

Driven by advancements in AI, research on automated P&ID symbol recognition has primarily focused on approaches utilizing deep learning models and Visual Language Models (VLMs). These studies aim to automatically extract equipment, piping, and instrumentation information from P&IDs and convert them into structured digital data. However, existing studies have limitations, such as the prohibitive costs of constructing massive training datasets, high computational resource consumption, and compromised positional precision. To overcome these issues, this study proposes an improved template matching technique utilizing a RoI-based mask-aware matching strategy and the IoU spatial similarity metric.

Deep Learning Model for Symbol Recognition

Deep learning-based approaches offer the advantage of simultaneously predicting the location and class of symbols within an image, enabling robust recognition even in complex P&ID environments where numerous symbols coexist. For instance, Gada. (2021) applied transfer learning by fine-tuning various detection models pre-trained on MS-COCO dataset, such as Single-Shot Detection Network, Region-based Fully Convolutional Networks, and Faster Region-based Convolutional Neural Networks (Faster R-CNN), on a self-constructed P&ID dataset. Experimental results showed that Faster R-CNN achieved the best performance with an F1 Score of 66.1%. Additionally, Kim et al. (2021) generated a P&ID symbol dataset using the SmartPlant P&ID program and adopted RetinaNet, which leverages Focal Loss, significantly improving the detection rate for small or overlapping objects and achieving an F1 Score of 96.2%. In a related effort, Gajbhiye et al. (2023) constructed a dataset by segmenting P&IDs into square images of various sizes and labeling them,and performed symbol recognition using You Look Only Once (YOLO) v5 model trained on this dataset, achieving an F1 Score of 93.0%. Furthermore, Su et al. (2024) incorporated a Squeeze-and-Excitation attention mechanism into the YOLOv5 model to enhance feature representation, achieving an F1 Score of 93.9% through this approach.

Despite the strong representational capabilities of these models, deep learning-based approaches require extensive labeled datasets and iterative training cycles to achieve satisfactory performance. As illustrated in Fig. 2, building a symbol detection model necessitates an iterative process of dataset construction, model training, model evaluation, and model retraining, which imposes significant time and resource burdens in real-world industrial environments. This dependency limits their applicability in environments where design standards change frequently, and new symbols are continuously introduced.

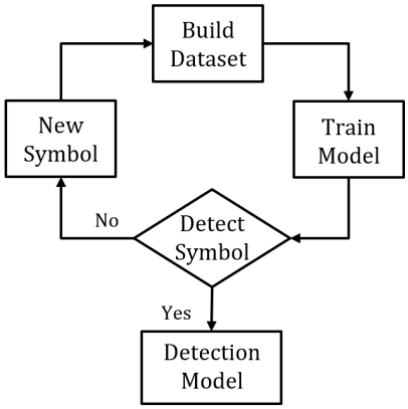

Figure 2: Building process of a deep learning model for symbol detection.

Visual Language Model for Symbol Recognition

Recently, P&ID recognition approaches based on VLMs have been proposed. Since VLMs can process images and text simultaneously, they can interpret symbols and text labels within P&IDs contextually. For example, Shteriyanov et al. (2025b) established a hybrid pipeline that interprets various formats of symbol legend without training through multi-modal prompting of VLMs and combines this with OCR-based drawing recognition results, recording 100% accuracy in legend classification and information extraction. Furthermore, Ghosh (2025) proposed a framework that utilizes VLMs as an automated quality evaluator for object detection results to verify the outputs of existing object detectors and identify missed objects. To overcome the limitations in the spatial reasoning capabilities of VLMs, the study combined visual, text, and geometric grounding, achieving an F1 Score of 87.6% in object identification.

While these studies demonstrate the potential of VLMs for P&ID interpretation, whether such results hold under the challenging visual conditions commonly encountered in real engineering drawings has not been sufficiently validated. In this regard, Shteriyanov et al. (2025c) introduced BlueprintSymVL, a benchmark for evaluating VLM symbol recognition. This benchmark is designed to isolate and test visual challenges inherent to the blueprint domain, such as symbol density, occlusion, and visual

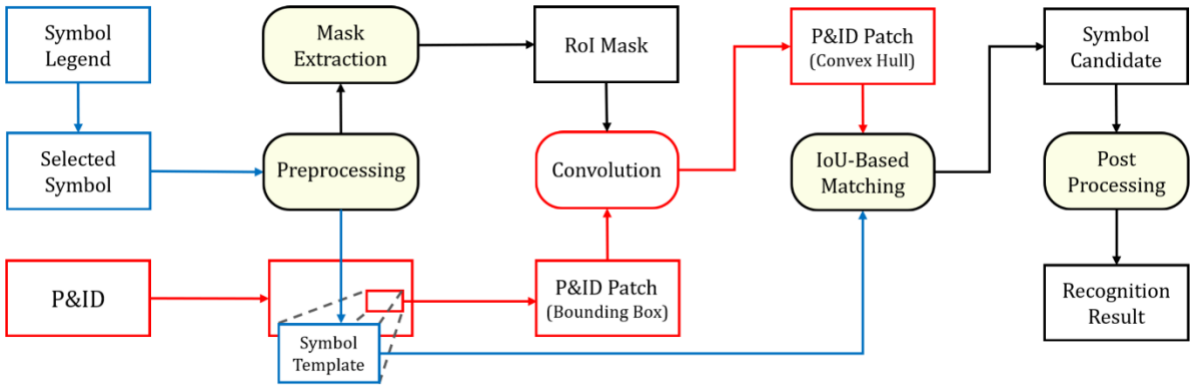

Figure 3: Flowchart of the proposed method. Blue and red paths represent symbol template generation and P&ID patch refinement, integrated for IoU-based symbol recognition.

similarity, and evaluates the visual generalization capability of models through a one-shot visual in-context querying strategy. An evaluation of four VLMs (GPT-4o, Gemini 2.5 Pro, InternVL 2.5 78B, and Qwen 2.5 VL 72B) showed that while the rate of simultaneously matching both symbol counts and labels reached up to 86% in simple scenarios, it dropped sharply to below 32% in dense conditions and below 38% in the presence of visually similar symbols.

In conclusion, VLM-based approaches can alleviate data scarcity as they handle diverse symbols without additional training. Nevertheless, these methods incur high computational costs due to image-based inputs, and recognition quality degrades substantially under such domain-specific challenges. Additionally, specifying the positional coordinates of symbols on P&IDs remains often infeasible with current VLM-based approaches.

Template Matching for Symbol Recognition

Before the emergence of deep learning model and VLMs, the most prevalent approach for symbol recognition was template matching (Kang et al., 2019). This method quantitatively calculates the similarity between a predefined template image and an input drawing to search for the location with the highest value. To quantify this degree of matching, various mathematical formulations based on pixel intensity distributions are employed as similarity metrics.

Representative similarity metrics include the Normalized Correlation Coefficient (TM-CCOEFF-NORMED), Normalized Cross Correlation (TM-CCORR-NORMED), and Normalized Squared Difference (TM-SQDIFF-NORMED) provided by the OpenCV library (OpenCV: Template Matching).

Specifically, the Normalized Correlation Coefficient normalizes the sum of the products of values after subtracting the mean from both the template and the image patch to a range of -1 to 1; a value closer to 1 indicates a perfect match, while a value closer to -1 implies an inverted match. Normalized Cross-Correlation normalizes the sum of the direct products of pixel values between the template and the image patch to a range of 0 to 1, where a value closer to 1 signifies a perfect match. Normalized Squared Difference normalizes the sum of squared differences between the pixel values of the template and the image patch to a range of 0 to 1, with a value closer to 0 indicating a perfect match.

Since these metrics evaluate similarity based on the statistical distribution or correlation of pixel intensities, they demonstrate robust matching performance in typical natural image environments characterized by illumination variations or noise. However, in P&ID environments characterized by binary properties (black and white pixels), these intensity-based metrics may not be intuitive. For instance, TM-CCOEFF-NORMED calculates similarity within a range of -1 to 1 based on the mean and deviation of pixel values. In binary images, there is a risk that such statistical operations may lead to an over-estimation of the score due to the dominance of matching background pixels, rather than directly representing the morphological similarity of the actual object.

Therefore, considering the binary characteristics of P&IDs, this study adopts IoU as the core metric for similarity measurement. IoU calculates the ratio of the intersection to the union between two areas, intuitively representing the degree of pixel overlap based on spatial occupancy rather than pixel values. Furthermore, for the purpose of this study, which requires verifying how accurately the P&ID patch refined by RoI aligns with the symbol template, the IoU-based approach, which imposes a strict penalty for morphological mismatch, is judged to be more suitable.

Methodology

Fig. 3 illustrates the overall workflow of the framework proposed in this study. The entire process consists of four stages: 1) Preprocessing and Symbol Template Construction, 2) RoI Mask Extraction, 3) IoU-Based Template Matching, and 4) IoM-Based NMS Postprocessing.

Preprocessing and Symbol Template Construction

To achieve symbol recognition in P&IDs using a template matching approach, it is essential to clearly define the target symbols and prepare standardized templates. In this study, to accurately reflect the actual symbol system used in the project, we referenced the symbol legend included in the P&IDs. Target symbols were selected based on their

frequency of occurrence and structural simplicity, and each symbol was extracted in an image format.

Since symbols in actual P&IDs do not maintain a form perfectly identical to the selected symbols, rotation, flipping, and scale adjustment were performed on the symbols prior to matching. However, certain symbols retain the same shape even after flipping or rotation. Since such cases reduce computational efficiency, rotation and flipping were performed first, followed by the removal of redundant variations.

Subsequently, scale adjustment was applied to prevent matching failures caused by minor size discrepancies. The symbol images processed in this manner were binarized to reduce background effects and ensure consistent similarity evaluation in IoU-based matching. Furthermore, optimal symbol templates for matching were constructed by applying a Bounding Box algorithm that computes the minimum enclosing rectangle of the symbol object to eliminate unnecessary margins. This series of preprocessing steps establishes a foundation for handling morphological variations in symbols without relying on learning-based approaches.

RoI Mask Extraction

Additionally, in this study, the Convex Hull algorithm was introduced to extract RoI mask to enhance the quality of template matching. The Convex Hull algorithm is a technique that computes the smallest convex polygon that tightly encloses all line segments and geometric shapes. By utilizing this, it is possible to define an optimal region that encompasses the entire symbol without being affected by complex internal structures or voids. As shown in Fig. 4, the extracted RoI is converted into a binary mask where the region of interest is assigned a value of 1 and the background is assigned a value of 0, enabling its direct utilization in the subsequent IoU-based template matching process.

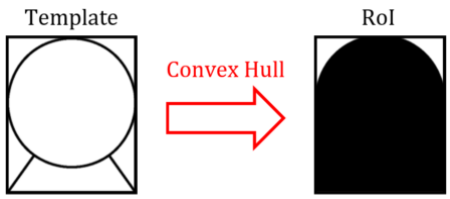

Figure 4: Example of RoI mask extraction results for Symbol Templates using the Convex Hull algorithm.

IoU-Based Template Matching

This study applies a template matching approach utilizing IoU as a similarity metric to evaluate the similarity between the preprocessed symbol templates and P&ID patches. Template matching is performed using a sliding window strategy, where each symbol template is moved with a fixed stride to overlap with the entire P&ID, and the IoU value between the symbol template and the underlying P&ID patch is calculated at each position.

The IoU metric is calculated as the ratio of the intersection area to the union area between the symbol template and the P&ID patch. This formulation enables a quantitative evaluation of pixel-level spatial overlap and ensures that higher similarity scores are assigned when the symbol position, scale, and shape are well-aligned. The IoU is defined as Eq. (1), where T denotes the symbol template and P represents the P&ID patch.

$$IoU = \frac{area(T \cap P)}{area(T) + area(P) - area(T \cap P)} \quad (1)$$

The calculated value of the IoU metric varies significantly depending on the margins of the symbol template. As the margins in the symbol template increase, more noise from the P&ID patch is included, leading to lower similarity values and, consequently, matching failure. Therefore, in this study, matching was performed through a more refined IoU calculation utilizing the RoI mask obtained in the previous step.

Specifically, the IoU between the symbol template and the P&ID patch is calculated by dividing the area of binary pixel intersection of the two regions by the area of binary pixel union of the two regions. Here, the area of union was calculated by summing the areas of individual regions and subtracting the area of intersection between the two regions. Specifically, the pixel area of the symbol template is calculated by summing all pixels constituting the symbol. The pixel area of the P&ID patch is calculated by summing the values obtained by convolution using the RoI mask as a kernel. Similarly, the intersection of the two regions can be calculated by summing the values obtained by convolving the result of applying the RoI mask to the symbol template and the P&ID patch. If the IoU value calculated through this process exceeds a predefined threshold, it is determined as a match and stored as a symbol candidate.

IoM-Based NMS Postprocessing

As a result of template matching, multiple duplicate symbol candidates are generated for a single actual symbol location. If such duplicate detections are not removed, multiple bounding boxes corresponding to the same symbol remain, thereby degrading the reliability of the recognition results. In the general object detection domain, this issue is commonly addressed using IoU-based NMS. However, since conventional IoU-based NMS relies on the union area of two bounding boxes to evaluate overlap, a problem arises where the IoU value is calculated to be low, resulting in failure to remove duplicates despite actual overlap, particularly when the difference in scale between two candidates is significant.

To address this limitation, this study applies an IoM-based NMS method. IoM is defined as the ratio of the intersection area between two candidate regions to the smaller of their areas. This definition allows for a high degree of redundancy to be assigned even when a smaller candidate is fully or partially contained within a larger one. This characteristic is particularly suitable for the P&ID environment, where physical overlap between symbols is rare, but inclusion relationships between candidates of different scales occur frequently. The IoM is calculated as Eq. (2), where A and B denote the

Bounding Boxes of two distinct Symbol Candidates, respectively.

$$IoM = \frac{area(A \cap B)}{\min\big(area(A),\ area(B)\big)} \quad (2)$$

Candidates are first sorted in descending order based on their IoU-based similarity scores, and the candidate with the highest similarity is selected. Subsequently, other candidates whose IoM values with the selected candidate exceed a predefined threshold are considered duplicates and removed. By repeating this process, a single final detection result can be derived for each symbol location.

Experiments

Experimental Setup

To evaluate the performance of the proposed RoI-based IoU template matching and IoM-based NMS approaches, this section details the template construction, preprocessing parameter settings, and experimental data composition. As shown in Fig. 5, a total of 16 basic symbol types were extracted from the symbol legend to construct the template. Template dimensions vary by symbol type, ranging from 150 × 80 pixels to 510 × 510 pixels. Additionally, rotation and flipping were applied to the basic templates, and duplicates were removed to produce 66 symbol templates. Scale transformations were then applied, resulting in a total of 198 symbol templates. The parameters used for preprocessing are summarized in Table 1. All experiments were conducted on a Windows-based local PC equipped with an Intel i7-11700KF CPU (3.60 GHz) and 64 GB of RAM, utilizing a total of 8 worker threads for matching computations.

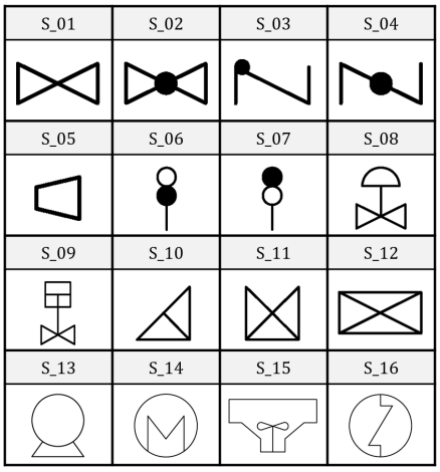

Figure 5: A total of 16 constructed Symbol Templates.

Table 1: Parameters used for preprocessing.

Parameters	Values
Rotataion	[0°, 90°, 180°, 270°]
Flippling	[True, Flase]
Scaling	[0.95, 1.0, 1.05]

Evaluation Dataset

To evaluate the practical applicability of the proposed method in industrial environments, four real-world plant P&IDs were utilized. These drawings were obtained from actual plant design projects and possess a high resolution of 19,867 × 14,034 pixels. Fig. 6 presents a representative example of the P&IDs used in this experiment, effectively illustrating the typical characteristics of real-world design drawings where various symbols, text, and fine connecting lines are intricately interwoven. Furthermore, the coexistence of symbols varying significantly in size and shape ranging from large equipment to small valves and instruments makes this dataset highly suitable for validating the robustness of the proposed method. In particular, small symbols such as valves and instruments often share similar shapes and tend to be densely clustered together, posing additional challenges for accurate recognition. These characteristics of the dataset play a crucial role in demonstrating the practical efficiency of the proposed method within real-world plant P&ID environments. The statistics of symbols contained in each drawing are summarized in Table 2.

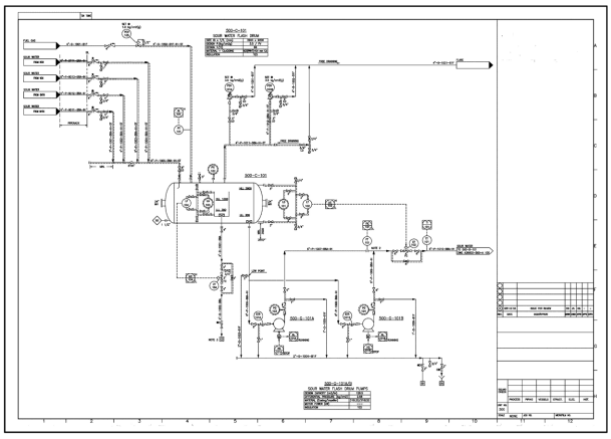

Figure 6: Example of P&ID (Drawing 1).

Tabel 2. Statistics of symbols contained in real-world plant P&IDs.

Symbol	s01	s02	s03	s04	s05	s06	s07	s08	s09	s10	s11	s12	s13	s14	s15	s16	**Total**

Evaluation Metrics

In this study, to quantitatively evaluate the matching performance of the proposed symbol recognition framework, the F1 score, which is the harmonic mean of Precision and Recall, was selected as the primary evaluation metric.

First, the validity of symbol recognition is classified based on the correspondence between the predicted symbol class and the Ground Truth. Cases where the predicted symbol class matches the ground truth are considered True Positives (TP). Conversely, cases where the predicted class differs from the actual class, or where a background region containing no symbol is misidentified as a symbol, are defined as False Positives (FP). Cases where an existing symbol is not detected are classified as False Negatives (FN).

In environments such as the dataset used in this experiment, where severe class imbalance exists or where the risks of False Positives and False Negatives coexist due to complex backgrounds, it is difficult to represent the comprehensive performance of the model using only single metrics like Precision or Recall. Therefore, this study adopted the F1 score as the definitive performance benchmark to objectively assess the model's robustness by balancing these two factors. The definition of the F1 score is as shown in Eq. (3).

$$F1 = \frac{2 \times Precision \times Recall}{Precision + Recall} = \frac{2TP}{2TP + FP + FN} \quad (3)$$

Experimental Results

This experiment conducted a comparative analysis of algorithm speed and matching quality among the conventional template matching methods provided by OpenCV, the standard IoU matching method (TM-IOU), and the RoI-based IoU matching method (TM-ROI-IOU).

First, the processing times of each algorithm were compared. Fig. 7 compares the time required to apply 198 preprocessed templates to a single P&ID. As shown in the graph, TM-CCORR-NORMED was the fastest, recording 328.03 seconds. In contrast, the TM-ROI-IOU proposed in this study was the slowest at 442.78 seconds, taking approximately 35% longer than TM-CCORR-NORMED. This increase in computational cost is primarily attributed to the additional pixel-level convolution operations required to apply RoI masks during the matching process.

Prior to evaluating matching quality, score interpretations were standardized to ensure a fair comparison across algorithms employing different similarity metrics. Specifically, for TM-SQDIFF-NORMED, where a value of 0 indicates a perfect match, the matching criterion was inverted (1 - value) to align with other metrics where higher values denote higher similarity. Under this standardized framework, the F1 score was assessed by increasing the matching threshold from 0.50 to 0.95 in increments of 0.05, as summarized in Table 3. Consequently, the TM-ROI-IOU demonstrated superior performance, achieving a peak F1 score of 0.992 at a threshold of 0.85.

Tabel 3. F1-Score of each algorithm according to threshold changes.

Threshold	0.50	0.55	0.60	0.65	0.70	0.75	0.80	0.85	0.90	0.95
TM ROI IOU (Ours)	0.443	0.743	0.850	0.961	0.978	0.984	0.984	**0.992**	0.907	0.393
TM IOU	0.838	0.864	0.871	0.974	0.978	**0.980**	0.971	0.957	0.831	0.308
TM CCOEFF NORMED	0.358	0.373	0.410	0.503	0.934	0.978	**0.980**	0.971	0.949	0.572
TM CCORR NORMED	0.348	0.372	0.379	0.403	0.494	0.899	0.961	**0.977**	0.964	0.788
TM SQDIFF NORMED	0.868	0.936	0.977	0.977	**0.977**	0.976	0.961	0.946	0.788	0.295

Discussion

Experimental results showed that the proposed template matching framework entails a higher computational cost than existing methods. This is attributed to the inclusion of the RoI mask extraction process to define valid regions within P&ID patches, as well as the subsequent convolution operations required throughout the matching process. Nevertheless, it achieves superior matching performance in terms of symbol recognition quality and reliability. Furthermore, the proposed method maintained stable performance even in real-world plant P&ID environments characterized by high resolution, a wide range of symbol sizes, dense arrangements, and complex piping structures. Notably, the improved results of RoI-based IoU matching over the non-RoI approach confirm that eliminating margins and minimizing unnecessary background calculations effectively mitigates missed detections caused by background noise. Fig. 8 illustrates examples of correctly recognized symbols in complex environments using the RoI-based IoU matching method.

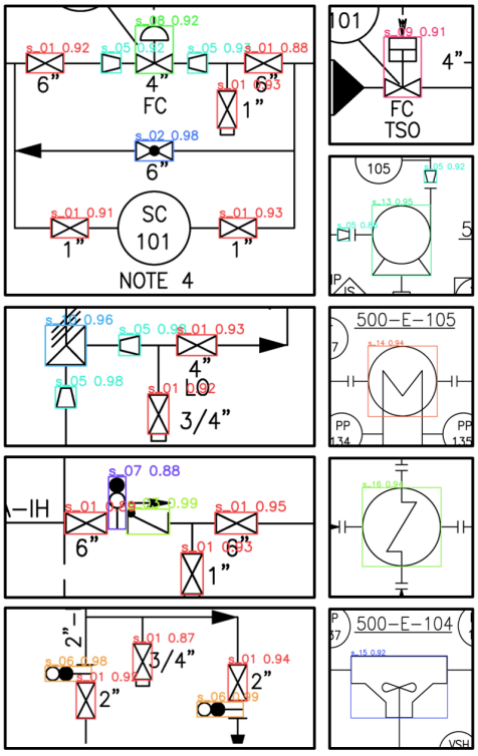

Figure 8: Examples of successful symbol recognition.

Although the proposed method successfully recognized the majority of symbols, limitations resulting in false positives and false negatives were observed for a minority of symbols. These failure cases can be categorized into three main types, as shown in Fig. 9.

First, there were cases where existing symbols were missed because their calculated similarity scores failed to exceed the threshold. For example, in the case of s_08, the calculated similarity fluctuated around the set threshold (0.85), failing to provide consistent matching results. Second, detection failures occurred when symbol deformation exceeded the scope of transformations covered in this study, such as rotation, flipping, or scaling. For instance, s_12 was situated within the boundaries of a specific equipment unit, causing its aspect ratio to change in accordance with the equipment's shape. Such geometric distortions could not be compensated for by the preprocessing steps of rotation or scale adjustment, rendering detection impossible. Third, false recognitions arose from inclusion relationships between symbols, where a larger symbol was misidentified as a smaller one. For example, s_09 was misclassified as s_01, and s_11 as s_10. This error is attributed to the connecting lines and piping attached to the larger symbol being included in the similarity calculation, which resulted in the smaller symbol (or a sub-part) yielding a higher similarity score than the actual larger symbol.

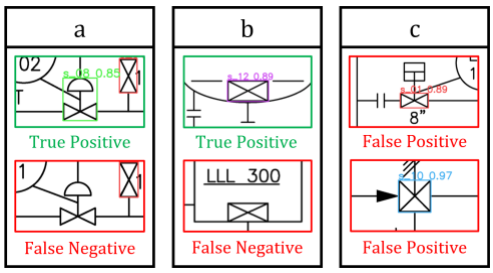

Figure 9: Examples of failed symbol recognition: a) Missed detection due to high threshold; b) Missed detection due to severe symbol deformation; c) Incorrect recognition of symbols in inclusion relationships.

Conclusion

This study addressed the industrial challenge of automated symbol recognition as a key method for reviewing and digitizing image-based P&IDs. To overcome the issues of semantic loss due to the conversion of P&IDs into image formats and the project-specific variations in symbol shapes and meanings, an extended template matching framework based on the symbol legend was proposed. The proposed method enables symbol recognition without the need for dataset construction or model training by directly leveraging the symbol legend defined in each project. Specifically, the detection process was refined by extracting RoI masks using the Convex Hull algorithm, and IoU-based matching with IoM-based NMS was introduced to provide a quantitatively interpretable and reliable recognition mechanism.

Comparative experiments demonstrated that the proposed framework is more effective than conventional template matching methods in real-world P&ID environments characterized by densely arranged symbols with similar shapes and complex piping structures. These results are significant in that they demonstrate that the proposed approach can serve as a robust symbol recognition technique for P&ID digitization in the field of engineering drawing analysis, which often suffers from data scarcity.

Despite these contributions, this study has several limitations. First, constructing symbol templates from the symbol legend involves labor-intensive manual effort, and symbols not included in the legend cannot be

recognized. Second, the generalization of the method is limited because rotation, flip and scale transformations are applied only within predefined parameters. Third, the system is sensitive to hyperparameter settings; if an appropriate matching threshold is not established, the system may fail to detect target symbols. Fourth, the sliding window approach incurs high computational costs, making real-time processing difficult. Finally, the reliability of the F1 Score evaluation for specific symbol classes is limited due to severe class imbalance in the P&ID dataset used for verification.

Future research will focus on addressing the limitations identified in the experiments. First, false recognitions arising from inclusion relationships are to be resolved by prioritizing labeling for larger symbols during the preprocessing stage. Additionally, more consistent and robust matching will be enabled by incorporating geometric similarity metrics for symbol shapes. Moreover, computational efficiency will be improved by exploring algorithm optimization and GPU-based parallel processing. Furthermore, an automated symbol template construction model will be developed from the symbol legend to alleviate the burden of manual effort. Finally, the reliability of results will be enhanced by applying this framework to a wider variety of industrial P&IDs.

Through these efforts, the proposed framework is expected to extend beyond symbol recognition itself and support practical engineering tasks in the plant industry, without requiring extensive training data or domain-specific model retraining. For instance, the recognized symbol types and their spatial arrangements can be cross-referenced with design rules to detect violations or linked with equipment datasheets to support P&ID quality reviews. Furthermore, comparing recognition results between revisions can enable systematic management of design change histories. Ultimately, this study is anticipated to contribute to accelerating the digital transformation of the plant industry by bridging the gap between legacy engineering documents and intelligent information systems.

A COMPARATIVE ANALYSIS OF IoT DATA PIPELINES FOR REAL-TIME MIXED REALITY VISUALISATION IN UNITY-BASED DIGITAL TWINS

Muhammad Shahzad[1], Joseph H. M. Tah[1], Avar Almukhtar[1], and Muhammad Younas[1]
[1]Oxford Brookes University, Oxford, United Kingdom

Abstract

Digital Twins increasingly rely on real-time IoT data, yet the end-to-end architectural implications of alternative integration approaches remain underexplored. This paper presents a controlled comparative analysis of three IoT data pipelines connecting The Things Network (TTN) to a Unity-based Digital Twin for mixed reality visualisation: cloud-centric pipelines using Amazon Web Services and Microsoft Azure, and a lightweight publish–subscribe pipeline based on direct MQTT delivery. By isolating the data integration layer, a benchmarking approach evaluates data transmission behaviour, persistence, integration complexity, scalability, and cost. The findings provide practical architectural insight into how pipeline design choices shape Digital Twin behaviour.

Introduction

Digital Twins are increasingly adopted in the built environment to integrate physical assets, sensing systems, and digital representations in support of monitoring, operation, and maintenance activities. As originally articulated by Grieves and Vickers (2016) and subsequently extended to construction and infrastructure contexts by Boje et al. (2020), Digital Twins enable continuous coupling between physical systems and their digital counterparts. By linking real-world measurements with digital models, they provide situational awareness. They also support informed decision-making across the lifecycle of buildings and infrastructure (Boschert and Rosen, 2016; Lu et al., 2020; Shahzad et al., 2025).

A fundamental requirement for operational Digital Twins is the reliable and continuous integration of real-time data from distributed sensors. Internet of Things (IoT) and related sensor technologies have widely deployed in buildings to capture environmental and operational parameters relevant to performance assessment and maintenance (El-Ammari and Hammad, 2019; Al-Nasser et al., 2024). At the network layer, Low-Power Wide-Area Network (LPWAN) technologies such as LoRaWAN enable scalable sensor deployments with low energy consumption (Centenaro et al., 2016; LoRa Alliance, 2025). However, as emphasised by Wang et al. (2013) and Tao et al. (2018), sensor deployment alone does not constitute a functional Digital Twin. Real-time data must be transmitted, processed, and delivered through an integration pipeline that is sufficiently robust, scalable, and responsive for operational use.

Immersive Digital Twin applications are increasingly reported in construction and facility management research. However, existing studies largely foreground application-level outcomes such as training, inspection, or collaboration, while treating the underlying IoT data pipeline as an implementation detail (Palmarini et al., 2018). In practice, IoT-enabled Digital Twin systems are commonly realised through either cloud-centric architectures, which provide managed ingestion, storage, and dashboard services, or lightweight publish–subscribe approaches that prioritise low-latency data delivery. Cloud platforms such as Amazon Web Services (AWS) and Microsoft Azure are frequently adopted for Digital Twin deployments due to their scalability and managed services (Lu et al., 2020; Al-Nasser et al., 2024), while messaging protocols such as MQTT are widely used for real-time IoT streaming (Thangavel et al., 2014).

At the platform level, several studies have presented comparative analyses of major cloud providers, most notably AWS and Azure, focusing on pricing models, security mechanisms, quality-of-service attributes, and service capabilities (Kotas et al., 2018; Eisa et al., 2020; Palumbo et al., 2021; Hameed et al., 2025). While these contributions provide valuable insight into cloud platform characteristics, they are typically conducted from a general cloud computing or enterprise systems perspective. As noted by Palumbo et al. (2021) and Eisa et al. (2020), such comparisons often rely on abstract performance metrics or simulation-based evaluation and do not examine how alternative cloud architectures behave when embedded within end-to-end Digital Twin data pipelines. Moreover, controlled comparisons that trace IoT data flow from sensing infrastructure to immersive visualisation environments under identical conditions remain limited.

This paper addresses this gap through a controlled comparative analysis of three end-to-end IoT data pipeline architectures that deliver live sensor readings from The Things Network (TTN) to a Unity-based Digital Twin. TTN is an open, LoRaWAN-based IoT network providing device management and standardised data forwarding services (TTN, 2023). The evaluated architectures comprise: (i) cloud-centric pipelines implemented using AWS and Microsoft Azure, providing

managed ingestion, serverless processing, and persistent storage (AWS, 2024a, Microsoft, 2024); and (ii) a lightweight publish–subscribe integration path in which Unity subscribes directly to sensor topics via an MQTT broker, enabling low-latency data delivery.

The conceptual scope of the study is illustrated in Figure 1, which positions the data pipeline layer as an intermediary between the IoT sensing infrastructure and the Digital Twin visualisation environment. Within this framework, the case study environment, TTN configuration, and Unity-based Digital Twin are held constant, and only the data pipeline architecture between TTN and Unity is varied. Mixed Reality (MR) and Virtual Reality (VR) are employed as representative high-demand real-time visualisation contexts such as live walkthroughs, remote asset inspection, and collaborative review where low latency, continuous updates, and immediate user feedback are critical for effective decision-making rather than as the primary objects of evaluation.

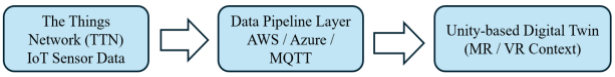

Figure 1: Conceptual Scope of the Study

The contribution of this work is threefold. First, it documents the implementation of three TTN-to-Unity data pipelines under identical case study conditions, enabling controlled architectural comparison. Second, it applies a structured benchmarking approach to evaluate IoT data pipelines across data transmission behaviour, platform capabilities, data persistence, Unity integration complexity, and architectural maintainability. Third, it synthesises the observed trade-offs to support evidence-informed selection of IoT data pipeline architectures for real-time Digital Twin visualisation in the built environment.

Case Study and Experimental Context

Case Study Overview

The study is based on an operational building used for teaching and research activities, instrumented with six IoT sensors for continuous environmental monitoring. The building provides a realistic yet controlled context for evaluating alternative IoT data pipeline architectures under normal operational conditions, without introducing domain-specific application bias.

Environmental monitoring was performed using Elsys CO_2 sensors deployed exclusively within the shared office space of the case study building. The sensors measure temperature, relative humidity, and CO_2 concentration. These are widely accepted indicators of indoor environmental quality in office environments and representative of sensing modalities commonly used in building monitoring and facilities management. The sensors operate on a low-power basis and are suitable for continuous, long-term deployment. Figure 2 illustrates the spatial distribution of the six deployed sensors within the shared office space, which provides the physical context for mapping measured conditions to corresponding locations in the Unity-based Digital Twin.

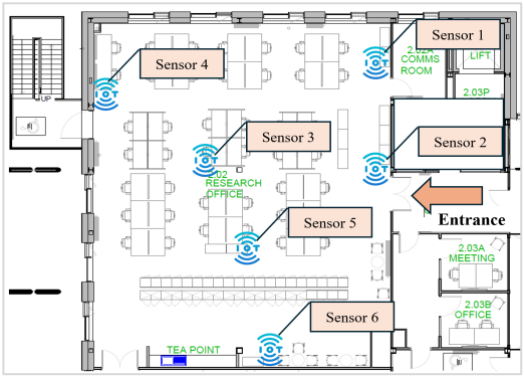

Figure 2 – Spatial deployment of IoT sensors within the case study building

All sensors communicated using a Low-Power Wide-Area Network (LPWAN) based on the LoRaWAN protocol. Sensor uplinks were received and managed by The Things Network (TTN), which served as the common IoT network layer across all experimental configurations. TTN was selected due to its widespread adoption, support for LoRaWAN devices, and ability to forward sensor data through standardised integration mechanisms. Importantly, TTN was already operational within the case study environment, ensuring a stable and continuously functioning network infrastructure and avoiding additional variability associated with network setup.

At the visualisation layer, sensor data were integrated into a Unity-based Digital Twin representing the monitored building. Sensor readings were mapped to their corresponding spatial locations within a three-dimensional model and updated dynamically in response to incoming data. MR and VR devices were used as representative high-demand visualisation contexts, where lag-free interaction and continuous state synchronisation are essential, while the visualisation logic and interaction mechanisms were kept constant throughout the study.

Controlled Comparison Strategy

To enable controlled architectural comparison, the physical sensing infrastructure, including sensor types, deployment locations, payload structure, and data transmission frequency, was held constant across all experiments. The sensor data transmission interval was configured at 10 minutes for all devices, ensuring consistent temporal resolution across all pipeline evaluations. The TTN configuration remained unchanged, ensuring identical data semantics and network behaviour for each pipeline.

The Unity-based Digital Twin, including the 3D model, data mapping logic, and update routines, was also held constant across all experimental scenarios. As shown in Figure 3, this setup fixes both the upstream sensing and networking layer and the downstream visualisation component. The data integration layer is isolated as the sole variable element.

All pipelines were implemented and executed in the same computing environment, using identical hardware and software configuration, to ensure that observed differences were not influenced by variations in computational resources or execution conditions.

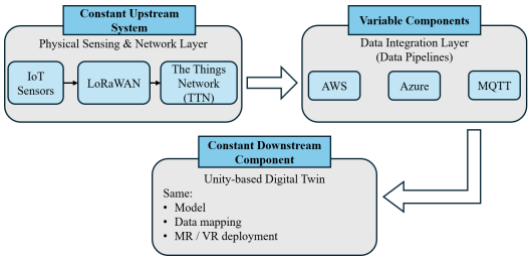

Figure 3 – Controlled Experimental Setup

Within this controlled configuration, three data pipeline architectures were implemented and evaluated: cloud-centric pipelines using AWS and Azure, and a lightweight publish–subscribe pipeline using an MQTT broker. This design ensures that observed differences in system behaviour, complexity, and capability can be attributed directly to the data pipeline architecture rather than to sensing, networking, or visualisation factors.

IoT Data Pipeline Architectures

This section describes the IoT data pipeline architectures implemented and evaluated in the study. All architectures connect the same upstream IoT network to the same Unity-based Digital Twin, enabling controlled comparison of alternative data integration approaches. A common baseline is provided by The Things Network (TTN), followed by three downstream pipelines that differ only in how sensor data are processed, stored, and delivered.

Common Baseline: TTN Data Flow

All sensor data originate from distributed IoT devices deployed within the case study building and are transmitted using the LoRaWAN protocol. Uplink messages are received and managed by The Things Network (TTN), which serves as the common IoT network layer across all experimental configurations.

Sensor uplinks are encoded as structured JSON payloads containing timestamped measurements and device identifiers. Payload structure and transmission frequency remain identical across all pipelines. TTN functions exclusively as a data forwarding layer, providing webhook- and MQTT-based interfaces to downstream systems without performing data processing or persistence. This baseline data flow configuration ensures that observed differences arise from downstream pipeline architectures rather than sensing or network variability.

Cloud-Centric Pipelines: TTN–AWS–Unity and TTN–Azure–Unity

The two TTN–AWS–Unity and TTN–Azure–Unity pipelines follow a cloud-centric architectural pattern designed to support persistence and structured data access. Sensor data are forwarded from TTN via webhooks to cloud ingestion endpoints, triggering serverless processing functions that perform lightweight payload parsing and validation.

Processed data are stored in managed cloud databases, enabling retention of both recent and historical sensor readings. An API layer exposes stored data to the Unity-based Digital Twin via HTTP-based requests. Unity retrieves updated sensor data at a fixed polling interval of 10 seconds, ensuring regular synchronisation between the cloud database and the visualisation environment. This pull-based access model decouples ingestion from consumption. However, it introduces multiple intermediary components between the IoT network and the visualisation layer.

Architecturally, the AWS- and Azure-based pipelines exhibit functional parity. Differences observed between them relate primarily to platform-specific tooling and configuration workflows rather than fundamental architectural design.

Streaming-Based Pipeline: TTN–MQTT Broker–Unity

The TTN–MQTT broker–Unity pipeline represents a lightweight, streaming-based architecture based on a publish–subscribe communication model. Sensor data are forwarded from TTN to an MQTT broker, from which the Unity application subscribes directly to relevant topics.

Data delivery is push-based and occurs as messages are published, enabling near real-time updates. Unlike the cloud-centric pipelines, this architecture introduces no intermediary processing or inherent data persistence. Sensor readings are therefore transient unless additional storage is explicitly introduced. This design prioritises immediacy and simplicity while shifting responsibility for data handling and temporal context to the consuming application.

Architectural Abstraction

Figure 4 presents an abstracted comparison of the two dominant pipeline paradigms evaluated: cloud-centric and streaming-based pipelines.

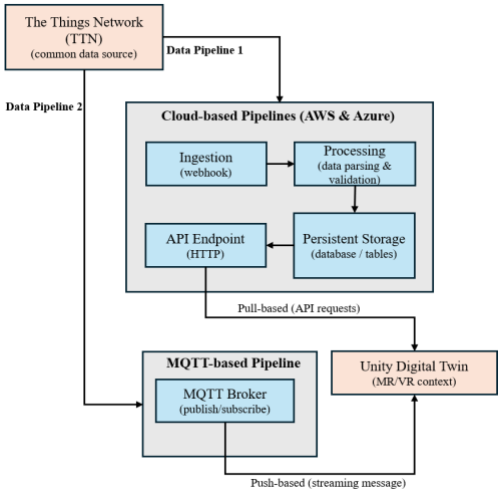

Figure 4 - Abstracted IoT data pipeline architectures connecting TTN to a Unity-based Digital Twin

The figure highlights differences in component composition, data flow, and data persistence while omitting platform-specific services. This abstraction provides architectural context for the benchmark evaluation presented in the following section.

Benchmarking Approach

The comparative evaluation in this paper adopts a structured benchmarking approach to assess alternative IoT data pipeline architectures supporting real-time Digital Twin visualisation. Consistent with established cloud and systems benchmarking practice, complex platforms are evaluated using common architectural and operational criteria rather than vendor-specific performance ranking (Kotas et al., 2018; Eisa et al., 2020). Accordingly, this study focuses on architectural behaviour and practical integration characteristics observed during implementation and deployment.

Benchmark Design Rationale

The benchmarking criteria were developed according to three principles: platform agnosticism, architectural relevance, and implementation grounding. First, the criteria are platform-agnostic, focusing on architectural and functional properties that can be compared across cloud-managed and publish–subscribe approaches rather than vendor-specific services. This aligns with established cloud benchmarking literature, where heterogeneous platforms are normalised into comparable capability and quality dimensions (Kotas et al., 2018; Eisa et al., 2020), and with more recent work emphasising architectural capability over provider-specific implementation detail (Hameed et al., 2025). Palumbo et al. (2021) further demonstrate the importance of vendor-neutral analysis when assessing end-to-end latency behaviour.

Second, the criteria are architecture-oriented, emphasising data flow, component responsibilities, and coupling between ingestion, persistence, and application access layers. This reflects evidence that system-level properties such as latency, responsiveness, and integration overhead emerge primarily from architectural composition rather than from individual services in isolation (Palumbo et al., 2021).

Third, the criteria are deployment-informed, grounded in deploying and troubleshooting multiple TTN-to-Unity pipelines in a real building context. While protocol-level studies quantify MQTT performance under controlled conditions (Thangavel et al., 2014; Ansyah et al., 2023), they do not capture the integration and operational challenges encountered in end-to-end Digital Twin deployments. Incorporating factors such as configuration effort, tooling complexity, and operational usability therefore extends existing benchmarking work toward application-facing Digital Twin systems.

Each pipeline was implemented and tested repeatedly under identical conditions. Benchmark assessments were based on direct observation of system behaviour during deployment, configuration, and runtime operation. Comparative evaluation was conducted using consistent criteria across all pipelines, ensuring that observed differences reflect architectural characteristics rather than experimental variability.

In this study, latency is defined as the elapsed time between sensor data transmission from TTN and its availability within the Unity-based Digital Twin. Based on repeated implementation observations, the MQTT based pipeline exhibited near real-time updates (typically within 1-2 seconds), whereas cloud-based pipelines introduced additional delay (approximately 5-8 seconds) due to ingestion, storage, and API retrieval stages.

Benchmark Categories

Based on these principles, including platform agnosticism, architectural relevance, and implementation grounding, six benchmark categories were defined.

Data Transmission Characteristics assess setup effort, communication mechanisms, and latency, including the distinction between push-based streaming and pull-based API access.

Platform Capabilities evaluate native support for data inspection, monitoring, and debugging.

Data Storage and Representation address persistence, ease of querying, and built-in visualisation or analytics.

Unity Integration Complexity captures software development kit (SDK) availability, programming effort, and runtime debugging effort.

Architectural Complexity and Maintainability consider component count, scalability, and suitability for sustained deployment.

Cost and Resource Implications capture licensing constraints, tooling requirements, and access to platform features relevant to academic and early-stage deployments.

Together, these benchmarks provide a concise basis for comparing cloud-based and streaming-based IoT data pipeline architectures under controlled conditions. Their application to the AWS-, Azure-, and MQTT broker–based pipelines is presented in the following section.

Comparative Analysis and Results

This section presents a comparative analysis of the three IoT data pipeline architectures evaluated in the study: TTN–AWS–Unity, TTN–Azure–Unity, and TTN–MQTT broker–Unity. The analysis applies the benchmarking approach defined in the preceding section and focuses on architectural behaviour observed during implementation and deployment. Results are presented using high-level comparison tables supported by restrained qualitative interpretation. The objective is not to rank platforms, but to identify architectural trade-offs relevant to real-time Digital Twin visualisation.

Comparison of Cloud-Based Pipelines: AWS vs Azure

Both the TTN–AWS–Unity and TTN–Azure–Unity pipelines follow a cloud-centric architectural pattern, employing webhook-based ingestion, serverless processing, managed storage, and API-mediated data

access. Both architectures support persistent data storage, structured querying, and controlled access from the Unity-based Digital Twin.

Despite the architectural parity, differences were observed in integration effort, workflow transparency, tooling requirements, and practical usability, particularly under student-tier account constraints. Table 1 summarises these differences across key architectural and implementation-oriented criteria.

Table 1. High-level comparison of AWS and Azure cloud-based IoT pipelines for digital twin data integration

Criterion	AWS	Azure
Overall architectural pattern	Cloud-centric, serverless	Cloud-centric, serverless
Data ingestion from TTN	Webhook-based	Webhook-based
Serverless processing	AWS Lambda	Azure Functions
Data persistence	Managed database (table-based)	Managed storage / tables
Querying capability (ease of data access and retrieval)	Strong, straightforward querying	Strong but more workflow-dependent
Data export (CSV/Excel)	Direct export from tables	Indirect; requires queries or external tools
Built-in dashboards (student tier)	Limited without paid services	Available for basic charts
Unity integration effort	Moderate	High
Workflow transparency	Relatively clear and linear	Fragmented, multi-step
Tooling requirements	Mostly web-based	Web + desktop tools (e.g. Storage Explorer)
Maintainability (ease of modifications)	High	Medium
Learning curve	Moderate	Steep
User Interface Usability	Relatively Intuitive	Complex

Table 1 compares the AWS- and Azure-based pipelines for digital twin data integration, focusing on how each cloud platform supports real-time sensor data delivery, persistence, and access within a Unity-based Digital Twin. The AWS-based pipeline exhibited a clearer and more linear workflow, enabling easier data access, modification, and maintenance during development. The Azure-based pipeline achieved comparable functional outcomes but required more extensive configuration, additional tooling, and multi-step workflows, resulting in higher development and debugging overhead. These differences reflect platform-level implementation characteristics rather than fundamental architectural distinctions.

Cloud-Based Pipelines versus MQTT broker-based Streaming

While AWS and Azure are architecturally comparable, the TTN–MQTT broker–Unity pipeline represents a fundamentally different integration paradigm. Rather than relying on cloud-managed processing and storage, this pipeline adopts a lightweight publish–subscribe model in which sensor data are streamed directly from TTN to the Unity application via an MQTT broker.

From a data transmission perspective, the streaming-based pipeline demonstrated lower end-to-end latency and simpler configuration, as it does not introduce serverless processing, databases, or API gateways. However, this architectural simplicity comes at the cost of data persistence, platform-level analytics, and historical access, which are inherent features of cloud-centric pipelines.

Table 2 – Comparison of cloud-based pipelines and MQTT broker-based streaming for Digital Twin data integration

Criterion	AWS/Azure	MQTT
Architectural paradigm	Centralised, cloud-centric	Decentralised, streaming
Data delivery model	Pull-based (API requests)	Push-based (publish–subscribe)
End-to-end latency	Medium (5-8 seconds)	Low (1-2 seconds)
Data persistence	Native and integral	Not provided
Historical data access	Supported	Not supported
Built-in analytics and dashboards	Available (tier-dependent)	Not available
Unity integration complexity	Medium to High	Low
Number of system components	High	Low
Setup and configuration effort	High	Low
Cost sensitivity (student tier)	High	Low
Suitability for live visualisation	Appropriate	Appropriate
Suitability for long-term monitoring	Appropriate	Limited
Data latency	Medium	Low

Table 2 summarises the key architectural differences as they affect real-time Digital Twin data integration, contrasting cloud-based pipelines with the MQTT broker–based streaming approach. The analysis indicates that streaming-based integration is fairly effective for immediate, real-time data delivery in live Digital Twin visualisation. In contrast, cloud-based pipelines provide stronger support for long-term monitoring, historical analysis, and system observability, but with higher integration overhead.

Architectural Trade-off Observations

The comparative analysis reveals several recurring architectural trade-offs across the evaluated pipelines.

Cloud richness versus simplicity – Cloud-centric pipelines provide a rich ecosystem of managed services, including ingestion, storage, monitoring, and analytics, supporting structured data management and operational visibility (AWS, 2024b). However, these capabilities require coordination of multiple components. In contrast, the MQTT broker–based pipeline minimises architectural footprint and setup effort but offers limited platform-level tooling.

Persistence versus immediacy – Persistent storage is a defining characteristic of cloud-based pipelines, enabling historical access and retrospective analysis (Palmarini et al., 2018; Qiu et al., 2025). By contrast, streaming-based pipelines prioritise immediacy by delivering data directly to the consuming application, supporting near real-time updates but offering no inherent data retention (Thangavel et al., 2014).

Integration overhead versus architectural responsibility – Cloud-based pipelines introduce higher integration overhead due to serverless processing, databases, and API layers, but centralise responsibilities such as data validation, persistence, and access control. Streaming-based pipelines reduce backend complexity but shift responsibility for data handling, temporal context, and robustness to the consuming application (Al-Nasser et al., 2024).

Summary of Findings

The comparative analysis demonstrates that no single IoT data pipeline architecture is universally optimal. Cloud-centric pipelines offer robustness, persistence, and extensibility, making them suitable for long-term, data-rich Digital Twins. Streaming-based integration prioritises low latency and simplicity, supporting responsive real-time visualisation with minimal backend overhead.

These findings reinforce that data pipeline selection should be guided by architectural alignment with application requirements, resource constraints, and system lifecycle considerations, rather than by platform capability alone. The implications of these architectural trade-offs for real-time Digital Twin visualisation are discussed in the following section.

Implications and Discussion

The comparative analysis demonstrates that architectural decisions at the IoT data pipeline level have direct and measurable implications for how effectively Digital Twins support real-time visualisation. While prior studies have examined cloud platform selection using quality-of-service metrics, simulation models, or abstract optimisation criteria (e.g. Kotas et al., 2018; Eisa et al., 2020; Hameed et al., 2025), such analyses are typically decoupled from operational Digital Twin deployments. By contrast, this study evaluates data pipeline behaviour under controlled but realistic conditions. It reveals how architectural composition shapes update continuity, data availability, and development and maintenance effort in real-time Digital Twin systems.

Latency, Update Continuity, and Immediacy

Latency is a critical determinant of real-time Digital Twin fidelity, as temporal misalignment between physical processes and their digital representations can undermine user confidence and operational reliability. As Wang et al. (2013) and Palmarini et al. (2018) have argued, delayed or inconsistent updates reduce the effectiveness of immersive and monitoring-oriented Digital Twins. In MR and VR environments, such latency can manifest as perceptible delays between user interaction and system response, disrupting the sense of immersion and reducing the reliability of real-time feedback. This is particularly critical in applications such as live walkthroughs and remote monitoring, where users rely on immediate visual updates to interpret environmental conditions and support timely decision-making.

The results indicate that publish–subscribe streaming architectures are architecturally conducive to lower end-to-end latency than cloud-centric pipelines, primarily due to the absence of intermediary storage, querying, and API retrieval stages. This design supports more continuous and immediate visual updates within Digital Twin. In contrast, cloud-based pipelines introduce additional processing layers associated with ingestion, persistence, and pull-based access, which can lead to discretised update behaviour. These observations suggest that low-latency streaming architectures are particularly well suited to live monitoring and event-driven Digital Twin applications, while recognising that such latency advantages arise from architectural simplification rather than from quantified performance measurements.

Data Persistence and Long-Term Use

Persistent data storage is a defining characteristic of cloud-centric IoT data pipelines and is widely recognised as essential for diagnostics, performance assessment, and maintenance planning in the built environment. Palmarini et al. (2018) and Qiu et al. (2025) emphasise that historical data enables Digital Twins to move beyond real-time state representation toward analytical and decision-support functions.

Consistent with this view, the analysis shows that cloud-based pipelines inherently support structured data retention and querying, enabling historical inspection and

aggregated representations within or alongside the Digital Twin. Streaming-based architectures, by contrast, prioritise transient data delivery and do not retain historical information unless supplemented by additional storage components. While this does not affect real-time update continuity, it constrains retrospective analysis, highlighting persistence and immediacy as complementary but not always compatible architectural objectives.

Integration Complexity and Architectural Responsibility

Integration complexity directly affects the feasibility and sustainability of Digital Twin implementations. Recent studies by Al-Nasser et al. (2024) and Hadjidemetriou et al. (2023) emphasise that Digital Twin viability depends as much on integration effort as on conceptual design.

The benchmark results indicate that cloud-centric pipelines introduce higher integration overhead due to the configuration of serverless processing, databases, and API layers. This complexity provides flexibility, access control, and extensibility, but increases development and maintenance effort. Streaming-based pipelines reduce backend complexity by enabling direct data delivery to the visualisation layer, but shift responsibility for data validation, temporal context, and robustness to the consuming application. This redistribution of responsibility clarifies why MQTT broker–based pipelines are not inferior, but rather represent a different architectural choice aligned with immediacy and simplicity.

Design Guidance and Context-Aware Architectures

The observed trade-offs confirm that no single data pipeline architecture is universally optimal. Cloud-based pipelines are most appropriate for Digital Twins intended as long-term, data-rich systems requiring persistence, analytics, and enterprise integration. MQTT broker–based streaming is advantageous where low latency, simplicity, and rapid deployment are prioritised.

Consistent with architectural Digital Twin literature (Wang et al., 2013; Palmarini et al., 2018), these findings also point toward the value of hybrid architectures. By combining streaming mechanisms for immediate data delivery with cloud-based services for persistence and analytics, hybrid pipelines can balance responsiveness with long-term data value. Rather than competing alternatives, cloud-centric and streaming-based pipelines should therefore be understood as complementary components within a broader Digital Twin ecosystem.

Overall, the results reinforce that IoT data pipeline selection should be guided by intended Digital Twin functionality, lifecycle requirements, and operational context. By treating immersive visualisation as a demanding application context rather than the primary object of evaluation, this study highlights how backend architectural choices shape the robustness, deployability, and real-time behaviour of Digital Twin systems in the built environment.

Conclusion

This paper presented a comparative architectural analysis of IoT data pipeline approaches supporting real-time Digital Twin visualisation in the built environment. Using a controlled case study, three end-to-end pipelines; TTN–AWS–Unity, TTN–Azure–Unity, and TTN–MQTT broker–Unity were implemented and evaluated under identical sensing, visualisation, and mixed reality deployment conditions. The data integration layer was isolated as the primary variable.

The findings demonstrate that data pipeline architecture significantly influences Digital Twin responsiveness, complexity, and functional scope, particularly in high-demand visualisation contexts such as mixed reality. Cloud-centric pipelines support persistence, scalability, and long-term data management, making them suitable for sustained and data-rich Digital Twin deployments, albeit with higher integration and operational overhead. In contrast, streaming-based pipelines prioritise architectural simplicity and immediacy, supporting responsive real-time visualisation but offering limited inherent support for historical data handling.

Beyond platform-specific performance claims, the study provides architectural insight into how data integration design choices shape the practical behaviour of real-time Digital Twins when deployed in immersive and interactive environments. Future research may extend this work through hybrid pipeline architectures that combine low-latency streaming with cloud-based persistence and analytics, as well as through quantitative latency evaluation and deployment at larger or multi-building scales.

Overall, the findings confirm that no single data pipeline architecture is universally optimal. Instead, effective pipeline selection should be guided by the intended role, lifecycle stage, and interaction demands of the Digital Twin, underscoring the importance of aligning backend data architectures with application requirements rather than adopting a one-size-fits-all integration strategy.

Abstract

The Level of Information Need introduced in ISO 19650 gained a standardized machine-readable data model with the LOINxml (ISO 7817-3). This paper presents the normative context of this standard with a short outline of the specification process of the LOINxml data model. Through systematic analysis of schema elements and design decisions, this work demonstrates how LOINxml enables structured, transaction-based requirement specifications supporting alphanumerical, documentation, and geometrical information across project lifecycles. The contribution establishes LOINxml as foundational infrastructure for digital information requirements while identifying threshold conditions and future research directions essential for industry implementation.

Introduction

Precise information requirements are critical for Building Information Modeling (BIM) information delivery and conformant project deliverables in the architecture, engineering, construction, and operation (AECO) industry (Sacks et al., 2025). Machine-readable representation of these requirements enables not only vendor-neutral definition, but also more precise requirements and higher quality of project deliverables. A framework for such requirement definition has been established in the Level of Information Need (LOIN) standards. While fundamentals have been specified in part 1 of ISO 7817, application guidelines are presented in part 2 (ISO/TS 7817-2, 2025), and a corresponding data model is defined in part 3. (ISO 7817-3, 2025). Of these three interrelated standards, this paper discusses the design decisions and intended applications of the ISO 7817-3 LOINxml schema.

This paper documents the context and design decisions of the data model presented in ISO 7817-3 (2025) to promote practitioner adoption. The context in which the data model is embedded is explained in the normative setting. Subsequently, the development process is explained. The data model published in ISO 7817-3 is then presented and discussed. The paper finishes with the conclusions and outlook.

Normative setting

The Level of Information Need (LOIN) concept was introduced in ISO 19650-1 (2018). However, the concept had to be elaborated into precise normative specifications, which has been done in the ISO 7817 series, where fundamentals and principles are described in ISO 7817-1 (2024), guidelines and application in ISO/TS 7817-2 (2025), and an XML-based data model in ISO 7817-3 (2025). ISO 7817-3, specifying a schema for the Level of Information Need, aligns closely with ISO 23387 (2025), which establishes a data template structure for construction objects based on the methodology for describing, creating, and maintaining properties in interconnected data dictionaries (ISO 23386, 2020) described in ISO standard 12006-3. This approach provides the concepts and relationships required to describe information about building objects (ISO 23387, 2025).

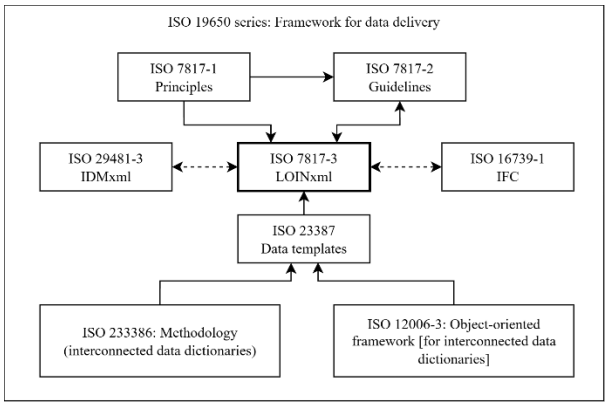

Figure 1: Normative context of ISO 7817-3.

In this context, a data template is a subset of the model ISO 23387 extends the ISO 23386 methodology, emphasizing template reusability and both standards harmonize with ISO 12006-3 (2023), thus enabling an object-oriented approach – a strong argument for adoption of the data templates elements in the LOINxml data model. This approach was implemented by importing

XML schema elements provided by ISO 23387 into the LOINxml schema, which represents the strongest form of integration. ISO 7817-3 coexists with ISO 29481-3 (2022) on the Information Delivery Manual (IDM). While both standards provide machine-readable XML structures for information requirements, IDM focuses on information requirements exchanged within specific use cases, whereas LOIN focuses on the data model for the level of information need. While being agnostic to specific data models for actual model contents, the LOINxml is compatible with the Industry Foundation Classes (IFC), among other formats and breakdown structures.

A strong principle implemented by LOINxml is the use of references to information provided in other data schema and resources. This may include references to data dictionaries, such as bSDD, for specifying ObjectTypes and Properties, or references to IDMxml data for referencing project milestones. The references are expressed by International Resource Identifiers (IRI) to allow easy lookup and retrieval, while providing a maximum of flexibility. The context of ISO standards relevant to the LOINxml data model are outlined in Figure 1. The LOINxml data schema can be used for file-based exchange (including multiple files referencing each other) but can also act as a blueprint for defining database schemas and providing access through REST (Representational State Transfer) APIs (Application Programming Interfaces).

Methodology

The development of the schema for ISO 7817-3 was conducted within the framework of standardization work (Vienna Agreement, 1991) for cooperation between the European Committee for Standardization (CEN) and the International Organization for Standardization (ISO) (European Committee for Standardization and International Organization for Standardization, 2016). Delegated experts from all interested countries participate in standard development. In the case of ISO 7817-3, experts came from Belgium, Canada, Czech Republic, France, Germany, Norway, South Korea, and the UK. Meetings were conducted virtually. Over the course of six years of development work, the meeting frequency varied between biweekly and approximately monthly (accounting for breaks and holidays). Figure 3 outlines the process. Other works aided in the development of this standard, such as Jeon et al. (2021); Jaud, Gregory and Borrmann (2021); Bolpagni et al. (2022); Abualdenien and Borrmann (2022); Son et al. (2022); Mellenthin Filardo et al. (2024a); Mellenthin Filardo et al. (2024b); Akbas et al. (2025); Zentgraf et al. (2025) among others.

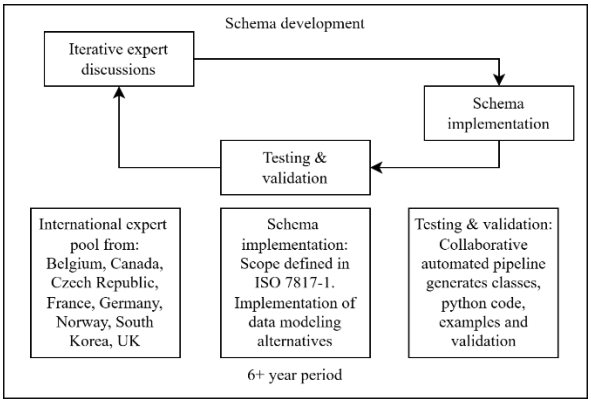

Figure 2: Overview of the schema development procedure

The schema scope derives from ISO 7817-1. Guidelines in ISO/TS 7817-2, developed parallel to ISO 7817-3, informed LOIN elaborations subsequently discussed, tested, and eventually incorporated into LOINxml. Substantive congruence between ISO 23387 and ISO 7817-3 necessitated parallel mechanism implementation. Collaboration through integration avoided duplicate work and contradictory approaches. Individual elements and mechanisms were iteratively discussed among experts.

Discussion material alternated between UML diagrams, XSD files, and XML examples using a collaborative repository. Automated actions generated classes from XSD files using xsData libraries. Python scripts produced and validated XML examples against the schema. XSD and example generation proceeded collaboratively through expert-proposed improvements across multiple iterations. Both XSD and XML files underwent expert review. Drafts circulated through designated internal committees until the standard entered its final phase.

Presenting the LOINxml

The root element of the LOINxml data model is the *LevelOfInformationNeed* element, which acts as a container for the *Specification* element(s), as shown in Figure 2. The *Specification* aggregates the elements *Prerequisites* (mandatory), for context information, *GeoReferencing* (optional), for coordinate system information, and *SpecificationPerObjectType* (optional, zero to many), for specifying requirements.

The *Prerequisites* element (Figure 4) establishes the transaction framework by specifying the purpose, information delivery milestone, and actors of the

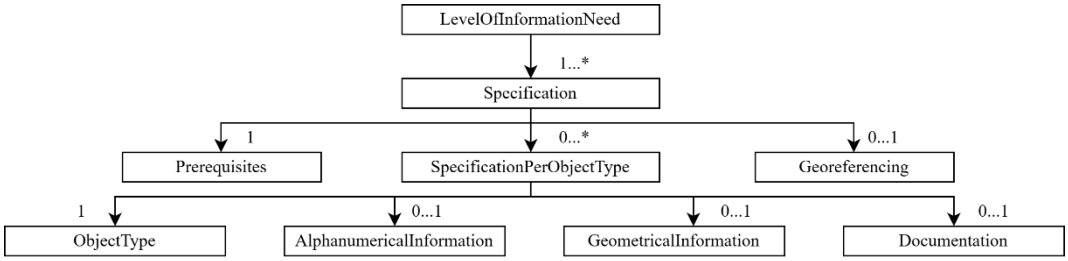

Figure 3: Simplified overview of the LOINxml data model. A detailed version of the schema can be found in ISO 7817-3.

LOINxml. The LOINxml is understood as a transaction limited to a receiving and a providing actor.

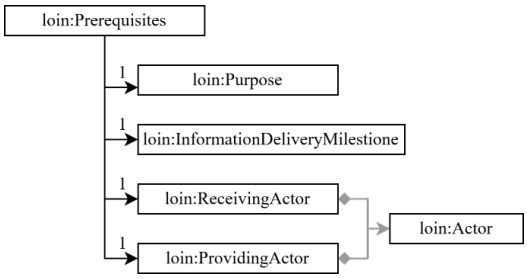

Figure 4: Structure of the Prerequisites element

The *Purpose* element provides the rationale for information need and includes name, optional definition, references, description, language, region, and dictionary links. The *InformationDeliveryMilestone* specifies delivery timing through name, optional description, references, and date/time. The *ProvidingActor* identifies the information provider through role, optional name, affiliation, description, and email. The *ReceivingActor* identifies the information recipient using the same structure as *ProvidingActor*. Varying actors or purposes require separate *Specification* instances rather than consolidated prerequisites. Multiple specifications with different prerequisites can coexist within one document.

The *GeoReferencing* element, shown in Figure 5, specifies the coordinate reference system and transformation parameters from model to coordinate reference system (CRS) coordinates. It comprises the elements *CoordinateReferenceSystem*, defining CRS type and datum, and *ModelCoordinateSystem*, establishing model origin and orientation within the CRS where multiple instances are possible.

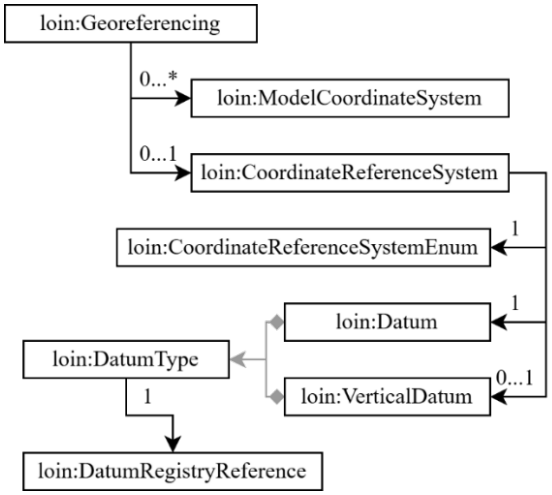

Figure 5: Georeferencing element structure

The *CoordinateReferenceSystem* defines the reference system through Type specifying CRS type as *ProjectedCRS*, *EngineeringCRS*, *GeographicCRS*, or *NotRequired*, *Datum* providing required horizontal datum, and *VerticalDatum* offering optional vertical datum. Each datum includes Name such as "EPSG:25832" or WKT2 string and Type as *DatumRegistryReference*. The *DatumRegistryReference* enables flexible geodetic registry specification per ISO 19127:2019 through *Name*, optional *Description*, and optional *RegistryReference* provided through a Unified Resource Identifier (URI).

The *ModelCoordinateSystem* element defines model positioning within CRS using generic coordinate names. *IsProjected* indicates whether the model inherits CRS projection distortion. *FirstCoordinate* specifies the first horizontal coordinate, typically Easting or Latitude. *SecondCoordinate* defines the second horizontal coordinate, typically Northing or Longitude. *Height* establishes the vertical coordinate. *XAxisAbscissa* and *XAxisOrdinate* provide optional model X-axis direction components. *UnitScale* offers optional model-to-CRS unit conversion. *HorizontalScale* provides optional horizontal distance scale factor.

Avoiding to “reinvent the wheel”, the LOINxml schema uses several elements from the data templates schema (namespace *dt*) defined in ISO 23387 (2025), in particular when it comes to the definition of properties, data types, and units. The schema employs Globally Unique Identifiers (GUIDs) and *ReferenceType* for element referencing within documents and across external resources. The schema definition of the used reference mechanisms is shown in Figure 6.

```
<xs:complexType name="ReferenceType">
    <xs:attribute ref="referenceURI" use="optional" />
    <xs:attribute ref="GUID" use="optional" />
</xs:complexType>
<xs:attribute name="referenceURI" type="xs:anyURI">
    <xs:annotation>
        <xs:documentation>
            Defines a referenceURI to identify a concept
            using URI
        </xs:documentation>
    </xs:annotation>
</xs:attribute>
<xs:attribute name="GUID" type="GuidType">
    <xs:annotation>
        <xs:documentation>
            Defines the GUID of a concept
        </xs:documentation>
    </xs:annotation>
</xs:attribute>
<xs:simpleType name="GuidType">
    <xs:annotation>
        <xs:documentation>
            The representation of a GUID, generally the id
            of an element.
        </xs:documentation>
    </xs:annotation>
    <xs:restriction base="xs:string">
        <xs:pattern value="[a-fA-F0-9]{8}-[a-fA-F0-9]{4}-
                           [a-fA-F0-9]{4}-[afA-
                           F0-9]{4}-[a-fA-F0-9]{12}" />
    </xs:restriction>
</xs:simpleType>
```

Figure 6: Schema definition of the elements from ISO 23387 used for linking in ISO 7817-3.

GUIDs provide unique element identification serving two purposes: establishing element identity and enabling internal cross-references. Most elements support the *dt:GUID* attribute for same-document referencing.

The *dt:ReferenceType* creates references via two attributes. The *dt:GUID* attribute references elements within the same document. The *dt:referenceURI* attribute references external resources. When both attributes are present, the reference points to a specific element identified by GUID within an external resource identified by URI. Referencing guidelines recommend using

dt:GUID alone for same-file references, *dt:referenceURI* alone for external resources, and both attributes for specific elements within external resources.

The *SpecificationPerObjectType* element defines information requirements for specific object types, such as walls, doors, or bridge abutments, binding object definitions to three requirement aspects: alphanumerical information, documentation, and geometrical information. Each Specification may contain multiple *SpecificationPerObjectType* elements, with one per deliverable object type. The structure comprises *ObjectType* defining the target object type as a required element, *AlphanumericalInformation* specifying required properties, quantities as optional, *Documentation* defining required documents as optional, and *GeometricalInformation* specifying geometrical requirements as optional.

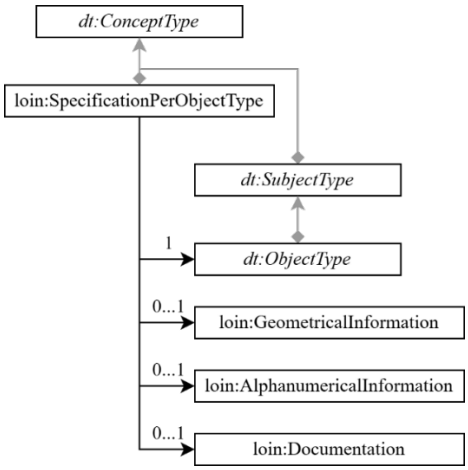

Figure 7: Structure of the SpecificationPerObjectType element

Since *loin:SpecificationPerObjectType* extends *dt:ConceptType* from ISO 23387, it includes Name and Definition elements separate from the *ObjectType* it addresses. Figure 7 shows the *dt:ConceptType* element and how it is incorporated in the LOINxml.

The *ObjectType* element identifies requirement targets using *dt:ObjectTypeType* from ISO 23387. Each object type requires a *dt:GUID* for internal referencing. Two main definition approaches exist: inline definition with Name, Definition, and metadata, or external reference via *dt:ReferenceDocumentRef* linking to libraries or other external resources. Multiple language variants support international projects as specified in ISO 23387. Version tracking occurs through *dt:MajorVersion*, *dt:MinorVersion*, and *dt:Status* as defined in ISO 23387. External references enable linkage to established classifications such as IFC or UniClass while maintaining internal GUIDs and optional local metadata.

A reduced instance example of a specification per object type element with emphasis on an object type definition using CityGML is shown in Figure 8. The *dt:ObjectType* is a child of the *dt:SubjectType* element, thus covering all the metadata of the *dt:ConceptType* element and allowing references defined in the subject type (reference for '*hasParts*' and '*isSubtypeOf*'). By aggregating specific information and associating it with a specific object type, the specification per object type container acts as a 'has' relation inherently (XML does not support relations in that sense).

Figure 8: XML instance example of an object type definition for a CityGML element

The *AlphanumericalInformation* element specifies required properties through several components. Its structure is presented in Figure 9.

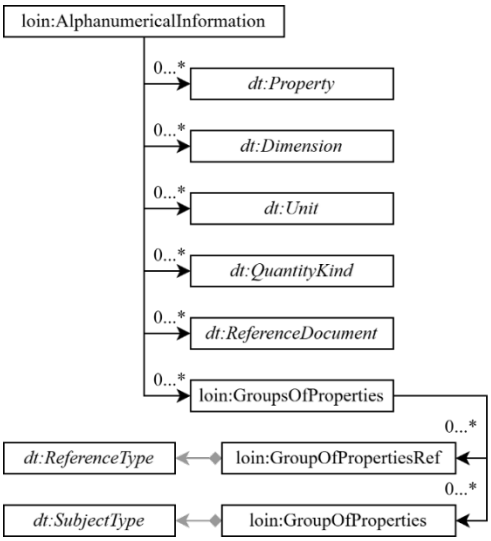

Figure 9: Structure of the AlphanumericalInformation element

Property defines individual property requirements either inline or referenced, with data types, constraints, and measurement references. *QuantityKind* provides quantity type definitions such as Length, Mass, or Pressure for inline properties or by referencing *Dimension*. *Dimension* expresses physical dimensionality (i.e., $L^1M^0T^0$) as SI base unit exponents, supporting inline units and quantity kinds. *Unit* specifies measurement units with conversion information including Scale, Base, Coefficient, and Offset. *DataType* specifying constraints. External definitions via *dt:referenceURI* on reference elements can point to standards like the Quantity, Unit, Dimension, and Type (QUDT) ontology (Hodgson, 2024).

Figure 10 shows an XML example of a self-contained LOINxml definition (inline in one file) while Figure 11 demonstrates the definition in separate files (e.g., one LOINxml and a separate Library with referenceable property definitions).

Figure 11: XML instance example outlining the linking mechanism (yellow highlight) of properties in separate files

GroupsOfProperties contains collections of related properties through inline *GroupOfProperties* or external *GroupOfPropertiesRef* elements. *ReferenceDocument* provides optional links to external dictionaries or standards.

The *GeometricalInformation* element defines geometrical requirements through five aspects, as shown in Figure 12.

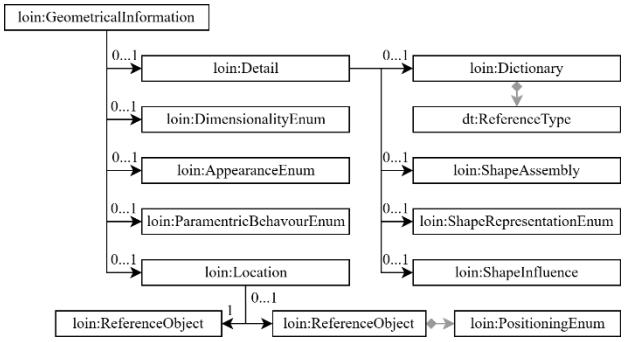

Figure 12: Structure of the GeometricalInformation element

The *Detail* aspect specifies geometry detailing information through a *Dictionary*, providing optional external definition references, *ShapeAssembly*, describing object assembly per ISO/TS 7817-2, *ShapeRepresentation* defining shape representation method per ISO/TS 7817-2, and *ShapeInfluence* establishing geometric feature requirements per ISO/TS 7817-2. The *Dimensionality* aspect describes dimensional representation as *0D, 1D, 2D, 3D*, or *NotRequired* per ISO/TS 7817-2.

The *Appearance* aspect specifies visual appearance requirements per ISO/TS 7817-2. The *ParametricBehaviour* aspect defines parametric behavior specification per ISO/TS 7817-2. The *Location* aspect establishes positioning method as *Absolute, Relative*, or *NotDefined* per ISO/TS 7817-2, where *RelativeOrAbsolute* specifies the positioning method as required and *ReferenceObject* provides the reference for relative positioning through GUID, filter, XML path, or natural language as optional.

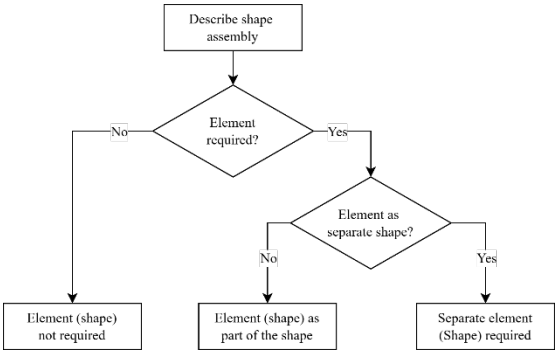

Figure 13: Simplified decision tree showing shape composition

The *Placeholder* attribute indicates placeholder-only geometry. *ShapeInfluence* specifies geometric feature representation with enumerated values according to the decision trees presented in ISO/TS 7817-2. A simplified version of the decision tree logic is outlined in Figure 13. The resulting enumerations (*NotRequired, No[Element], [Element]AsPartOfShape,* or *SeparateShapes*), and optional *ThresholdDimension* for size thresholds.

An XML example is given in Figure 14 to show application of the geometrical information.

Figure 14: XML instance example showing a geometrical information definition

The *Documentation* element specifies required documents via one or more *Document* elements. Each *Document* defines name as the document identifier, description specifying content as optional, *ReferenceDocument* providing external specification references as optional, *Format* establishing required file format with name and version, and optional classification attributes including type, form, and content.

Discussion of design decisions

The LOINxml data model prioritized reusing established principles and respecting existing frameworks. A major consideration was the breakdown structure foundation.

While IFC is widely established in AECO industry, not all requirements can be defined within the IFC data schema due to receiving actors' limited IFC knowledge or requirement nature. Projects requiring alternative breakdown structures are not uncommon. To enable broad application, the ISO 7817-3 (2025) data model remains agnostic, permitting any breakdown structure. The design supports multiple breakdown structures, enabling requirements spanning various disciplines. Though this decision introduces known challenges, the primary objective was allowing requirement definition as receiving actors deem necessary. Translating formalized requirements into IFC or other formats constitutes a subsequent step.

LOIN specifications require prerequisites elements while georeferencing and specification per object type remain optional. This ensures LOINxml specifications always include contextual information. The transaction-based model restricting specifications to one receiving and one providing actor was deliberate. Complex actor relationships such as sub-contractors or multiple providing actors were considered. However, such transactions vary either in purpose, warranting separate specifications, or in requirements themselves as with sub-contractors or separate providing actors delivering partial models. Given LOINxml's extensive linking options for alphanumerical information and flexible property structuring, the two-actor solution balances clearly framed requirements with lightweight definition.

The *GeoReferencing* structure separates CRS definition from model positioning through distinct *CoordinateReferenceSystem* and *ModelCoordinateSystem* elements. This separation acknowledges that multiple model coordinate systems may exist within a single CRS, supporting scenarios where different project components use different local origins or orientations within a shared global reference frame. The use of generic coordinate names (*FirstCoordinate, SecondCoordinate, Height*) rather than CRS-specific terminology (Easting, Northing, Latitude, Longitude) enables the schema to accommodate projected, geographic, and engineering coordinate systems uniformly. The *IsProjected* parameter addresses the fundamental distinction between models that inherit CRS projection distortion and those maintaining true-to-reality geometry, reflecting practical considerations in infrastructure versus building modeling workflows. The optional transformation parameters (*UnitScale, HorizontalScale, XAxisAbscissa, XAxisOrdinate*) provide flexibility for complex coordinate transformations but increase specification complexity and potential for misapplication.

The integration of multilingual capabilities through ISO 23387's *dt:ConceptType* enables specifications to function across language boundaries without translation or duplication. This design decision reflects the international nature of construction projects and standards development but introduces complexity in specification authorship and maintenance where multiple language variants must remain synchronized. The inclusion of versioning metadata (*MajorVersion, MinorVersion, Status*) at the object type level enables tracking of definition evolution over time, supporting change management and specification maturity assessment. However, the schema does not enforce versioning constraints or define version compatibility rules, leaving version management protocols to implementation conventions rather than schema-level enforcement.

The distinction between *ObjectType* definition and *SpecificationPerObjectType* implements a separation of concerns where object identity remains independent of requirement specification. This architecture permits the same object type to appear in multiple specifications with varying requirements while maintaining consistent identity through GUIDs. The extension of *dt:ConceptType* from ISO 23387 enables the specification itself to carry metadata distinct from the object it addresses. This dual-layer approach supports requirement versioning and modification without altering object type definitions, facilitating reuse across different project contexts and specification documents.

The schema accommodates both inline definition and external referencing across multiple element types, reflecting a fundamental tension between self-contained specifications and distributed definition management. Inline definitions create complete, autonomous

documents requiring no external dependencies but introducing redundancy when similar definitions recur across specifications. External referencing through *dt:referenceURI* reduces redundancy and enables centralized maintenance of definitions but creates dependencies on external resources whose availability and versioning must be managed. The property definition chain exemplifies this design where inline properties require complete definition of supporting *Units, Dimensions,* and *QuantityKinds*, while externally referenced properties inherit these definitions from their source dictionaries. This flexibility accommodates varying organizational capabilities and project requirements but places responsibility for consistency management on specification authors.

The decomposition of requirements into alphanumerical, documentation, and geometrical aspects reflects established information modeling paradigms where object attributes, associated documents, and geometric representations constitute distinct information categories. This separation enables independent specification of each aspect's requirements, supporting scenarios where different aspects require different levels of detail (for lack of a better word) or where responsibility for different information types resides with different project participants. The optional nature of all three aspects acknowledges that not all specifications require all information types. However, this structure assumes these three categories comprehensively cover information needs, potentially constraining representation of emerging requirement types such as behavioral specifications or process-related information.

The universal application of GUIDs for element identity establishes a stable referencing mechanism independent of element names, positions, or hierarchical relationships. This approach supports requirement traceability and change management by providing persistent identifiers that remain valid across document modifications. The distinction between *dt:GUID* for internal references and *dt:referenceURI* for external references, with their combination enabling references to specific elements within external resources, implements a two-tier resolution strategy. Internal resolution operates within document scope without external dependencies, while external resolution requires access to referenced resources. The schema's guidance to prefer GUID-only for internal references and URI-only for external resources suggests optimization for reference resolution performance and reliability, though the combined approach enables precise external element targeting when necessary.

The five-aspect geometric requirements structure (*Detail, Dimensionality, Appearance, ParametricBehaviour, Location*) aligns with ISO/TS 7817-2 guidelines for geometric specification. This decomposition treats geometric information as multidimensional rather than monolithic, acknowledging that different project phases or use cases may require different geometric characteristics. The *ShapeInfluence* mechanism within *Detail* enables fine-grained specification of individual geometric features with threshold-based rules, supporting complexity management where minor features may be omitted while significant features require explicit modeling. However, the reliance on enumerated values for each aspect constrains expressiveness to predefined options, potentially limiting specification of novel geometric requirements not anticipated in the enumeration design.

The practical implementation of the proposed schema necessitates a shift from purely geometric modeling toward robust semantic integrity, requiring rigorous alignment between proprietary parametric environments and standardized data structures. This integration typically demands the development of bespoke middleware or API-driven scripts to facilitate the mapping of local attributes to schema-specific fields, thereby ensuring that data fidelity is maintained throughout the project lifecycle. Furthermore, the operationalization of the schema is contingent upon the precise calibration of the Level of Information Need, which prevents computational overhead by restricting data density to the specific requirements of defined project milestones. In practice, the schema finds utility i.e. in the automation of quantity takeoffs and the enhancement of multi-disciplinary coordination through automated data validation; this allows for the identification of "data gaps" where physical components lack the requisite metadata for facility management.

Conclusions

The schema represents a significant advancement in formalizing information requirements specification across different dimensions of detail within the AEC industry, providing technical mechanisms for precise, machine-readable requirement definition. The schema's utility depends not primarily on its technical merits but on ecosystem development including software tool support, reference resource availability, practitioner capability building, and governance framework establishment. These ecosystem elements remain underdeveloped, suggesting near-term adoption will be limited to advanced organizations and pilot projects rather than achieving broad industry penetration. The schema provides necessary technical infrastructure for digital information delivery but proves insufficient without surrounding social and technical systems.

Future success depends on recognizing schema implementation as a socio-technical challenge requiring coordinated development of technical, organizational, and human capabilities rather than purely a standards adoption problem.

Acknowledgments

The authors would like to thank ISO, CEN and national standardization bodies and collaborators for the support throughout the development of the mentioned standards, especially CENT/TC 442/WG 2 and JWG ISO/TC 59/SC 1

Abstract

Construction projects, which are prone to delays and budget overruns, struggle to transform fragmented data streams into coherent intelligence. We propose a novel approach to monitoring that combines onsite data capture, agentic workflows and knowledge graph architecture to provide a foundation for evidence-based progress tracking. This approach is built on an ontology for structured schedule management that unifies concepts from domain-specific ontologies and Autodesk Construction Cloud. Autonomous AI-driven agents enable knowledge evolution by interacting with a knowledge graph. This lays the foundation for a living digital twin that adapts as new data emerges, supporting consistency checking and cross-system integration.

Introduction

Construction project execution involves large volumes of heterogeneous data, including schedules, building information models, and field reports, yet this information is rarely transformed into timely and coherent project intelligence. This gap continues to contribute to schedule delays and cost overruns, particularly during the execution phase where coordination and interpretation of evolving site conditions are critical (Gómez-Cabrera et al., 2023). In this context, effective schedule management depends on continuously reconciling plan and actual status, identifying emerging deviations, and relating observed site conditions to the activities and building elements they affect. Digital twins have been proposed as a means to address these challenges by maintaining synchronized digital representations of physical assets and construction processes. In construction, digital twin information systems have been framed as closed-loop mechanisms that explicitly represent and compare project intent and project status to support production control and decision making (Sacks et al., 2020). Central to this perspective is the interpretation of observations in relation to planned work. Prior studies show that progress understanding and predictive analyses become possible when site observations are grounded in a formalized project representation capturing spatial and temporal structure (Lilis et al., 2017). In practice, however, sustaining a "living" construction digital twin remains difficult, as information is heterogeneous, incomplete, and distributed across tools and stakeholders, complicating the maintenance of a coherent and queryable project state. Recent work has increasingly explored semantic and ontology-based approaches to structure construction information for digital twin applications, highlighting the role of explicit representations in integrating planning, monitoring, and derived knowledge across systems. In parallel, knowledge-graph-based approaches demonstrate how BIM data, schedules, and site information can be fused into machine-interpretable representations supporting analysis and downstream services (Katsigarakis et al., 2022). Despite these advances, many approaches either remain primarily representational without clear operational workflows, or focus on analytics without maintaining an explicit, inspectable project state over time. Building on these directions, this paper proposes an ontology-grounded, agentic framework for AI-driven schedule management in digital construction twins. The approach introduces the Intelligent Construction (INTC) ontology, which provides a unified semantic model integrating building topology, construction planning, on-site observations, and construction management concepts drawn from BOT, Digital Twin Construction (DTC), and Autodesk Construction Cloud (ACC). The ontology governs a construction knowledge graph that serves as persistent project state and supports explicit representation of observations, evidence, and state assertions. Over this shared representation, we define an agentic knowledge workflow in which specialized agents ingest project data, align observations with planned activities and building elements, and derive evidence-backed progress and deviation assessments. The framework is evaluated through an observation-to-insight pipeline instantiated in a controlled construction setting and validated using competency-question-driven queries over the resulting knowledge graph.

Related Work

Construction Site Monitoring

Construction site monitoring research has largely focused on two complementary problems: capturing as-built conditions and interpreting those conditions relative to planned scope and sequence. Prior work shows that integrating multiple monitoring modalities with BIM improves the completeness and reliability of project status acquisition compared to any single technology alone (Hasan

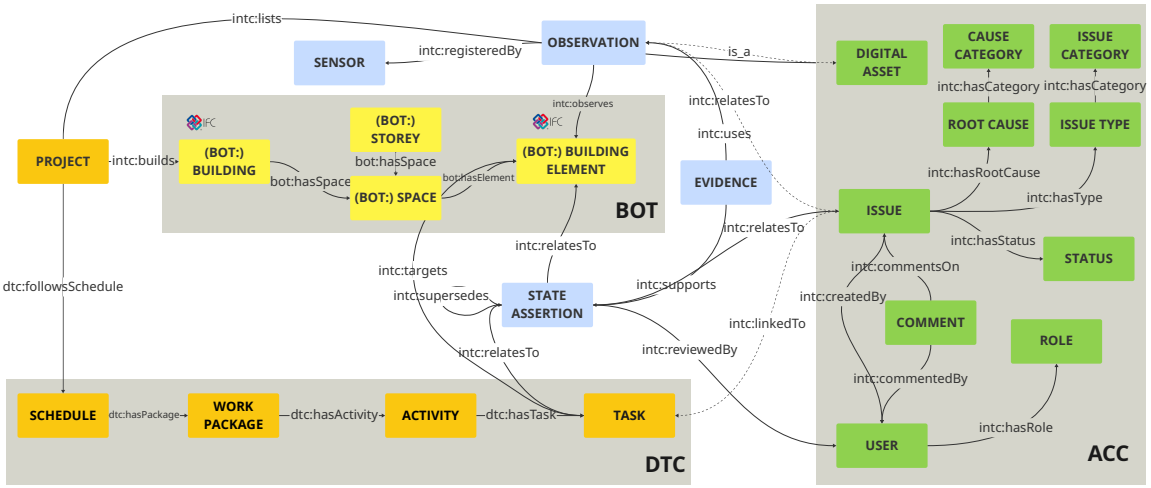

Figure 1: General overview of the INTC ontology

and Sacks, 2023). However, the central challenge remains not sensing per se, but interpreting heterogeneous observations in relation to formal project representations. Vision-based progress monitoring has received particular attention due to the practical availability of site imagery and time-lapse feeds. While recent systems have progressed beyond coarse, binary reporting toward richer state descriptions, they continue to face challenges related to occlusion, viewpoint variability, and robust mapping from detected signals to the project's formal objects and activities (Pal et al., 2023). As a result, visual signals alone often fail to produce reliable, attributable progress assessments. More recent work has explored lifting monitoring outputs into structured project knowledge rather than treating them as disconnected detections. Knowledge-graph based approaches demonstrate how BIM data, schedules, and site observations can be fused into machine-interpretable representations that support analysis and downstream services (Katsigarakis et al., 2022; Pfitzner et al., 2024). However, many such approaches either remain primarily representational, without clear operational workflows, or focus on analytics without maintaining an explicit, inspectable project state over time. This gap motivates our focus on persistent, evidence-linked representations that support plan–vs–actual reconciliation and traceable progress interpretation.

Ontologies for Construction

Ontologies provide a standardized machine-readable terminology to describe complex data and processes present in the construction process, while also enabling semantic interoperability across software capabilities involved in a construction project. Construction ontologies are an active research area, with multiple proposals that go from mid-level ontologies, such as the Digital Construction Ontology Suite (DiCon) (Zheng et al., 2021) or the Digital Twin Construction Ontology (DTC) (Schlenger et al., 2025), which attempt to cover all relevant aspects in the construction process, to domain-specific ontologies for scheduling, BIM data management, compliance and real-time site observations. Getuli (2020) presents a comprehensive study on knowledge modeling in construction planning, while Wu and Ma (2023) automatically generate construction schedules by combining constraint rules and genetic algorithms and Avogaro et al. (2024) proposed an IFC-based application for process scheduling. In the BIM data management field, Balaji et al. (2016) presented a unified schema for building elements, while Pauwels and Terkaj (2016) proposed ifcOWL, an attempt to convert IFC EXPRESS schemas into a usable ontology. In an attempt to address the practicality issues of ifcOWL, Rasmussen et al. (2020) published BOT, a shallower ontology focused on the topological relationships between building spaces. Ontologies such as OntoBPR from Hagedorn et al. (2025), or the Architecture, Engineering, Construction Compliance Checking and Permitting Ontology (AEC3PO) from Dridi et al. (2024) allow the modeling of compliance and permitting process using semantic web tools. Sensor-related ontologies like the Semantic Sensor Network Ontology (SSN) from Haller et al. (2018) or the lightweight ontology for sensors, observations, samples, and actuators (SOSA) from Janowicz et al. (2019) define a comprehensive vocabulary that enables the modeling of site monitoring activities.

AI-driven Agentic Frameworks

Recent work has increasingly framed large language models as agents, systems that interleave reasoning with tool use and state updates to support structured decision-making. ReAct (Yao et al., 2022) formalizes this paradigm by combining reasoning and acting in multi-step workflows, improving robustness and interpretability. While subsequent frameworks extend these ideas with modular orchestration, memory, and tool connectivity, most agent stacks remain domain-general. In construction, effective agent behavior requires grounding actions and inferences in a formal domain model and a continuously maintained project state, motivating our ontology- and knowledge-graph-centered approach.

Proposed Approach

The INTC ontology

Knowledge management in our approach is centered on a construction knowledge graph whose topology is governed by the Intelligent Construction (INTC) ontology. The INTC ontology acts as a connective tissue for four main areas of interest in construction: building information model (BIM), construction scheduling, on-site observations and construction management, the last one covered by Autodesk Construction Services (ACS), linking all these fields in a simple yet robust way. See Figure 1 for an overview of the INTC vocabulary and check (GitHub, 2026) for a version of the ontology, serialized in Turtle format. The BIM-related terminology is built upon an integration of the BOT and ifcOWL ontologies, to increase the coverage of building elements while considering IFC as a common input format for BIM data. The integration with the DTC ontology provides the required scheduling terms, while a one-to-one mapping with ACS concepts allows the definition of construction management concepts at the ontological level. The vocabulary for on-site observations is kept simple, focused less on sensor-related aspects and more on the modeling of insights derived from captured sensor data (see Figure 1 for an overview of the INTC vocabulary). The integration with ACS and the insights-driven on-site monitoring are the main reasons for the design on the INTC ontology.

INTC – ACS connection. ACS provides a comprehensive set of tools to interact with construction data stored in the Autodesk Construction Cloud (ACC). The ACC data model is intrinsically linked to the ACS services; however, there is no ontology to properly describe it. The INTC fills that gap, bringing ACC concepts like roles, users, and issues, among others, and adding semantic relationships between them. In order to avoid replicating the ACC data in the INTC knowledge graph, all entities related to ACC define an URN parameter that links to the corresponding resource for retrieval.

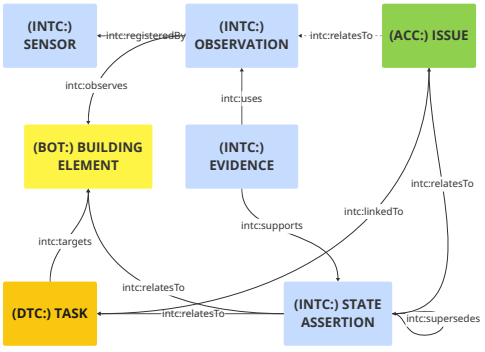

Figure 2: Observations, evidences, and state assertions in the INTC ontology

On-site observations in INTC. The sensor-related module of the INTC ontology aims to describe insights from on-site observations and how they connect with building elements, schedule activities, and potential ACC issues (see Figure 2). An important concept is the "Observation", captured by a "Sensor" (a camera, a microphone or any other sensing device) and used by a "Evidence". An "Evidence" leverages multiple "Observation" to support a "State Assertion" with a certain level of confidence. "State Assertion" is another central concept in this module and can be seen as a sort of update on the building element and the corresponding task in the schedule that targets it. An assertion might also eventually be related to an ACC issue, thus connecting the on-site monitoring with the ACC world. In summary, the core idea behind this design is that the progress of a task, associated with a building element, can be tracked through the associated state assertions, which are supported by evidence built upon observations. The "Ontology Validation" chapter describes a real-life scenario in which all these concepts are leveraged.

Agentic Knowledge Workflow

To operationalize AI-driven schedule management within a digital construction twin, we define an agentic knowledge workflow in which specialized agents operate on a shared construction knowledge graph governed by the INTC ontology (see Figure 3). The knowledge graph serves as the persistent project state and as the main coordination structure: agents record extracted information as typed entities and relations with provenance, timestamps, and confidence. Coordination is event-driven rather than purely sequential, so updates to graph state can activate subsequent processing steps while preserving an auditable record of how project understanding develops over time. The agentic workflow is decomposed into the following roles:

ACC Ingestion Agents (read-only). Retrieve authoritative project artifacts from Autodesk Construction Cloud (ACC) via Autodesk Platform Services (APS) and represent BIM/model artifacts, schedule structures, and documentation/specifications as INTC-aligned entities.

Semantic Linking Agent. Establishes and maintains the links between building elements, tasks, and relevant documentation/specifications required for monitoring, while preserving the provenance of these links.

Visual Observation Agent. Processes site images, registers each image as a DigitalAsset, and creates structured Observation entities linked to the most likely building element and task, while retaining confidence for perception and localization.

Progress and Deviation Agent. Uses newly added or updated observations to build Evidence supporting State-Assertion entities describing task progress and plan vs actual deviation. These outputs should be interpreted as evidence-based assessments rather than as ground truth. Conflicting evidence or assertions may coexist in the graph with their provenance and confidence, allowing later evidence or human review to refine the effective project state without removing prior interpretations.

ACC Sync Agent. Propagates selected progress updates back to ACC via APS. Synchronization is gated: low-confidence or conflicting interpretations are held for hu-

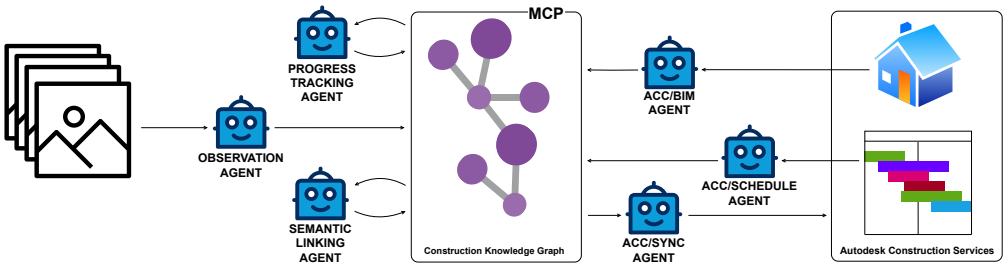

Figure 3: Simple, single-purpose agents operating on the construction graph

man review before write-back.

Overall, ACC provides the authoritative project context, while the knowledge graph provides the semantic structure through which site imagery is connected to observations, evidence, and state assertions for progress tracking and deviation assessment.

Observation-to-Insight Pipeline

The observation-to-insight pipeline converts raw observations into evidence-grounded project knowledge that can be compared against the plan to support activity-level progress monitoring and issue surfacing. The pipeline assumes an initialized project graph (from ACC ingestion and semantic linking) containing Task (planned activities) and BuildingElement entities, plus links to relevant requirements (e.g., execution specifications). This aligns with the DTC architecture that emphasize explicitly managing planning information, monitoring inputs, and derived knowledge in a unified structure (Schlenger et al., 2025).

Figure 4 instantiates the pipeline in the context of image-based progress monitoring as follows: For each new site image, the system (i) registers the file as a DigitalAsset (URI/URN, timestamp, capture metadata), (ii) applies a computer vision toolchain to extract candidate signals (e.g., detected components, stage indicators, potential defects), consistent with vision-based progress monitoring trends in construction (Pal et al., 2023). Next, (iii) it instantiates one or more Observation entities that are explicitly linked to the originating DigitalAsset and grounded to the most likely BuildingElement and Task (preserving uncertainty via confidence scores and, if needed, multiple candidate links). This "data → structured knowledge → metrics" flow is consistent with approaches that lift continuous image capture and object detection outputs into a knowledge-graph representation for construction process analysis (Pfitzner et al., 2024). Finally, with this pipeline in place, (iv) we can consolidate observations over time to maintain a current plan-vs-actual view at the activity level and emits actionable exceptions as Issue entities (e.g., suspected non-compliance or defect), each traceable through an Issue → Observation → DigitalAsset evidence chain. Where appropriate, issues can be exported back to ACC (e.g., as ACC Issues) under guarded policies (confidence thresholds and/or human approval).

While the individual stages of this pipeline (image capture, visual interpretation and progress reporting) are well represented in prior work, the central challenge lies in the alignment step: reliably mapping site observations into the project's object-activity model in a way that remains inspectable over time. In many existing systems, this alignment is either implicit (hard-coded mappings from detections to BIM objects, or transient (performed ad hoc for a specific metric or dashboard), which limits both extensibility and auditability. As a result, downstream "insights" often collapse heterogeneous evidence into a single status signal, obscuring how conclusions were reached and making them difficult to contest or revise as new information arrives.

The pipeline described here treats alignment as a persistent knowledge modelling operation. Observations are explicitly instantiated as first-class entities that mediate between raw digital artefacts and higher-level project claims. This allows multiple, potentially competing interpretations of the same evidence to coexist, each grounded in the project graph with explicit confidence and provenance, rather than forcing early commitment to a single explanation.

Experiments

Building on the pipeline logic introduced above (see Figure 4), we conducted a set of experiments focused on progress tracking using time-indexed site imagery. We assess the effectiveness of the ontology in: (i) grounding visually observable state changes in a knowledge graph instance, and (ii) maintaining an evidence-linked and traceable representation of construction state updates. It should be noted that our evaluation is intentionally scoped to the pipeline's semantic backbone rather than the end-to-end performance of the agentic workflow.

Experimental Setup

Our experiments are based on the ongoing construction of a real-scale mock-up room conducted in one of the Autodesk Technology Center in Boston. Figure 5 shows the 3D BIM representation of the room. The workshop floor is instrumented with multiple fixed cameras positioned to capture time-lapse sequences of construction activities from different angles.

Our setup takes Neo4j, a graph database following the Labelled Property Graph (LPG) as the storage solution for the construction knowledge graph. The INTC ontology is represented in RDF and serialized using the Turtle syntax, and

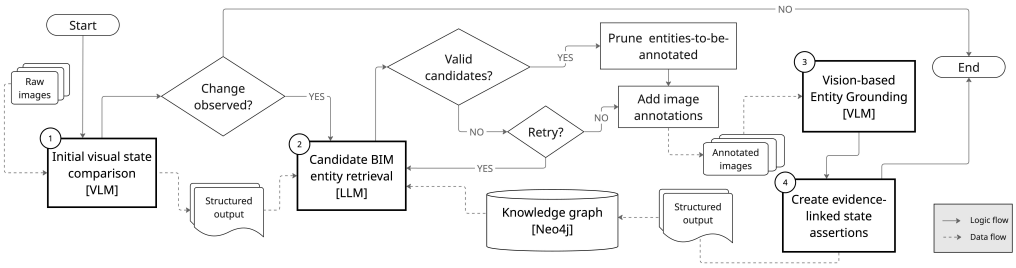

Figure 4: Logic and data flows of the observation-to-insight pipeline in the context of image-based progress monitoring; Steps 1–3 represent agentic enrichment of ingested imagery, while Step 4 establishes evidence and writes state assertions to the knowledge graph

Figure 5: 3D model of the mock-up room

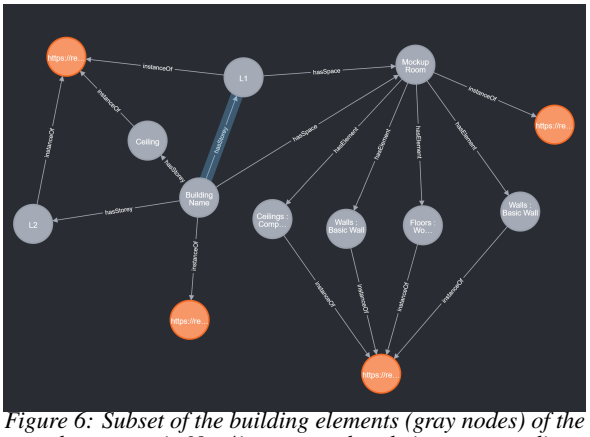

Figure 6: Subset of the building elements (gray nodes) of the mock-up room in Neo4j, connected to their corresponding ontology classes (orange nodes)

we leverage Neo4j's Neosemantics package to import it into the graph, forming the ''TBox'' (vocabulary) layer in the database. In order to link the instance data (''ABox'') with the vocabulary, we label the instance nodes with a single ''Instance'' label and link them with the corresponding class in the ''TBox'' with an ''instanceOf'' predicate, and ensure that all created relationships comply with the restrictions defined in the vocabulary, thereby leveraging ABox consistency while preserving key RDF semantics within an LPG environment (see Figure 6).

Figure 7 demonstrates instantiation of the main INTC ontology constructs, where the main subject of monitoring is the progress (stateType=''PercentComplete'') of one of the wall elements. An overview of instantiating the ontology artiacts for imagery observations is as follows:

Incremental ingestion: The camera captures from the the monitoring interval are represented as Observation instances (with stable external storage identifiers). Note that other sources of information in different formats, such as the site inspection report (text file), can be also represented as observation nodes (see top-left of Figure 7).

Agentic enrichment: The frames from the start and end of the current interval are fed to the image enrichment pipeline (see Figure 4), where a Vision Language Model (VLM) first compares the images to detect visible state changes. Then, the ACC/BIM agent (LLM-based) uses the generated structured change descriptions (in JSON format) and queries the BuildingElement nodes within the Neo4j instance to retrieve a set of likely BIM entity candidates that are set to be visible within the camera's field of view. Finally, it uses annotated overlays (pre-computed) to match each change to the correct BIM GUID by re-invoking the VLM for entity grounding.

Evidence establishment: The enriched observation artifacts become materialized as EvidenceItem nodes. Maintaining this explicit evidence layer is critical because multiple observations may support/contradict a single assertion (derived conclusion), and a single observation may be re-used to support multiple conclusions (e.g., element-level status and task-level completion). Evidence units can also carry indicators and references to intermediate outputs (e.g., confidence, image segmentation masks generated throughout enrichment steps).

State assertion: We use StateAssertion nodes to represent time-scoped and evidence-backed claim about the evolving condition of a subject entity. Each assertion node is associated with a set of key properties, e.g., StateType label (here ''PercentComplete''), state value (here percentage float), validity time (instant or interval), and provenance metadata (e.g., pipeline version). In the scenario depicted in Figure 7, we can see how multiple evidence units (originating from different sources at different times) can support a new assertion about the task's completion and supersede an existing one, while preserving the auditability chain from drawn conclusions back to raw observations.

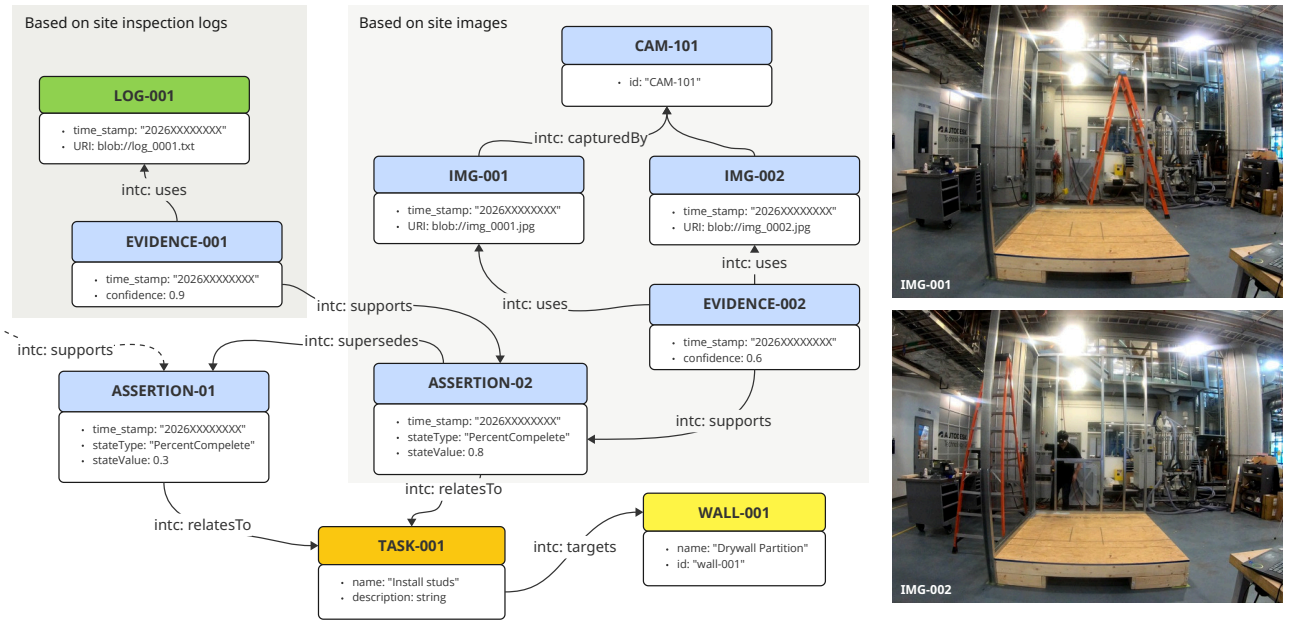

Figure 7: Example of ontology instantiation illustrating observation-to-insight pipeline in an experimental setting

Table 1: Summary of ontology validation competency questions

Category	Validation Purpose	Example Competency Question
Effective Progress State	Resolve multiple associated assertions into a single effective state (via validAt, confidence, etc.)	What is the current effective progress state of a given BuildingElement?
Temporal Reconstruction & Trajectories	Reconstruct progress as-of time t (via validAt); progress state evolution as a time series (trajectory, rates, stagnation)	What was the progress state and completion rate of a BuildingElement as of a time t?
Traceability & Evidence	Enable auditability: trace assertions to evidence, sensors, and raw data references	What evidence (observations) support a specific progress update?
Revisions & Updates	Track non-destructive revisions and state assertions history (when, what, who)	Was a progress state revised? what was the updated value? who initiated?
Spatial Context	Contextualize progress spatially (aggregate/filter by Zone/Space)	What is the progress of a given BuildingElement within a given Space?

```

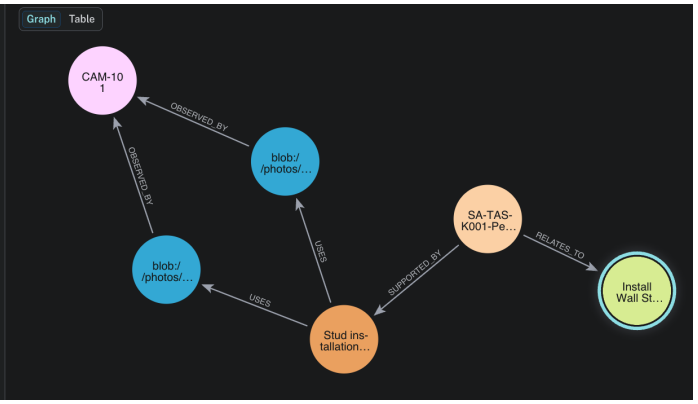

Figure 8: Example of CQ queries: retrieving latest state assertion and its chain of evidence for the data depicted in Figure 7

Validation

We adopt a Competency Question (CQ) methodology (Wiśniewski et al., 2019) to validate whether our proposed knowledge structuring can support the core representational requirements of the intended agentic workflow. The CQs were derived by first distilling the recurring information needs implied by the observation-to-insight pipeline (e.g., grounding, provenance) and then refining and prioritizing them through discussions with the domain researchers involved in the mock-up room deployment. A summary of the key patterns studied here is presented in Table 1. Each CQ is instantiated as Cypher query statements executed over the Neo4j instance, which contains data from the observation enrichment pipeline, as well as synthetic data needed to support the monitoring of the wall's construction progress. An example query associated with the scenario depicted in Figure 7 and it corresponding results are shown in Figure 8. To facilitate reproducibility of the validation results, QC evaluations are represented in a native LPG model (not RDF-based). The full list of questions studied in our experiments can be found in a designated public repository (GitHub, 2026).

Discussion

Our experiments indicate that our proposed ontology can support essential query patterns such as, "what changed," "why do we believe it changed," and "when did this belief become valid/invalid," using explicit representations. One of the key practical implications of our proposed ontology can be attributed to its support for traceable and auditable progress monitoring updates. First, it separates raw observations from interpreted claims about progress, which allows the system to retain historical assertions (including potentially conflicting ones) while updating the current estimate as further evidence becomes available. Second, the explicit linking of assertions to evidence and inference provenance makes each reported progress state inspectable: a user (or downstream analysis) can retrieve the originating sources (e.g., images, site logs), the intermediate evidence artifacts (enriched observation), and the method used to generate the claim (e.g., agent's model version). These aspects are crucial for construction practice, since field teams and project managers often have access to large volumes of signals (images, site reports, schedule logs), but the bottleneck lies in converting those signals into accountable estimates (state assertions) that can be traced back to evidence and acted upon. Moreover, progress updates and issue reports routinely require justification, especially when they trigger downstream actions such as schedule replanning, payment approvals, or rework decisions.

Our proposed representation is intended to be applicable across two complementary consumption modes. First, it can support deterministic workflows through formal queries embedded in conventional software. Second, it offers a structured representation for AI-enabled components and agentic workflows. Importantly, this dual use is enabled by a representation that remains relatively minimal: it captures the constructs required for traceability of evolving states without imposing an extensively granular design that can cause scalability issues for the broader system.

Finally, our evaluation primarily validates CQ answerability, however, does not directly quantify the advantage of the proposed model over existing data structures used in conventional schedule tracking systems. Although we demonstrate that the representation supports critical query patterns, we have not yet measured downstream impacts. In addition, our evaluation setup focuses on the construction of wall elements in a controlled environment. While this scenario can provide a clear sequence of visually observable states, other trade activities (e.g., mechanical/electrical rough-ins) may exhibit subtler visual indicators and greater ambiguity in mapping observations to relevant subjects or require additional sensing modalities. As such, the present contribution should be interpreted as a novel approach towards deviation assessment in construction progress.

Conclusions and Future Work

This paper introduced a semantic backbone for construction digital twins in the context of progress tracking. The proposed ontology provides a principled way to ground heterogeneous site observations into the planned project context by linking them to semantically-related entities (e.g., building elements or tasks). It enables the digital twin to maintain an evolving plan–vs–actual view as a set of time-scoped, evidence-backed assertions that remain queryable, interoperable, and inspectable as project knowledge is incrementally updated over time.

Future work should link the proposed representation to operational metrics and assess how effectively AI agents can exploit it, while clearly separating representational capability from agent performance. Larger-scale validation under more diverse sensing conditions remains necessary. The approach also opens avenues toward quality-aware progress monitoring and evidence-based causal analysis.

CONNECTING DOTS: HARNESSING DIVERSE PERSPECTIVES FOR THE INTEGRATION OF DIGITAL BUILDING PERMITS AND LOGBOOKS

Pedro Mêda[1], Judith Fauth[2]
[1]Project Manager/Invited Assistant Professor, CONSTRUCT, ICS – Institute for Sustainable Construction, University of Porto, Faculty of Engineering, Porto, Portugal
[2]Postdoctoral Researcher, Technical University of Munich, Munich, Germany

Abstract

The integration of Digital Building Permits (DBP) and Digital Building Logbooks (DBL) is increasingly recognised as essential for sustainable and data-driven construction and building lifecycle management. This study examines how European initiatives, including permitting platforms, logbook gateways, city Digital Twins and building stock observatories, contribute to DBP and DBL integration, often implicitly. Using a step-by-step thematic analysis of stakeholder and expert interviews, the research identifies shared data foundations, maturity gaps and governance challenges. The findings outline initial pathways for aligning fragmented initiatives and support the development of coherent and interoperable DBP and DBL ecosystems.

Introduction

The pace of digitalisation in the built environment sector has gained new momentum amid growing sustainability focus (Papadaki *et al.*, 2023). Requirements in terms of energy efficiency, the rational use of resources, and the implementation of more circular practices have led to new demands for data availability and accessibility, while also giving purpose and direction to the digitalisation of processes (European Parliament and European Union Council, 2022). Data-driven instruments, long assumed to be needed, are emerging, such as the Digital Product Passport for Construction (DPP_C) and the Digital Building Logbook (DBL) (Papadaki *et al.*, 2023). These instruments are intended to span many domains, aiming to meet the abovementioned requirements. Also, they are meant to work in combination with existing digital technologies such as Building Information Modelling (BIM) and Geographic Information Systems (GIS), to name a few (Calvetti, Mêda and Sousa, 2021). There is the intuition that several initiatives not specifically targeting DPP_C and DBL are already using or will need to use the same data. Not recognising the connections can introduce several constraints on the path towards efficiency, sustainability, and modernisation in the construction and built environment sectors. Therefore, this study seeks to identify whether there are connections to be made by considering diverse perspectives. Based on the observations, it aims to provide initial guidelines that support different paths to achieving a common goal, with a main focus on DBL.

The DPP_C focuses on product data. Within the context of the new Construction Products Regulation, it serves to disclose the declaration of performance and conformity, including the essential characteristics, and to enable harmonised marketing across the EU (European Parliament and the Council of the European Union, 2024b). Furthermore, the digital tools developed are designed to preserve the data and expand their use, as the products will be incorporated into construction projects and built objects (European Parliament and the Council of the European Union, 2024b). The DBL is building-centred (Mêda *et al.*, 2022). It is envisaged as a multi-level, multi-layer information container that collects, connects, and supports relevant construction-related data at land cadastre, built object, and building unit levels, to be made available for multiple purposes (Grow, 2023). Its initial motivation was the energy performance of buildings, establishing a common framework and data points for this specific output (Gómez-Gil, Espinosa-Fernández and López-Mesa, 2022). However, it was realised that, given the data requirements, a set of additional purposes could be achieved within the same effort (Gómez-Gil *et al.*, 2022). Notwithstanding, the energy-related purpose has been a major driver, and this is now part of the EU legal framework under the new Energy Performance of Buildings Directive (EPBD) (European Parliament and the Council of the European Union, 2024a). The observation of the relationships at the building level and construction process life cycle led to exploratory research on the alignment, benefits and synergies with another long-recognised research domain, critical for the efficiency of building construction; the building permitting process (Noardo *et al.*, 2022; Fauth and Seiß, 2023; Fauth *et al.*, 2025). Further, the EU's Renovation Wave strategy and the Affordable Housing plan heavily rely on data to increase knowledge of the European built stock, its uses, performance, and resource potential, among other key figures (European Commission, 2020, 2025). Digital instruments are needed to collect, manage and process that data. The DBL, the Digital Building Permit (DBP), other associated concepts and the Digital Twin (DTw) platforms are fundamental pieces to make it happen (CEN/TC 442, 2026)(Calvetti *et al.*, 2025).

The present study, grounded on the constructivist paradigm (Cobb, 2006), builds on recent works that have demonstrated the relationship between the DBL and the

DBP concepts and, subsequently, the added value of assessing and forecasting the potential synergies between them (Mêda, Fauth, Schranz, Sousa, *et al.*, 2024; Mêda, Fauth, Schranz, Urban, *et al.*, 2024). Moreover, this work aims to explore further how various initiatives currently underway can contribute to this integration (Fauth, J.; Mêda, P.; Gisbert Ferrer, P.; Flickenschild, M.; Babok, 2025). A step-by-step thematic analysis (Naeem *et al.*, 2023) is conducted based on interviews with qualified stakeholders with in-depth knowledge of the permitting and logbook domains. The selection is related to their involvement in the development and implementation of initiatives in affiliated domains. This enables qualitative assessments based on diagrams to define a conceptual model, supported by a maturity framework, for DBP and DBL integration. The aim is to discuss the need to set paths that can help industry stakeholders understand the landscape of concepts and how initiatives pointing to other goals can be adjusted or already partially cover the scope of what DBP and DBL want to achieve. In this sense, the research questions are as follows: Considering different existing initiatives, how do they perceive DBP and DBL integration? Considering their specific objectives, how can these initiatives contribute towards that integration? Which actions (maturity increments) can be done to foster that integration?

Following this Introduction, the present research starts with a background that systematises the problem and the contributions from previous research. The explanation of the methodology employed follows to present the results from the thematic analysis. A discussion on the main aspects to be considered as part of a maturity framework is provided, together with study limitations and future perspectives. The work finalises with a conclusions section in which the answers to the research questions are presented.

Background

The Transition pathway for Construction has paved the way for the industry to advance towards the green and digital transition goals (Papadaki *et al.*, 2023). Despite developments and evolutions in understanding, this document remains a cornerstone of the EU's strategy for a Sustainable Built Environment (SBE).

The accomplishment of an SBE relies on the ability to have available buildings/built stock data for a wide range of purposes, from theoretical models of energy efficiency to energy performance monitoring, space identification and their maintenance plans and requirements, bill of materials, quantities for reuse/recycling, change of ownership, dangerous substances in products, planning of investment needs, among others. The DBL, working as a DTw enabler at the building level (Staff, 2021), helps unlock the buildings' unawareness of these dimensions.

However, a DBL needs to be deployed early in the design phases and will need to interact with databases, processes, platforms, and tools to link, collect, organise, compile, and manage data points (Mêda *et al.*, 2022). While BIM is often identified as one of the main components of digitalisation strategies for construction, those often struggle to explore metadata or the Level of Information Need (LOIN) in the BIM model (ISO, 2018). Data-driven processes, such as building permitting, require a clear identification of the required data points (Bloch and Fauth, 2023). Significant research exists on the digitalisation of building permits, with some focusing on BIM (Ullah, Witt and Lill, 2022).

Interestingly, despite the research community's growing interest in DBL, this remains quite unknown (Fauth, J.; Mêda, P.; Gisbert Ferrer, P.; Flickenschild, M.; Babok, 2025), meaning that stakeholders recognise the need for a type of database or information container capable of capturing and retaining the necessary data, but don't assume it as a logbook. This realisation was only perceived during the study on the synergies between DBL and DBP (Fauth, J.; Mêda, P.; Gisbert Ferrer, P.; Flickenschild, M.; Babok, 2025). The study findings confirmed that integration between logbooks and permits is both feasible and emerging, creating opportunities to reduce duplication, automate compliance checks, and streamline processes. The benefits range from improved housing delivery to more accurate environmental performance and administrative efficiency. It is worth highlighting efficiency gains from faster procedures, as well as improved transparency and trust through centralised, validated data (Fauth, J.; Mêda, P.; Gisbert Ferrer, P.; Flickenschild, M.; Babok, 2025). However, not understanding how relationships and interactions work across different perspectives or purposes is more than just a challenge; it can lead to misunderstandings. These misunderstandings can result in shortcomings, inefficiencies, and, more critically, blockers and frustrations regarding the innovations being implemented.

Research on permits is more extensive, with multiple relevant contributions. Recently, several European projects have been finished. These have helped people understand the differences between EU countries and the plans to make building permits more digital (European Commission, 2023). In this context, and with relevance to the present study, four maturity levels have been established regarding DBPs. They are as follows: 1) paper-based, 2) digital paper, 3) digital BIM-based process, 4) digital BIM-based process with GIS (European Commission, 2023).

Methodology

As mentioned, the present research builds on previous work, including desk research (Moore, 2018) and literature reviews, to provide an overview of existing scientific studies and strategic documents at the EU level focusing on DBL, DBP, and their combination. As part of those studies, a series of semi-structured interviews was performed to capture impressions from a sample of relevant stakeholders directly involved in digitalisation initiatives, with additional insights from experts (Fauth, J.; Mêda, P.; Gisbert Ferrer, P.; Flickenschild, M.; Babok, 2025). These interviews lasted about 1 hour and were conducted in October/November 2025 (Table 1). A semi-structured interview guideline was intended to cover several topics related to permitting and logbook

integration, with a focus on housing projects. The interviewees gave their permission for transcription. To ensure confidentiality, sensitive data were anonymised.

Table 1: Example of a table where the caption should be on top of the table

	Stakeholder type	Exper-tise	Country Region	Experi-ence
1	Municipality Dep. Head	DBP	Estonia	10 years
2	Project manager	DBL	Flanders	10 years
3	Project manager	DBP/GIS	The Netherlands	10 years
4	Municipality Dep. Head	DBP	Austria	15 years
5	Project manager	EPBD	Europe	15 years

Given the specific contexts and objectives, different conventions were used to express similar topics. Therefore, a step-by-step thematic analysis process, as proposed by Naeem (Moore, 2018), was followed. This process comprises the following steps: 1) Transcription, familiarisation with the data and selection of quotations, 2) Selection of keywords, 3) Coding, 4) Theme development, 5) Conceptualisation through interpretation of keywords, codes and themes. Despite familiarity with the data, transcription and selection of quotations from the recordings were performed manually for each interview from start to finish. This was because the important information was scattered across different places rather than presented as answers to specific questions. The next step involved selecting relevant keywords to explain and define the objectives and key features of the initiatives. However, because the interviewees had different nationalities, it was necessary to take two distinct analytical steps to ensure everyone understood the topic the same way. 1) Relationship between different concepts in each initiative; 2) Classification of keywords in the following categories: “scope”, “data type”, “process/deliverable”, “concept”, “requirement/rule” and “technology”. Implementing these steps involved coding and theme development. An inductive coding approach was practised as the concepts emerged directly from the interview data. To ensure coding consistency, an audit trail was established. From the initial narrative descriptions of each initiative, keywords were refined to yield the final themes, along with diagrams summarising the descriptions. Specific colours and shapes are used to highlight the labelling in the diagrams. These elements are detailed in the following section.

Results

This section addresses the individual results based on the thematic analysis steps. Descriptive overviews of the initiatives and the simplified diagrams are presented. Due to space constraints, the description was preferred over the diagrams. However, a more complete graphical perspective is provided for the first case presented to exemplify the work performed. Additionally, authors use dashed lines on the diagrams to show ongoing and future developments. As mentioned before, from existing studies and the initiatives to be presented, the integration between the DBP and the DBL has not been the focus or the driving objective. The section ends with an analysis of all the cases, identifying the overlaps and setting a common framework.

Digital construction platform (Estonia)

Regarding the e-construction platform initiative in Estonia, here defined as digital construction platform (for generalisation purposes), the developments were focused on achieving a multi-module solution that could 1) Contribute to the establishment of a Digital Twin at the country scale; and 2) Set a governance framework for construction processes life cycle digitalisation. To put these aspects in place, BIM and GIS were considered, along with existing legacy documentation and data points, such as the national building registry, the cadastral database, and land spatial planning. Other relevant data types were considered, such as the ownership, tax data, utilities networks and consumption data (energy and water). Some of these legacy data types originate from building permitting processes; therefore, BIM-based permitting was implemented to streamline compliance checks and assessments for issuing permits and to make relevant data available for other phases of the construction life cycle. Although the DBL is not a clear and individualised concept in the system, many of the data types, data points and potential features are considered, making its materialisation as a “*de facto*” feasible concept (Figure 1).

In summary, this initiative demonstrates a high level of maturity in digitalisation and, more importantly, in the relationship between processes, requirements, data types, and legacy databases to materialise a Digital Twin at the country level. A strong concern was expressed regarding the necessity for the country to invest in achieving a common national information ground (for buildings and other construction types and layers), despite the potential interest in supporting owner-specific needs. The building dimensions are paramount in the strategy, and although the DBL was not recognised as a component of the system architecture, its role, positioning, and potential uses are recognised. Moreover, substantial DBL data and associated features are already embedded in the system.

Logbook-centered initiative (Flanders)

This initiative assumes as its main objective providing a single data gateway for building owners (residential and non-residential) to have access to relevant buildings' legacy data. Many features of the DBL are covered by this gateway, which centralises existing data from Governmental and municipal databases, including those for spatial planning and environment, heritage, building registry, energy and water supply and consumption, building quality, materials, and waste. It should be noted that this is official national data. However, building owners are at liberty to contribute additional information and data points to the gateway, including alterations and

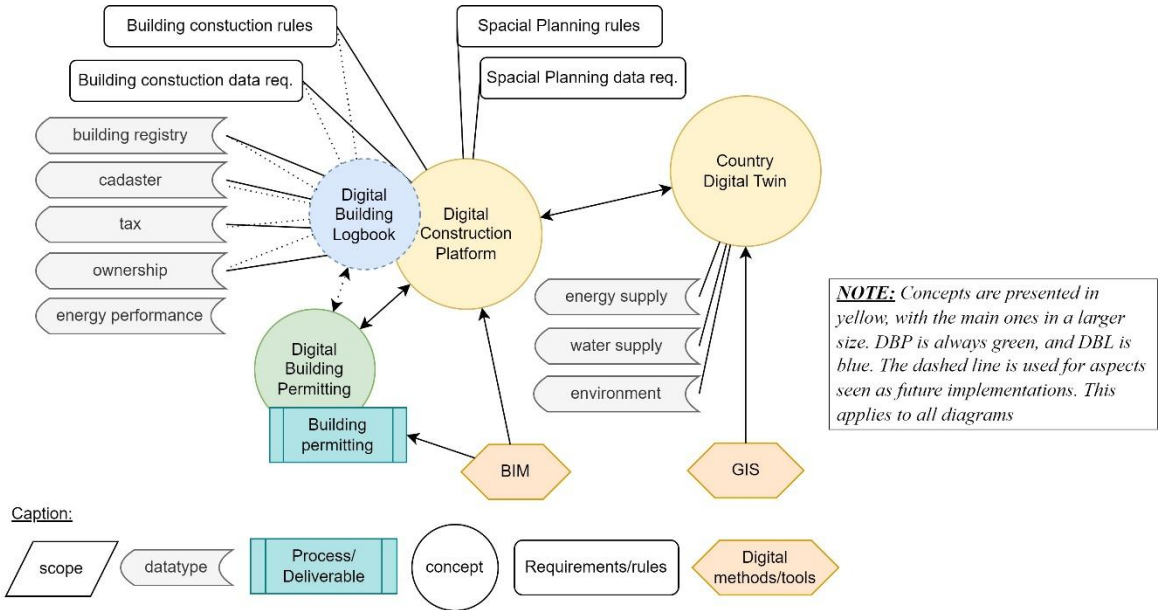

Figure 1: Schematic diagram of digital construction platform

maintenance actions. Following an initial development, setting a relationship with the building permitting processes was identified as a strategic step. In this respect, metadata and documentation for the initial permit and subsequent permits can be tracked. It is recognised that this DBL's primary concern is capturing legacy data and making it available. Improved features are required to capture additional data types and more dynamic data. In this respect, the forecasted steps align with the goal of developing a city platform where these features will be developed and integrated with the DBL (Figure 2).

In this case, the initiative began without searching for an integration between DBL and DBP. During development and implementation, it was recognised that this would not only make sense but could also add value to the initiative's governance.

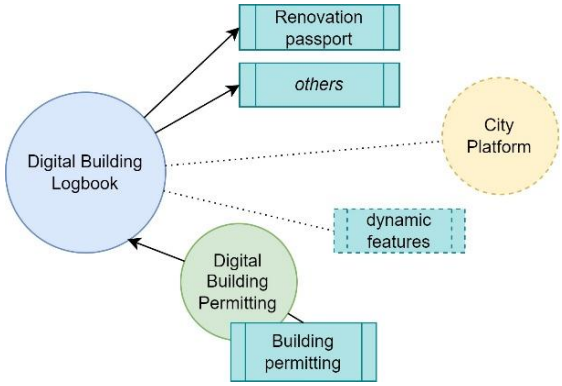

Figure 2: Simplified diagram for the initiative focused on the DBL.

City Digital Twin (The Netherlands)

The aim of this initiative is to build a platform that can materialise a digital twin at the city level. At the core of the goals is improving city operations in terms of efficiency, costs, and resource consumption. To accomplish them, several data sources were brought together from city maps, georeferencing systems, transport network information, and buildings' blueprints. The next step aimed to create a 3D city model. In this respect, and with regard to buildings, this requirement aligns with existing building permitting requirements, which already demand a BIM methodology and establish a set of information delivery specifications focused on openBIM. Linked data is used to aggregate data from the building level to the city level (Figure 3).

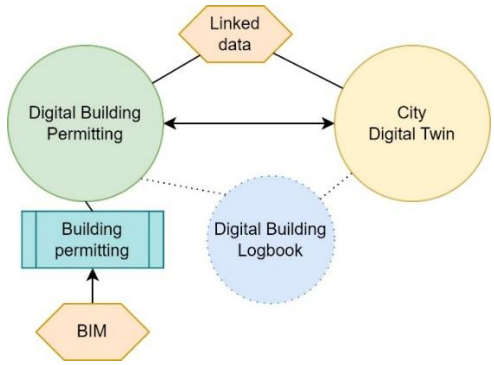

Figure 3: Simplified diagram for the initiative focused on the city's digital twin.

In this process, it made sense to integrate BIM-based permitting processes into the city's digital twin platform to enable observation of construction evolution related to DBP procedures and to streamline compliance checks for subjects such as spatial planning and available utilities. It is recognised that, for now, most available building data reflects the "as-design" condition, and only specific data points reflect the "as-built". However, this is part of the developments under consideration.

In summary, although the DBL was not recognised as a component for the city's digital twin systems architecture, its role, positioning, and potential uses were perceived. It was clear that logbook data and some features are already embedded in the system, although not structured with the vision of providing a structured Digital Building Logbook.

Single gateway for municipal permitting (Austria)

In this case, the initiative originated from the idea of centralising all permitting procedures on a single platform. Considering the wide range of permits that citizens can request from an authority, from kindergarten for children to car parking spots, urban waste containers, or construction operations, just to name a few, the objective was to provide a common access point. In this respect, building permits were identified as one of the relevant types to consider. The developments centred on dematerialising the process by establishing digital mechanisms and disclosing common rules for submissions by type. This new system links with the authority that receives all required documentation in PDF format to start the compliance checks. It is recognised that, at this moment, the system is working as intended, but there is the notion that improved digitalisation can be incorporated into building permitting procedures, namely through the use of BIM, augmented reality, and artificial intelligence (Figure 4). In this respect, considering the growing requirements for permitting in terms of data; as CO_2 consumption, materials used and recycling potential, among others; having all building-related data in one place — the logbook — would improve the initiative's goals.

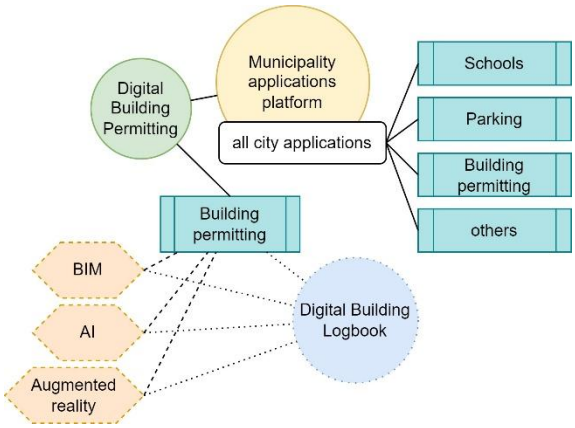

Figure 4: Simplified diagram for a single gateway for municipal permitting.

The building permitting processes require substantial documentation, and new requirements are being introduced that will increase the amount and complexity of that documentation and the compliance-checking procedures. It is acknowledged that digital technologies will be pertinent in addressing and rendering the new requirements tangible. The concept of a "data lake" storing all pertinent building information with the objective of streamlining the permitting process is both desirable and advantageous for a range of other requirements that extend beyond the scope of permitting. In this respect, it is important to be aware of how a DBL can quickly meet requirements for materials and recycling.

Building stock observatory (Europe)

Despite the different scope and dimensions, addressing this initiative is relevant given its alignment with the research's scope and the additional layer it adds to national-level initiatives. The EU building stock observatory is associated with the Energy Performance of Buildings Directive (EPBD) and aims to cover a broad range of energy-related topics, including energy consumption, building elements and installed technical building systems, energy performance certificates, nearly zero-energy buildings, and renovation rates. In this respect, renovation passports and the energy performance of buildings databases defined in Article 22 of the EPBD constitute key data sources (European Parliament and the Council of the European Union, 2024a). The EU building stock observatory combines data from member states on the energy performance of buildings, building types, building registries, and the number of permits by type. This information originates from multiple databases maintained by statistical bodies and authorities responsible for issuing energy performance certificates (EPCs). While these mechanisms are recognised as being important for the observatory's initiation, it is acknowledged that reducing data duplication, enhancing systematisation, and ensuring more reliable and accurate data are pivotal considerations. In this respect, the logbook is envisaged serving as the repository for the building's data, interacting with and collecting data from processes throughout the building's life cycle, such as permitting, renovations, maintenance, and other events (Figure 5).

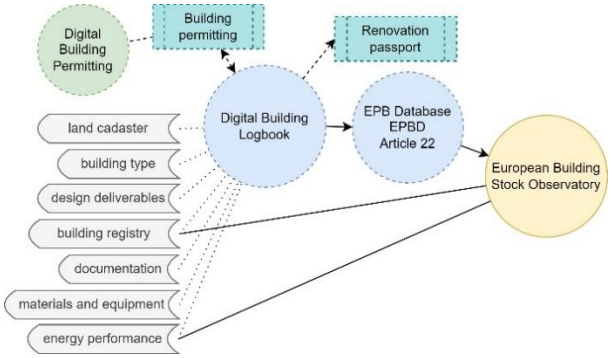

Figure 5: Simplified diagram focused on the Building Stock Observatory.

Despite the fact that this initiative is firmly rooted in the energy performance of buildings, it was acknowledged that its success will be contingent on the successful organisation of all relevant building data. Energy-related data constitutes only a fraction of this, with additional data sources including the technical solutions employed, equipment, spatial dimensions and orientation, among others. In this particular context, it is noteworthy that the DBL is mentioned in the EPBD in relation to the renovation passport. Considering that a substantial part of the observatory data comes from statistical offices, it is relevant to note that its origin lies in permitting processes. Therefore, although not explicitly mentioned, the outcomes of permitting play a critical role in enabling the observatory as it works today, suggesting that more digital processes in permitting would be beneficial.

Setting a common ground

Despite the varying scopes of the initiatives, a strong overlap and a sequencing of objectives can be established, as these work with building data and processes associated with building construction (building permitting) and operation (energy efficiency). Of greater significance is the observation that DBP and DBL are prevalent despite the variations.

The thematic analysis indicates that the integration of DBP and DBL is widely recognised as both desirable and feasible. However, it was not explicitly included in the initiative's initial objectives. Furthermore, in the post-interview period, integration is regarded as being of the utmost importance. This, despite the general absence of DBL realisation at the time when the development strategies for the initiatives were formulated. In most cases, this is justified because the DBL studies were still being developed or because the widespread understanding of its role was still very low.

It is also worth noting that existing data sources are already related, linked, or associated with DBP or DBL-like functionalities. Building registry data, ownership, tax, design deliverables, energy performance, or legal documentation for building use constitute good examples. However, in terms of support, these can still be paper-based, PDF-based (images or metadata), GIS- or BIM-based (metadata), or a combination of these. On another level, city or country existing data sources, such as land cadaster or spatial planning, as well as characteristics of facilities such as water and energy supply, environmental constraints, among many others, also provide similar support. This represents a critical aspect that enables not just logbooks and permits, but also all the objectives mentioned for each initiative. In this respect, the gaps regarding a common national information ground, the uneven maturity across municipalities/countries, the confusion about definitions (stakeholders may want a "data container" but not call it a logbook), the varying data quality ("as-design" vs "as-built"), the governance and ownership questions, the compatibility with legacy systems, and scalability of metadata/LOIN definitions should be assumed as main barriers and concerns. Figure 6 aims to combine, in a single diagram, all the concepts, data types, digital methods/tools, and processes/deliverables that were approached individually.

Discussion

Digital Building Permits and Digital Building Logbooks are common and are perceived as critical to the success of initiatives like the ones explored. Increasing the maturity of each concept and working on its integration will expand the capabilities of city and country platforms, boosting the data availability, relationship and accuracy for the European Building Stock Observatory and, more importantly, improving the knowledge on buildings and their units for a wide range of stakeholders and purposes, from ownership management, real estate, city governance, and networks capacity, among many others.

Previous studies (Fauth *et al.*, 2024, 2025) demonstrate that building permits vary substantially from a process perspective. However, the object is the same, meaning that there is a common ground for the data needed to run these processes. Digital Building Permits already have maturity levels associated. It is evident that the initiatives under consideration vary in their DBP maturity, as indicated by the available information. With regard to the DBL, the establishment of maturity levels remains to be accomplished, a prerequisite for the formulation of a maturity framework centred on their integration.

In this respect, the present research points out some relevant aspects that will need to be considered in that definition, such as:

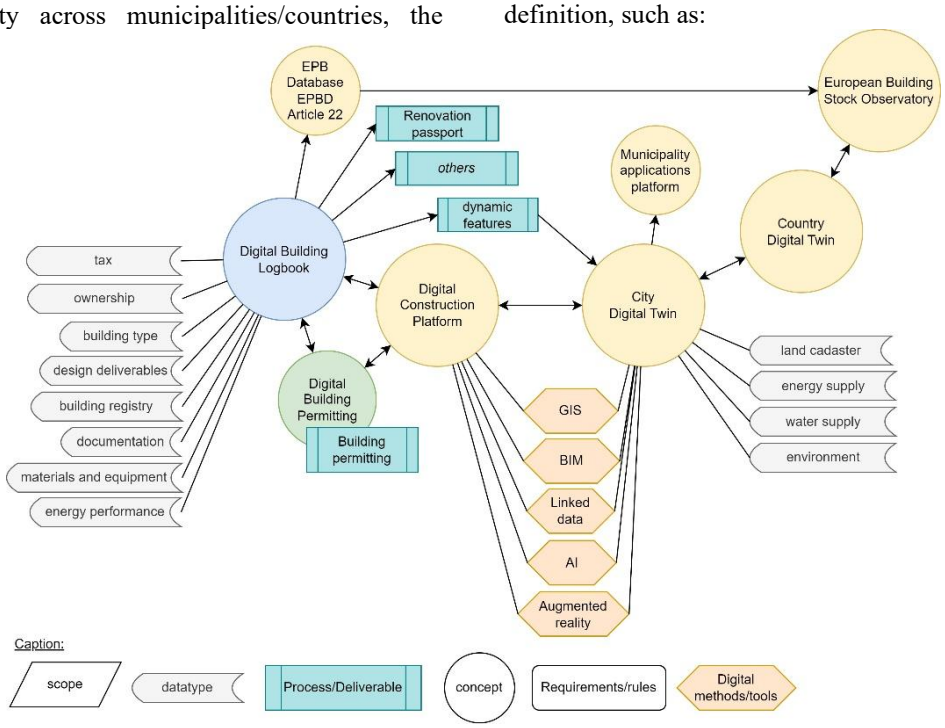

Figure 6: Complete diagram merging the initiatives.

- Identification of the life-cycle phases and associated data points covered, example “as-designed”, “as-built”, “as-use”, “all”, “only few”
- Data inputs, in relation to existing databases, such as land cadaster, permits, tax, ownership, others
- Data formats, in which form is the data associated to the DBL (similar to the DBP maturity levels)
- Use of GIS and BIM as supporting ground for the data (yes, no, to what extent)
- Level of integration, made visible to what extent the data overlaps are harmonised
- Data points status, dynamic vs static data
- Range of features covered or already implemented on the DBL (energy efficiency, ownership assessment, permitting, renovation passport, material passports, among others)

It is imperative to emphasise that the initial point of adoption, as evidenced by the diverse initiatives, has a substantial influence on subsequent integration, given their divergent approaches to the aforementioned aspects. In this regard, there is a perceived need to expand the studies and make a stronger push to define a comprehensive common framework for DBL.

Finally, it was observed that the motivations for the initiatives vary substantially. From country- and municipality-level strategic visions to meet legal requirements, there are several enablers for similar initiatives to take place. Notwithstanding, the clarification regarding DBP and DBL adoption and their integration is perceived as a critical enabler or barrier. Given the wide variety of legal diplomas involved, the EU, its member states, and municipalities' legal frameworks will need to provide stakeholders with clear guidance on how to approach these concepts.

The present research has limitations that are associated with the number of interviews and initiatives approached. In addition, the focus was more on the initiatives' organic aspects, seeking similarities rather than on the data points covered, which will be a topic for future research.

Working on all the abovementioned aspects, focusing on the existing data and how it can support the integration, and expanding knowledge of other initiatives are part of future research actions.

Conclusions

While previous studies were more theoretical, this study investigated existing real-life initiatives, bringing a new level of realisation on regarding the integration of Digital Building Logbooks and Digital Building Permits.

Considering the initial research questions, the following conclusions can be drawn:

- Integration between DBP and DBL is perceived as necessary and beneficial, but typically emergent rather than planned. Initiatives often embed DBL-like data without naming it, and they view DBP/DBL integration as a logical step to reduce duplication, enable compliance automation, and support policy goals.
- The perception varies depending on the scale/level: country platforms think in terms of governance and canonical data; city platforms focus on process simplification; observatories focus on data quality and standard datasets.
- It was observed that each initiative brings complementary assets:
  - Digital construction platforms bring governance, canonical identifiers, cross-domain linking, and scalability;
  - DBL gateways: owner-facing data aggregation, provenance/version control, owner workflows;
  - City Digital Twins: spatial integration, visualisation, operational data linking, as-built updates;
  - Permitting platforms: front-end submission workflows, compliance checking, documentation-based or BIM-based, metadata validation;
- Building stock observatories: regulatory requirements, standardised datasets, reporting needs that motivate upstream digitalisation.

As mentioned in the introduction, in addition to DBP and DBL, the Digital Product Passport for Construction integration within this framework is paramount and warrants further research.

Recognising the synergy between DBP and DBL is imperative, as only by overcoming the fragmentation of concepts can we avoid barriers to innovation and unlock the true potential of a modern, transparent built environment.

PROJECT MANAGEMENT WITH IFC: TOWARD AN OPEN-BIM FRAMEWORK

Riccardo Padoan[1], Lidia Pinti[1], Jan Karlshøj[2]
[1]Department of Civil, Mechanical and Environmental Engineering, University of Trento, Italy
[2]Department of Civil and Mechanical Engineering, Technical University of Denmark, Denmark

Abstract

Successful construction management relies on interoperability, cost estimation, and scheduling. Current practices suffer from fragmented processes and data loss, due to proprietary silos and lack of automation. This research proposes a computational framework to optimize 4D and 5D BIM workflows by enriching the IFC schema. Through *IfcOpenShell*, the methodology provides semantic validation via IDS and collaboration via BCF, facilitating extraction of properties and quantities, scheduling, cost estimation, and resource allocation. Results indicate that an integrated OpenBIM framework using IFC as the primary source improves reliability. The contribution is a reproducible, open-source framework providing a methodology for multi-dimensional BIM management.

Introduction

Building Information Modelling (BIM) transformed the Architecture Engineering Construction (AEC) industry from a static 2D representation to a dynamic parameterized data environment. Despite the methodological maturity suggested by international standards like ISO19650:2018 series, a significant ”BIM gap” persists between theoretical frameworks and professional practice (Abanda et al., 2025). The industry relies on closed-proprietary software that creates rigid sequential dependencies that restrict interoperability (Lou et al., 2021) and facilitate the propagation of human errors (Sacks et al., 2018). Integrating BIM with process simulations can address these uncertainties, transforming the model into a decision-support environment capable of mitigating delays and overcoming the limitations of closed systems (Wang et al., 2014). Managing complex 4D and 5D datasets within these environments often requires intensive visual programming (Lou et al., 2021), such as *Dynamo*, to handle the overwhelming volume of repetitive tasks inherent in Quantitative Take Off (QTO) and Bill of Quantities (BoQ). Furthermore, empirical evidence suggests that BIM-based QTO is still rarely applied in practice due to the complexity of the software and incomplete data extraction methods (Alathamneh et al., 2024). The effectiveness of these workflows is inherently linked to the level of information needed which defines the usefulness of the model throughout the life-cycle (Pinti and Bonelli, 2022). In this context, the granularity of information is crucial to calibrate data density and prevent data gaps and over-modeling (Bolpagni and BIMe Initiative, 2016). Interoperability is facilitated by Industry Foundation Class (IFC), which provides machine interpretability of information and allows automation of workflows (Avogaro and Zanchetta, 2025). For project management purposes, entities such as *IfcWorkPlan*, *IfcWorkSchedule* and *IfcTask* regulate temporal aspects, while *IfcCostSchedule*, *IfcCostItem* and *IfcCostValue* provide the foundation for economic estimation. Recent advances, such as Information Delivery Specification (IDS) and BIM Collaboration Format (BCF), have further enhanced the ability to define computer-interpretable requirements and streamline model-based coordination (Fischer et al., 2025). To address these systemic inefficiencies, this research investigates the transition toward OpenBIM computational framework (McGinley et al., 2023). Although current IFC-based exchanges support object-level data, the integration of automated 4D and 5D logic remains insufficiently explored outside of proprietary silos (Avogaro and Zanchetta, 2025). This study proposes a methodology to reliably extract, manipulate, and validate project data by leveraging open-source logic. By bypassing the limitations of proprietary ecosystems, the research proposes a methodology toward the ”Total BIM” (Disney et al., 2022) vision, where the digital model serves as the primary source of truth for contractual and management purposes (Pinti and Bonelli, 2022). The paper is organized as follows: Section 2 provides a Literature Review of the IFC schema and construction management. Section 3 and 4 detail the Materials adopted and Key Concepts of the framework, while Section 5 describes the implemented Methodology. Finally, Section 6 and 7 present the Discussion of results and the Conclusion with future research directions.

Literature Review

IFC and Construction Management

The IFC, currently an ISO16739-1:2018 with *IFC4 ADD2 TC1*, provides an extensible, vendor-neutral schema designed to facilitate semantic interoperability within the AEC industry. Unlike proprietary formats, the IFC structure is organized into a four-level hierarchical architecture (Resource, Core, Interoperability, and Domain), allowing for the digital representation of complex construction domains, including actors, processes, and resources.

In the context of construction management, the schema lies in its ability to establish an explicit *IfcRelationship* between the physical component of the building, *IfcProduct*, and the management-related entities. This study exploits the ontological robustness of the IFC schema to synchronize three critical domains: temporal, economic, and resources-based.

IFC, IDS and BCF

The IDS represents a standard that defines Information Requirements (IR) as both human-readable and computer-interpretable (Fischer et al., 2025). The main purpose is to overcome the traditional limitations of exchanging requirements through non-interoperable formats, such as PDF documents, which often hinder automation and data accessibility. By specifying entity types, properties, and classifications, IDS enables automated compliance checks, ensuring that the IFC model contains the semantic richness necessary for 4D and 5D analysis (Fischer et al., 2025). For example, a gap addressed by design firms and public administration is the practical implementation of IR through IDS, particularly in linking Work Breakdown Structure (WBS) to IFC entity (deMarco et al., 2024). While the IFC schema defines the data model, the BCF standard serves as a model-based communication protocol (Lou et al., 2021). By linking IFC entities with BCF topics, stakeholders can communicate and collaborate without sharing the entire model, establishing traceability through *GlobalId*.

IFC and QTO

Despite the potential of BIM-based workflows, a recent systematic review suggests that QTO is still predominantly performed using 2D methods due to software complexity, modeling effort and data inconsistency (Alathamneh et al., 2024). The effectiveness of QTO depends on consistent data and standardization of information exchange (Pinti and Bonelli, 2022). IFC provides a concrete framework for defining measurable elements through *IfcQuantitySet* (Karlshøj and Proctor, 2025). The specification distinguishes between Base Quantities, which provide standardized geometric measures for early-stage estimation, and Custom Quantities, which allow the integration of local rules of measurement or specific professional requirements.

IFC and Project Scheduling

IFC provides a solution to data fragmentation by providing a standardized schema for time information (Xue et al. (2015); Avogaro and Zanchetta (2025)). *IfcWorkPlan* represents the central 4D entity, structuring all the information needed to complete complex activities. The scheduling hierarchy is managed through *IfcRelAggregates* which decomposes *IfcWorkPlan* into specific *IfcWorkSchedules*, and *IfcRelAssignsToControl* which links temporal elements directly to physical *IfcProduct* components. Individual activities are instantiated as *IfcTask* entities, organized through *IfcRelNests* and characterized by temporal data via *IfcTaskTime*. Logical dependencies are established through *IfcRelSequence*, while *IfcRelAssignsToProcess* maps *IfcProduct* instances to their corresponding *IfcTask* anchoring the physical geometry of the digital twin to the temporal workflow. *IfcWorkCalendar* defines standardized working (*WorkingTime*) and non-working (*ExceptionDate*) periods, providing precise control over working-time constraints and supporting accurate sequencing, thus strengthening the connection between temporal and physical dimensions in the 4D BIM environment (Noardo et al., 2022).

IFC and Cost Estimation

IFC schema supports financial information, through entities such as *IfcCostSchedule* for structuring, *IfcCostItem* for element-based assignment, and *IfcCostValue* for price definitions (Pishdad and Onungwa, 2024). Current research utilizes these capabilities to overcome the limitations of parameter-based 5D workflows. Cassandro et al. (2024a) proposed a methodology implemented through *IfcOpenShell* library that used *IfcCostItem* to establish a direct relationship between costs and IFC geometric entities, proving to be more effective than the 5D BIM approach based on simple assignment of parameters and attributes. The approach was validated in a second study on a structural model, demonstrating its effectiveness in optimizing cost estimates for public tenders and minimizing human error by anchoring *IfcCostItem* instances to official price lists (Cassandro et al., 2024b). *IfcCostSchedule* organizes *IfcCostItem* entities into a coherent hierarchy through *IfcRelAggregates*, ensuring the validity of financial data throughout the building's life-cycle. The entity supports hierarchical nesting through *IsNestedBy* and *Nests* relationships, ensuring that total costs remain the verifiable sum of subordinate items Cassandro et al. (2024a). *IfcCostItem* is linked to one or more *IfcCostValue* instances to define price breakdowns across materials, equipment, and labor, providing a native foundation for BoQ generation that current practice consistently replaces with external spreadsheet-based workflows.

IFC and Resource Allocation

Resource allocation is critical for successful project management, as it directly influences site safety, spatial coordination, and the feasibility of both schedules and budgets. Within the IFC schema, *IfcConstructionResource* provides the formal structure defining activity resources (Avogaro and Zanchetta, 2025). The schema supports complex resource containers through *IfcCrewResource* and *IfcSubContractResource*, which aggregate elementary resources - *IfcLaborResource*, *IfcConstructionEquipmentResource* and *IfcConstructionMaterialResource* - into functional units through *IfcRelNests*. By linking resources to specific tasks and costs, the schema provides the documentation necessary to justify expenses, verify work progress, and maintain a historical record of resource performance, which is important for transparent project reporting and future cost benchmarking (Pinti and Bonelli, 2022).

Research gap

Despite the ability of the IFC schema to support construction data management, current studies often treat model validation, project scheduling, and cost estimation as isolated processes (Avogaro and Zanchetta, 2025). Despite the expressive power of its scheduling, cost, and resource entities, these native capabilities remain largely underutilised in practice, consistently replaced by proprietary tools that fragment data across disconnected pipelines and never write information back into the schema. Recent contributions have successfully standardized IDS and cost estimation processes, demonstrating that machine-readable data is essential to reduce human errors and legal disputes in public tenders (Cassandro et al. 2024a; 2024c). However, a significant gap remains regarding the dynamic synchronization of time scheduling, cost estimation and resource allocation within a unified OpenBIM workflow. This fragmentation prevents the AEC industry from reaching the "Total BIM" vision (Disney et al., 2022), where the model serves as the only source of contractual and operational information (Pinti et al., 2022). The lack of a transparent methodology capable of orchestrating these different IFC domains remains the main barrier to a fully automated OpenBIM environment. This study addresses this deficit by proposing an integrated framework that leverages open-source computational logic to synchronize IR with multidimensional project control.

Materials

The proposed framework is developed within Free and Open Source Software (FOSS) ecosystem, with the aim to provide a transparent and accessible alternative to proprietary BIM tools. This choice is aligned with the current academic necessity of "Supporting the OpenBIM transition" (McGinley et al., 2023), ensuring open data and long-term interoperability. Adopting a "decoupled" approach, the framework performs data multidimensional (4D and 5D) management and enrichment, independently of the original authoring software avoiding the "black-box" logic of commercial tools. This ensures full compliance with OpenBIM standards and the ISO16739-1:2018 specification, through controllable and verifiable data manipulation. The core logic is implemented in *Python* (v3.10+) taking advantage of its extensive ecosystem in data science and AEC automation. To ensure maintainability reproducibility, the environment is managed via a *Virtual Environment* (.venv) architecture and a *requirements.txt* protocol, while version control is maintained via *Git*. The framework uses *IfcOpenShell* (v0.8.4) documentation as the core engine providing bidirectional access to IFC data structures and allowing users to navigate model hierarchies and resolve inverse relationships between physical components and their semantic properties (Noardo et al., 2022). The technological stack and the standardized protocols integrated into the framework are summarized in Table 1.

Table 1: Technological stack and data exchange protocols

Category	Component	Function
Rendering	*ThatOpen*, *Three.js*	Browser-based fragment rendering via *WASM* and GPU acceleration.
Validation	*IfcTester*, IDS	Automated compliance check of requirements via *XML* IDS files.
Interoperability	BCF, *JSON*	Issue tracking via *IfcOpenShell* and state persistence.
Analysis	*Pandas*, *NumPy*	IFC transformation into *DataFrames*.
Visualization	*Plotly*	Interactive 4D/5D charting.

Key Concepts

The proposed framework establishes a digital workflow designed to automate the validation and data enrichment of IFC models (Noardo et al., 2022). The process begins with model viewing and the validation, then the framework executes a set of algorithms to integrate 4D and 5D information into the system. The methodology is built upon seven fundamental concepts:

i. IDS and BCF: The framework treats (IR) as machine-readable document, verifying that the model contains the correct classifications and geometric properties before any calculation, through IDS (Fischer et al., 2025). If discrepancies are found, the BCF module enables a traceable feedback loop (Lou et al., 2021).

ii. QTO and Cost Estimation: To ensure accurate budget control, the framework performs an automated Quantity Take-Off. The total project cost is calculated by summing direct costs with indirect components (Liu et al., 2014):

$$C_{tot} = \sum_{i} \sum_{j=1}^{n} (Q_j \times R_j) + C_{indirect} \qquad (1)$$

where Q_j is the quantity extracted from the validated IFC geometry and R_j is the unit price mapped from standardized price lists. Each unit price comprises three cost components: $R_j = R_{mat} + R_{equ} + R_{lab}$ (materials, equipment, labour).

iii. Time Estimation: The framework calculates task durations using two methodologies:

- Synthetic Method: Derived from labour cost incidence (I_{man}) provided by regional price lists ($C_{man} = C_{tot} \times I_{man}$).
- Analytical Method: Based on specific production rates and unit labour costs (UP_{man}) directly associated with quantities ($C_{man} = Q \times UP_{man}$).

The total man-hours (H) are converted into working days (T_g) considering the size of the operative crew (N_{so}): $T_g = H/(8 \times N_{so})$.

iv. Program Evaluation and Review Technique (PERT) Scheduling: To account for construction uncertainty, durations are treated as random variables. The framework calculates the expected duration (T_A) using a beta probability distribution:

$$T_A = \frac{a + 4m + b}{6} \tag{2}$$

where m is the most likely duration (T_g), a is the optimistic estimate ($0.75m$), and b is the pessimistic estimate ($1.75m$). This approach ensures a robust Critical Path Method (CPM) evaluation and the identification of critical path activities.

v. Resource Allocation: Each task is linked to a multidimensional array of resources, including costs, materials, equipment and specialized labour. This exhaustive mapping is critical for site safety management, as it enables the identification of spatial-temporal overlaps between hazardous activities and ensures that safety protocols and required certifications are explicitly associated with each operational unit.

vi. Task Sequencing: Construction activities are sequenced through standard logical dependencies (F-S, S-S, F-F, S-F) and visualized through Gantt chart and *DataFrames*.

vii. Cash Flow: The framework aggregates the results of the 4D and 5D synchronization to perform automated financial forecasting. By setting incomes and expenses, the system generates cumulative cost distributions, allowing project managers to monitor the financial health of the project, identifying potential liquidity gaps and comparing budgets against real-time projections.

Methodologies

The workflow in Figure 1 guides the reader towards the logic of the framework, which illustrates the integration of IFC data validation and collaboration, followed by automated quantity extraction necessary for a dynamic project management phase.

IFC Export and Import

The framework approach begins with input standardization through two modules: export configuration and model import. To ensure data quality, the system generates *JSON* files that translate the *IFC4X3_ADD2* specifications into parameters ready for authoring software. Subsequently, the IFC import module loads the file and initializes the working environment. Using *IfcOpenShell*, the framework performs a structural audit that detects the schema version and verifies the integrity of the file. This step is crucial to confirm that the model is ready for semantic enrichment and 4D and 5D analysis.

3D Visualization Architecture

The 3D visualization module handles high-density IFC data by moving processing to a decoupled client-side pipeline. Data are passed as *NumPy uint8* memory blocks from the *Python* backend to a custom *React* component, bypassing the overhead of text-based encodings. The core engine, powered by *WebAssembly*, *Three.js*, and the *That Open Company* ecosystem, converts the model into *Fragments* to group identical geometries and to optimize *GPU* performance. This approach enables native browser-based rendering, eliminating the need for external BIM viewers. To ensure data persistence, camera matrices are serialized into *JSON*, while session stability is maintained through a memory management logic that purges geometry buffers from *VRAM* during module transitions.

IDS and BCF

The framework ensures data consistency through an automated workflow that bridges the gap between IR and collaborative management. This process relies on IDS to validate the model requirements and BCF to communicate discrepancies. The validation engine utilizes *IfcTester* to ensure that IR are machine-readable and to verify the compliance of the model. By parsing *XML*-based IDS files, the tool validates whether the model contains all the required information without manual intervention. Users can dynamically define rules based on IFC classes and *PropertySet*, which the system validates using a robust lookup strategy via *IfcOpenShell*. Using *ifcopenshell.util.element.get_psets*, the engine extracts granular properties and element attributes, transforming complex model hierarchies into a structured *Pandas DataFrame*. This approach identifies missing properties or invalid values, calculates real-time compliance metrics, and generates visual reports using *Plotly*. To close the coordination loop, the framework integrates a synchronization logic between the 3D viewer and the reporting module. When a non-compliant element is identified, the system captures the current state of the model viewer—including camera projection matrices—as standardized snapshots. These visual cues are associated with the specific validation failure. Leveraging the *IfcOpenShell* BCF module, the framework serializes these discrepancies into a *.bcfzip* archive. This package contains the necessary *markup.bcf* and *project.bcfp XML* structures, allowing the identified issues to be re-imported into any BIM authoring software. This ensures a feedback-based workflow where requirements are not only verified, but effectively communicated for resolution.

Properties and Quantities Extraction

The framework transforms IFC models into structured datasets through a schema-independent extraction pipeline based on the *ifcopenshell.util* module. The module dynamically extracts each *IfcPropertySet* instances attached to *IfcProduct* elements, resolving *IfcRelDefinesByProperties* relationships to capture property names, values, and data types with full *GlobalId* traceability. This approach

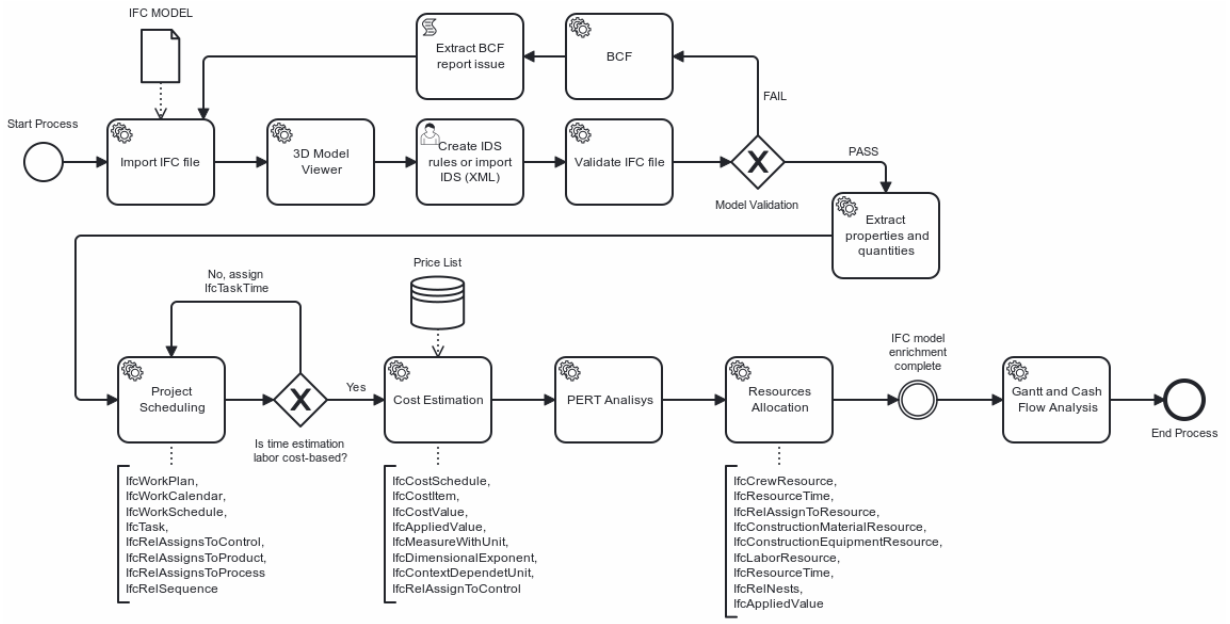

Figure 1: Framework logical process.

ensures compatibility with both standard property definitions (*Pset_**) and custom sets. Geometric quantities are retrieved by parsing *IfcElementQuantity* entities through the inverse *IsDefinedBy* attribute. The extraction logic processes physical quantity subtypes including *IfcQuantityArea*, *IfcQuantityVolume*, *IfcQuantityLength*, *IfcQuantityCount*, and *IfcQuantityWeight*, supporting both standard *BaseQuantities* and domain-specific (*Qto_**) sets. *Pandas* and *NumPy* transform IFC hierarchies into tabular *DataFrames*, enabling efficient grouping, filtering, and quantity calculations for cost estimation and scheduling. Each row represents a property or quantity instance with element identification, classification metadata, source discriminators, and value containers. Furthermore, the extracted quantity incorporates a diagnostic layer that flags potential duplicate entries across element classes. Records that share identical quantity values within the same IFC class are highlighted as potential duplicates. In the test model, for example, querying *NetArea* on *IfcSlab* elements on *F_00 Level* revealed a raw aggregate of $81,807.68\text{m}^2$ against a potential corrected value of $2,586.36\text{m}^2$, demonstrating the capacity to highlight suspicious duplicate quantities of the same element.

4D Scheduling

The temporal dimension is integrated into the model by implementing the IFC schema via the *ifcopenshell.api.sequence* module. The framework establishes a hierarchical structure in which an *IfcWorkPlan*, declared within the *IfcProject* via *IfcRelDeclares*, serves as the main container for multiple *IfcWorkSchedule* entities. Operational constraints are defined via *IfcWorkCalendar*. The framework utilizes *sequence.add_work_time* and *sequence.assign_recurrence_pattern* to specify working hours and recurring exceptions. Individual tasks are instantiated as *IfcTask* entities using *sequence.add_task*. The system supports recursive nesting via *IfcRelNests* via *nest.assign_object*, allowing complex work packages to be broken down into granular subtasks. Each task is associated with an *IfcTaskTime* object via *sequence.add_task*. Through *sequence.assign_process*, the framework identifies which elements are operated upon, while *sequence.assign_product* defines the physical output of each task, defining *IfcRelAssignsToProcess* and *IfcRelAssignsToProduct*. Task sequencing is managed through *IfcRelSequence* relationships created via *sequence.assign_sequence*. The framework supports standard dependency types, enabling dynamic CPM analysis directly within the OpenBIM environment.

5D Cost Estimation and BoQ

The cost estimation framework automates the generation of BoQ by synchronizing costs with the IFC geometric data using the *ifcopenshell.api.cost* and *ifcopenshell.api.control* modules. By importing an external price list (.csv) and instantiating an *IfcCostSchedule*, the framework creates an *IfcCostItem* for each price line using *cost.add_cost_item*, aggregating three distinct *IfcCostValue* entities representing materials, equipment, and labour costs via *cost.add_cost_value*. Each value is associated with an *IfcMeasureWithUnit* and to overcome naming discrepancies between model elements and price list descriptions, the system implements a fuzzy semantic mapping using *difflib.SequenceMatcher*. The pipeline first filters candidate price rows by IFC class using *IfcMatch* field, a classification column manually aligned to the price list structure, retaining only entries compatible with the element type. Within this, *difflib.SequenceMatcher* computes string similarity between the normalized element name and each filtered candidate, and the highest-scoring entry is selected. For example, element

"HEB Søjle_N:HE180B:371924" - following the convention *FamilyType:TypeName:GlobalId* - correctly matches *"Stålsøjle HE-B 180"* in the *Molio* price list despite the structural difference (similarity score = 0.47). Once validated, *control.assign_control* establishes the definitive link between the *IfcElement* and its *IfcCostItem*, which are logged and surfaced to the user, who can manually correct erroneous assignments by removing individual *IfcRelAssignsToControl* relationships and re-triggering the pipeline. Quantity extraction follows a hierarchical priority logic to ensure accuracy, where net measurements are preferred over gross ones. The framework automatically handles unit conversions by querying *IfcUnitAssignment*. The final economic output is structured as a relational *DataFrame* where costs are filtered and aggregated by *IfcBuildingStorey* using *IfcRelContainedInSpatialStructure* relationships. For each element, the unit price R_j is derived from the sum of the costs of materials, equipment, and labour retrieved from the corresponding *IfcCostItem*, ensuring hierarchical budget breakdowns by level and for the entire project.

Resource Allocation

The resource allocation module integrates construction resources with scheduling by instantiating *IfcConstructionResource* entities and linking them to scheduled tasks via the *ifcopenshell.api.resource* module, supporting *IfcCrewResource* and *IfcSubContractResource*. For each *IfcTask*, the framework determines its *ScheduleDuration* through a PERT analysis in which the total labour hours, extracted from the BoQ, are adjusted based on a defined *crew_size*. To ensure accuracy, the module queries *IfcWorkCalendar* to identify *WorkingTimes* and *ExceptionTimes*. The result is converted into an ISO 8601 duration string and assigned to an *IfcTaskTime* entity through a custom function. Using *resource.add_resource*, a parent resource container is instantiated with attributes, and an *IfcResourceTime* entity is created via *resource.add_resource_time* to store the total labour hours. The parent resource is then assigned to the task via *resource.assign_resource*, establishing an *IfcRelAssignsToResource* relationship. For crew-managed tasks, the parent resource is decomposed into child resources (*IfcLaborResource*, *IfcConstructionEquipmentResource*, and *IfcConstructionMaterialResource*) nested via *IfcRelNests*. Time and financial attributes are embedded in this hierarchy: *IfcLaborResource* instances receive an *IfcResourceTime* object where the *ScheduleWork* attribute reflects the adjusted man-hours, while cost data for all resources is stored via *IfcAppliedValue* entities within the *BaseCosts* attribute. This structure enables a recursive cascade where root tasks and *IfcWorkSchedule* are automatically updated by aggregating the *ScheduleStart* and *ScheduleFinish* dates of their nested sub-tasks, ensuring global time and economic consistency across the IFC model.

GANTT and Cash Flow analysis

The proposed framework processes the previous IFC entities to generate integrated Gantt charts and cash flow visualizations, by extracting task schedules and linking them to cost and resource data. The system reconstructs the project hierarchy by crossing *IfcRelNests* and *IfcRelAggregates* relationships, extracting data from each *IfcTask*. The costs are then mapped to the timeline by intersecting *IfcRelAssignsToProcess* (linking tasks to products) and *IfcRelAssignsToControl* (linking products to cost items), aggregating categorized materials, equipment, and labour expenses. Financial forecasts distribute costs proportionally across task durations rather than treating them as point-in-time events. For example, a multi-week construction activity spreads its total cost across the execution period based on the proportion of work hours in each time window. Processing these data streams through *Pandas*, construction costs are integrated with external incomes and expenses to generate cumulative cost distributions and net cash flow metrics, enabling accurate liquidity planning and early identification of funding gaps, providing a decision support for financial sustainability. This integrated approach establishes a bidirectional link between the IFC model and the project's temporal financial health, fulfilling the "Total BIM" (Disney et al., 2022) requirement of using the digital model as the primary contractual and management record.

Results and Discussion

The results shown in Table 2 demonstrate that the proposed framework bridges the gap between static IFC models and dynamic project management. By automating the "validation loop", only high-quality data populate the model, reducing the manual effort required for compliance checking. Unlike proprietary workflows, the proposed framework operates entirely within the native IFC schema; all scheduling, cost, and resource data are co-located within a single model and semantically linked through native IFC entities. This ensures that any design or on-site change propagates consistently, reducing the operational overhead of maintaining data consistency across multiple proprietary tools. Enriching 4D and 5D entities directly ensures that all project management data remain queryable, portable, and auditable, without requiring any software outside the open-source eco-system overcoming the fragmentation that OpenBIM tries to prevent (Sacks et al., 2018). The proposed framework provides immediate visibility into cost and schedule changes, and by preventing the "cascade effect" of unexpected expenses, the system enables reliable decision-making that protects the quality and overall performance of the project. However, significant challenges and limitations have been revealed in the implementation phase. In particular, the integration of 3D visualization components highlights the gap between BIM data and graphical engines. Furthermore, to overcome current gaps in the *IfcOpenShell* library with respect to specific modules, the framework implements custom algorithms to

manage specific hierarchical scheduling complexities. In addition, the intricate relationships and nesting of resource entities made the attribute manipulation complex. While *difflib.SequenceMatcher* provides a scalable baseline for semantic mapping, the test model revealed a structural limitation: across 1 006 elements assigned scores ranged from 0.12 to 0.51 (avg. 0.32), confirming that the primary safeguard is the IFC class pre-filter, while within-class ambiguity requires manual verification. This suggests that integrating standardized classification systems, such as WBS codes or Uniclass classification, would mitigate string similarity inaccuracies and improve reliability. Finally, while *GlobalId* instability across re-exports remains a known OpenBIM challenge, the framework ensures data persistence by establishing associations within a single pipeline, provided that the downstream workflow preserves native IFC entities.

Conclusions

This research proposed an integrated OpenBIM framework designed to transform digital models into active decision-support tools for integrated construction management. Responding to the operational workflows of design firms, public administrations, and construction site managers, the framework bridges regulatory requirements and construction practice. Its main contribution lies in its ability to mitigate repetitive tasks associated with manual data entry, often the main cause of human error and project delays. By providing an accessible alternative to expensive proprietary software, the framework makes high-level BIM management feasible even for smaller organizations and public administrations. Despite these advances, the framework has limitations: it assumes a single authoritative IFC file as its primary data source and complex architectural and Mechanical, Electrical, Plumbing (MEP) models could face challenges with highly complex geometries or intricate systems. The granularity of the data and non-linear relationship between components in these systems challenge data extraction and quantification, requiring more specialized analysis rules. Based on these findings, work is underway to evolve this framework into a user-friendly standalone tool. While qualitative validation is currently being conducted to assess its impact on professional workflows and its effectiveness in diverse project environments, quantitative validation will be conducted to measure the framework's performance in terms of time-saving and error reduction compared to traditional manual methods. Future implementations will address the above limitations and may extend to versioning control, IoT-based site monitoring, and Life Cycle Assessment (LCA) integration. The use of OpenBIM standards ensures high scalability and reproducibility, while the use of *Python*-based technologies ensures the framework's implementation in cloud environments, facilitating collaborative management. Furthermore, to enhance user accessibility, the implementation of a Natural Language Processing (NLP) interface is envisioned. This would allow non-expert users to query the IFC model in natural language (Nabavi et al.,

2023).

AN EXTENSIBLE GRAPHQL API FOR FINE-GRAINED ACCESS TO BUILDING INFORMATION MODELS

Nepomuk Wolf[1,2], Sebastian Esser[1,2], and André Borrmann[1,2]
[1] Chair of Computing in Civil and Building Engineering, Technical University of Munich, Germany
[2] TUM Georg Nemetschek Institute, Technical University of Munich, Munich, Germany

Abstract

Building information exchange in large projects remains largely file-based, although many applications require only small, task-specific subsets of data. This paper addresses the need for element-level, transactional access to building information in web-based BIM workflows, including visualization and model analysis. While direct IFC-to-web mappings are technically feasible, they often result in complex schemas and verbose queries. We present a simplified GraphQL API that enables fine-grained access to building information while abstracting IFC complexity. Through atomic geometry resources, flattened property access, and a modular schema structure, the approach improves usability, query readability, and application-oriented BIM data access.

Introduction

Efficient information retrieval is a fundamental requirement of modern Building Information Modeling (BIM) workflows. While the Industry Foundation Classes (IFC) standard provides a comprehensive framework for representing geometry, topology, and rich semantic information, current practice remains largely centered around file-based exchange. IFC models are typically transferred as monolithic STEP files, forcing client applications to load entire datasets, even when only a small subset of information is required. This paradigm creates information silos that hinder low-latency data access and complicate the integration of emerging workflows, such as web-based visualization, digital twins, and AI-assisted analysis.

As the Architecture, Engineering, Construction and Operation (AECO) industry moves toward higher levels of BIM maturity, the demand for element-level, transactional access to model data is increasing. Many practical use cases require only partial model views, such as web-based visualization, quantity takeoff, or coordination workflows. In these scenarios, transferring and processing complete IFC files introduces unnecessary overhead and latency.

Previous work by Wolf et al. (2025) demonstrated that a direct 1:1 mapping between the IFC schema and GraphQL is technically feasible. However, the resulting API closely mirrored the complexity of the IFC schema, so even simple queries required traversing deeply nested relationships such as property assignment or geometric representations. Moreover, the heterogeneity of IFC geometry forces clients to possess detailed prior knowledge of internal modeling constructs.

This observation parallels a broader development in the Linked Data ecosystem of the building industry, where direct schema mappings have increasingly been replaced by more abstract and modular representations of building information.

Inspired by this paradigm shift, the research presented in this paper moves away from strict schema mirroring and toward the design of a tailored GraphQL API for BIM data access. Instead of exposing the full internal structure of IFC, the proposed interface provides a lightweight, extensible skeleton that prioritizes simplicity and practical usability. Complex hierarchical constructs are flattened, geometry and properties are treated as atomic leaf nodes, and building elements are exposed as directly queryable resources. At the same time, the API remains agnostic to the underlying data source and can operate on traditional IFC STEP files as well as with alternative storage backends.

In contrast to Large Language Model (LLM)-based interfaces, which may support natural-language interaction but do not themselves guarantee deterministic or structurally validated access to BIM data, GraphQL provides a strongly typed and self-documenting interface with automatic query validation.

The research question of this paper is: How can a tailored GraphQL API support fine-grained, interoperable access to building information while reducing query complexity compared to direct schema mappings? The scope of this work is read-oriented access for AECO workflows, with a particular focus on spatial structure, properties, and geometry.

This paper presents the architecture and design decisions of this simplified GraphQL interface, whose public software repository is cited in (Wolf, 2026), and shows how modular schema extensions enable the integration of external data sources, such as data sheets, databases, or sensor platforms, without requiring disruptive API versioning.

Technical Background and Related Works

GraphQL is a web-based API paradigm that combines a schema definition language, a query language, and a runtime for resolving client-defined queries. Originally introduced to address limitations of REST-based data fetching, such as over- and under-fetching of resources, it has since become a widely adopted approach for structured

data access. GraphQL APIs are strongly typed and self-documenting, allowing client applications to precisely define the structure and scope of requested responses. These characteristics make GraphQL particularly relevant for BIM-related scenarios in which clients frequently require only a small, task-specific subset of a much larger building model.

In recent years, GraphQL has also attracted growing interest within the AECO research community, where its potential for structured and fine-grained access to BIM-related data has been explored (Alexiev et al., 2023; Werbrouck et al., 2019b,a). Beyond the BIM domain, studies have evaluated GraphQL as an alternative to REST-based APIs. While REST can achieve lower raw response times in static scenarios, GraphQL has been shown to use resources more efficiently when data requirements change frequently (Lawi et al., 2021). Its declarative query model also mitigates overfetching, which is particularly relevant for BIM applications with large models (Quiña-Mera et al., 2023).

From Monolithic IFC Mappings to Modular Semantic Representations

The move toward tailored, API-driven access to IFC data is part of a broader evolution in building data standards, which increasingly favor modular, element-level information retrieval over monolithic, file-based exchange (Zhu et al., 2025). Early attempts to integrate IFC with web technologies were led by the Linked Data community. The ifcOWL ontology provides a 1:1 bidirectional mapping of the EXPRESS-based IFC schema into RDF (Beetz et al., 2009). While semantically complete, this approach resulted in very large graphs and highly verbose query patterns, mainly due to ordered collections and objectified relationships (Pauwels et al., 2015). As a response, the Linked Building Data community shifted toward smaller modular ontologies such as the Building Topology Ontology (BOT) (Rasmussen et al., 2021) and the Building Element Ontology (Pauwels, 2018). This transition demonstrated the benefits of lightweight structural skeletons that preserve essential semantics while reducing query and modeling complexity.

GraphQL and Semantic Web Approaches for Building Data Access

Rather than treating GraphQL and Semantic Web technologies as competing paradigms, recent research has explored their integration. Several approaches propose GraphQL as a client-facing interface for RDF and SPARQL backends (Gleim et al., 2020; Karalis et al., 2023). Taelman et al. (2019) compare architectural patterns for bridging GraphQL and RDF, while Angele et al. (2022) demonstrate that GraphQL can reduce query complexity for RDF-based datasets and enable closer alignment with ontology-driven data models.

A similar challenge arises when exposing IFC data through GraphQL. Wolf et al. (2025) demonstrated that a direct 1:1 mapping from EXPRESS to GraphQL is technically feasible. However, the resulting schema inherited much of the structural complexity of IFC, leading to deeply nested queries and frequent reliance on inline fragments. In addition, GraphQL lacks native support for several EXPRESS features, which further complicates schema design and client-side querying. This limitation mirrors earlier experiences from the Linked Data community: preserving the entire source schema maximizes formal completeness, but often at the cost of practical usability.

Toward Modular and Transactional BIM Data Exchange

In parallel to these developments, the IFC 5 roadmap explicitly promotes modularization, normalization, and object-level data exchange to support transactional workflows and partial model access (van Berlo et al., 2021). This direction aligns closely with the design motivation of the present work.

Geometry representation poses a comparable challenge in both GraphQL- and RDF-based approaches. In ifcOWL, geometry is mapped directly according to the IFC schema, which leads to extremely large datasets and high structural complexity (Pauwels et al., 2017). Wagner et al. (2020) provide an overview of alternative geometry handling strategies in Linked Data. Bonduel et al. (2019) demonstrate the possibility of abstracting geometry into atomic entities and embedding external formats such as OBJ or glTF. These findings align with the design decisions presented in this work, which treat geometry as an atomic resource optimized for downstream visualization and analysis tasks.

Proposed GraphQL API Design

The proposed API design follows four primary objectives: (1) to enable fine-grained, element-level access to building information without requiring full-file transfers, (2) to reduce query complexity by abstracting verbose IFC relationship structures, (3) to remain agnostic to the underlying data representation in order to support heterogeneous backends, and (4) to provide a modular foundation that can be extended with domain-specific information without introducing breaking changes. These objectives guide the simplification of spatial structures, the flattening of property access, the abstraction of geometry representation, and the modular extension mechanism described in the following sections. Rather than adopting a strict 1:1 mapping of the IFC schema, the proposed design follows a handcrafted, lightweight core schema that captures only the essential structural concepts. This should be understood as a task-oriented abstraction rather than a complete reproduction of the original data model. Although the initial development was driven by IFC models and their STEP-based serialization, the resulting API is not tied to a specific source format. Instead, the modular architecture enables the resolution of data from heterogeneous backends, such as files in arbitrary formats (for example RDF, JSON,

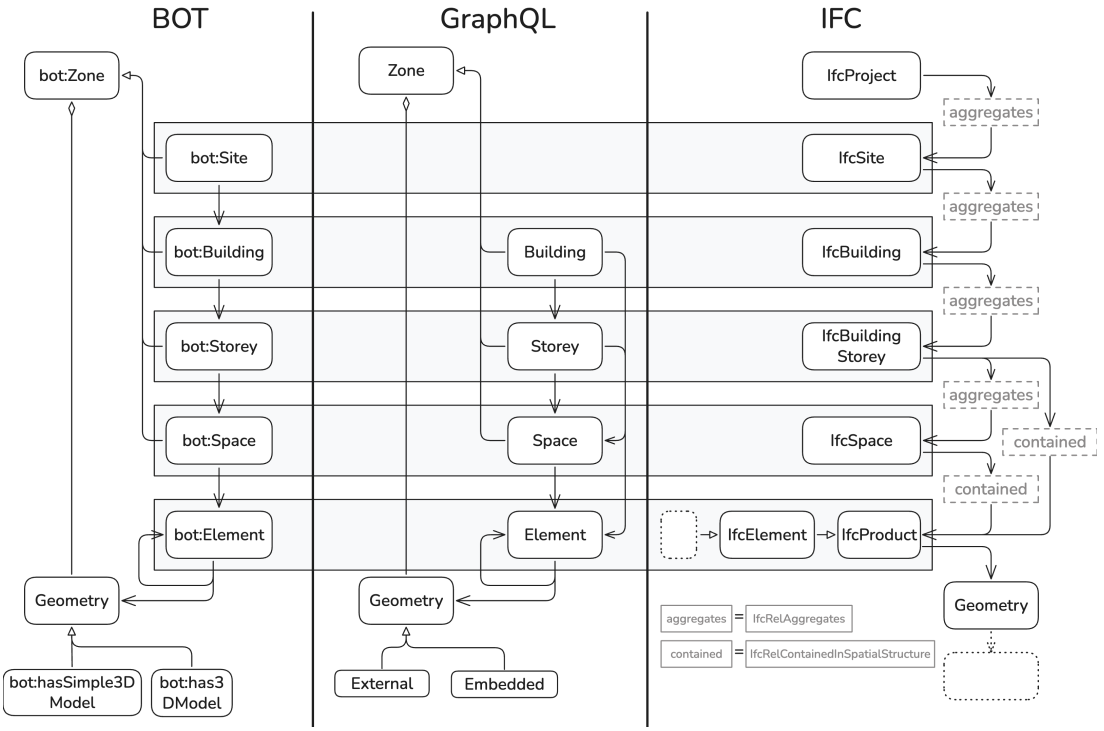

Figure 1: Similarities and differences between the spatial structure in BOT, IFC, and the GraphQL API

XML) or databases.

Spatial Structure and Topology

The core of the API design is a simplified spatial hierarchy that is conceptually aligned with the Building Topology Ontology (BOT) while remaining compatible with common IFC modeling practices. This structure provides a simplified navigation model for client applications and serves as the primary entry point for accessing spatially organized building data. To reduce traversal complexity, the API adopts a hierarchical zone model based on BOT and introduces a common `Zone` interface implemented by the `Building`, `Storey`, and `Space` types. In contrast to IFC, where spatial containment is expressed through objectified relationships (e.g., `IfcRelAggregates`), these relationships are represented directly as fields of the respective types. This significantly reduces query depth and improves readability while preserving the underlying semantic structure. Figure 1 illustrates the resulting schema structure and highlights the similarities and differences between BOT, IFC, and the proposed GraphQL API. Despite substantial simplification, the high-level organization remains closely aligned with IFC's spatial concepts. The most notable deviation is the elimination of intermediary relationship entities, which are replaced by direct associations exposed at the API level.

To support spatial reasoning and topological queries, the API additionally exposes explicit relationship fields between zones, including `partOf`, `intersects`, and `adjacent`. These relations follow the conventions established by BOT and enable expressive spatial queries without requiring clients to traverse low-level relational constructs. Building elements such as walls, windows, and slabs are represented using a generic `BuildingElement` type instead of directly mirroring the deep inheritance hierarchy of IFC. The concrete IFC subtype is preserved as a field on the `BuildingElement` type. This design trades explicit schema-level inheritance for a flatter and more compact API structure while trying to maintaining access to semantic type information. Element-level containment is supported through the `contains` and `partOf` fields, enabling the representation of nested component relationships, such as windows hosted within walls. In addition, building elements can be attached to any of the `Zone` subclasses (Building, Storey, Space), following the flexible attachment model defined in BOT. This differs from typical IFC usage patterns, where most building elements are associated with `IfcBuildingStorey` and furnishing elements with `IfcSpace`. Listing 1 shows an excerpt of the corresponding GraphQL schema definition.

Not all semantically rich IFC structures are directly exposed in the compact core schema. More complex concepts, such as material assignments or links to external classification systems, can instead be resolved dynamically through dedicated resolver functions. In this way, the simplified API surface remains stable, while the server can still retrieve and integrate richer information from IFC relationships or from additional backend systems when required.

Flattened Property Access

A direct 1:1 mapping of the IFC property hierarchy results in verbose queries that require traversing multiple intermediate entities such as `IfcPropertySet` and

```
interface Zone {
    id: ID!
    name: String
    geometry: Geometry
    contains: [Zone]
    elements: [BuildingElement]
    partOf:[Zone]
    intersects: [Zone]
    adjacent: [Zone]
}

type Building implements Zone{...}

type Storey implements Zone{...}

type Space implements Zone{...}
```

Listing 1: GraphQL schema excerpt for spatial structure and zone hierarchy

`IfcPropertySingleValue`. While this level of detail is valuable for authoring and editing workflows, it provides limited benefit for most read-oriented client applications and significantly reduces query readability.

To address this issue, the proposed API collapses objectified property relationships and exposes properties directly as a field of the `BuildingElement` type.

In IFC, properties are additionally organized into property sets (psets), which provide semantic grouping and contextual meaning. Preserving this information while maintaining a flattened access pattern can be achieved in two ways. The first approach is to explicitly model property sets as separate entities attached to each building element, each containing a collection of properties. The second approach is to associate a `pset` attribute directly with each property, thereby retaining grouping information without introducing an additional layer of nesting.

Both approaches preserve the original semantics, however, they differ in terms of query ergonomics rather than expressive power. Since typical client queries focus on retrieving individual properties rather than entire property sets, the second approach is adopted. This design minimizes structural overhead while still allowing semantic grouping information to be accessed when required.

Listing 2 shows that the association between properties and property sets is preserved in two complementary ways. First, the `pset` field can be explicitly requested as part of the `Property` object. Second, the `properties` field of the `BuildingElement` type supports filtering by property set name, enabling selective retrieval of properties belonging to a specific `pset`.

Atomic Geometry Representation

Geometry is one of the most relevant information categories in building models. It also represents one of the most complex aspects of the IFC data structure. A direct 1:1 mapping of IFC geometry entities into GraphQL needs to represent highly verbose and heterogeneous geometry representations, including boundary representations (BREP), swept solids, meshes, constructive solid geometry (CSG), and parametric extrusions. As a result, client applications either need prior knowledge of the underlying modeling paradigm or need to request multiple alternative representations simultaneously, in order to formulate valid queries.

```
type BuildingElement{
    geometry: Geometry
    guid: ID!
    name: String
    contains: [BuildingElement]
    partOf: [BuildingElement]
    properties(pset: String): [Property]
}

type Property {
    name: String
    value: JSON
    pset: String
}
```

Listing 2: GraphQL schema excerpt for building elements

This limitation conflicts with the declarative nature of GraphQL, where clients explicitly specify the expected response structure. Since the geometric representation type of an element is not known in advance, a fine-grained schema-level exposure of IFC geometry significantly increases query complexity.

To address this issue, geometry is treated as an atomic attribute within the API design. In this context, atomic means that the client accesses the geometry as a single leaf node rather than traversing the internal construction logic of the IFC model. Instead of exposing the internal structure, the complete geometry of an element is abstracted behind a single `geometry` field and can therefore be returned as a single unit in the GraphQL response. This design removes the need for the client to know in advance whether the underlying IFC geometry was modeled as BREP, extrusion, CSG, or another representation type.

This abstraction is intentionally lossy. Part of the expressive power of the original IFC representation is no longer directly available once geometry is exported into a downstream exchange format or otherwise reduced to an atomic resource. In particular, procedural and parametric geometry definitions are typically not preserved when exporting to commonly used geometry exchange formats, which limits the ability to reconstruct design intent or perform fine-grained semantic reasoning on geometric constructs. The same tradeoff applies more generally throughout the proposed schema design: direct access to the full internal IFC graph is reduced in favor of improved query readability and simpler client-side interaction.

Geometry Transfer Strategies

The API supports two complementary strategies for transferring geometric data, depending on performance requirements and application context.

External Geometry: In this approach, geometry is stored in an external resource such as a file server or object storage system. The corresponding resolver returns a URI referencing the geometry file. This strategy enables efficient handling of large datasets, supports streaming and caching, and avoids inflating GraphQL response payloads.

Embedded Geometry: Alternatively, geometry can be embedded directly into the GraphQL response. Since GraphQL responses are (typically) encoded as JSON, the geometric representation must be serializable into a compatible format. This can be achieved in two ways:

- Text-based geometry formats, such as OBJ or WKT can be embedded directly as strings.
- Binary geometry formats can be encoded as a string (for example using Base64-encoding) and transmitted together with metadata describing the format and encoding method.

While Base64 encoding increases payload size and requires decoding on the client side, it enables the transfer of arbitrary geometry formats in a self-contained manner. For this reason, both embedded and externally referenced geometry representations are supported by the prototype API.

To demonstrate the flexibility of this abstraction, the prototype implementation supports multiple geometry formats, including OBJ, GLTF, GLB, WKT, BREP, and STL. The schema itself remains agnostic to specific formats and can be extended without modifying the core API definition. Each client application has full control over the format of the returned geometry and can choose between one of the supported formats. Listing 3 shows a response object, containing geometry in the OBJ format both as external and embedded representation.

Modular Schema Design

A central design principle adopted from the Linked Building Data community is to keep the core schema compact while enabling domain-specific extensions. This separation allows the API to remain lightweight and stable, while still supporting specialized application requirements such as energy analysis, cost estimation, or environmental assessment. GraphQL natively supports this paradigm, as types and fields can be extended without introducing breaking changes or requiring explicit API versioning.

Unlike REST-based interfaces, where modifications to response payloads often require version management to avoid disrupting existing clients, GraphQL enables clients to explicitly define the requested response structure. Newly added fields therefore remain invisible to existing client applications unless they are explicitly queried. This property enables incremental schema evolution while preserving backward compatibility.

Beyond the static core schema, the proposed implementation introduces a modular extension mechanism that dynamically loads schema fragments together with their associated resolver functions. Each extension contributes additional fields and data sources without modifying the base API definition. Resolver functions establish the connection between these abstract schema fields and concrete backend services and are executed only when the corresponding fields are requested by the client.

To demonstrate this mechanism, an example extension was implemented that augments the `BuildingElement` type with a `dataSheetURL` attribute. This field establishes a link between a building element and an external product data sheet, when such information is available. The referenced data is not part of the base API schema and is typically not contained in IFC models, yet it is highly relevant for many downstream workflows such as specification, procurement, and facility management.

Listing 4 illustrates the schema snippet required to extend the core API. In addition to the schema extension, a corresponding resolver function is provided that dynamically searches for and retrieves a matching product data sheet URL when the field is requested by a client. The same mechanism can also be used to expose more complex information that is not represented as a simple core field, such as material associations or external classification data. This example demonstrates how heterogeneous external information sources can be integrated transparently into the API without modifying the underlying core data model.

Evaluation and Discussion

This section presents a qualitative evaluation of the proposed API design with respect to query expressiveness, modular extensibility, and practical limitations. Rather

```
extend type BuildingElement {
    dataSheetURL: String
}
```

Listing 4: GraphQL schema extension for linking external product data sheets

than benchmarking response times or comparing implementation performance, the evaluation focuses on the usability of the schema through representative query scenarios and the prototypical API implementation. The selected examples were chosen to cover two central requirements of purpose-driven BIM data access: retrieving connected information across multiple relationship levels and integrating external information without modifying the core schema.

Query Example 1: Connected Data Retrieval

Many BIM workflows require access not only to individual elements but also to related entities connected through spatial, containment, or topological relationships. Typical examples include retrieving all components of a storey together with their subcomponents, or navigating from structural elements to embedded openings or installations. In conventional REST-based APIs, such workflows would require multiple sequential requests and additional client-side aggregation logic. The proposed GraphQL API enables retrieval of connected information across multiple relationship levels within a single query. Figure 2 illustrates this capability by querying all load-bearing walls of a given storey and the windows contained within each wall. The query traverses the spatial hierarchy and containment relations and explicitly specifies the required response structure, in this case *guid* and *name* for each wall and *geometry* for each window. This example was selected because it combines several of the central design goals of the proposed schema: element-level filtering, traversal across hierarchical and containment relationships, and access to geometry as an atomic resource. It therefore demonstrates how the API supports connected data retrieval in a compact and application-oriented way. This example also showcases the integration of geometry in the form of a reference to an external resource.

Query Example 2: Modular Data Enrichment via Schema Extensions

Many analysis and decision-support workflows require information that is not natively contained in IFC models, such as environmental indicators, cost metrics, or product-specific metadata. As described previously, the proposed API addresses this challenge through a modular extension mechanism that allows additional fields to be introduced.

Figure 3 shows the result containing information from the IFC model alongside additional information in the form of the reference to an external data sheet related to the element. This example was chosen to evaluate extensibility rather than traversal complexity. It demonstrates that the API can federate information from the core building model together with external resources through resolver-based schema extensions, without requiring changes to existing query structures or disruptive API versioning.

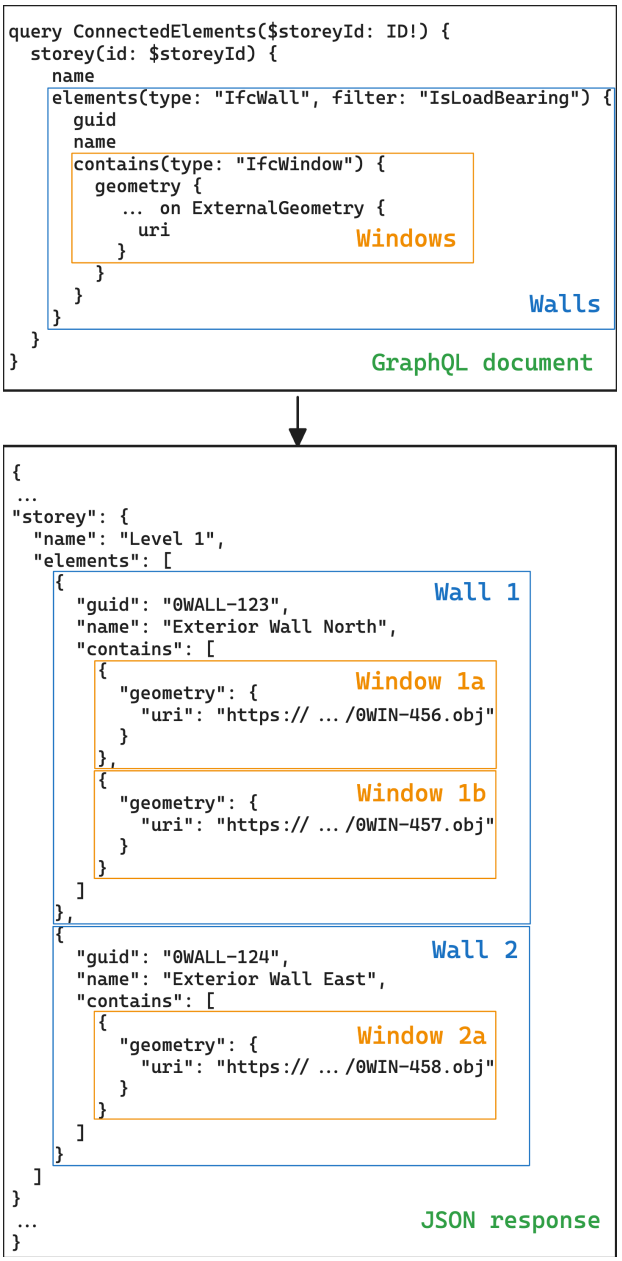

Figure 2: Requesting related elements with filtering

A key conceptual difference between the proposed GraphQL interface and SPARQL-based access to building data lies in the interaction model and query abstraction level. SPARQL provides direct access to RDF graphs and exposes the full underlying data model, which enables complex pattern matching but requires detailed knowledge of ontology structures. In contrast, the proposed API deliberately abstracts underlying data representations and exposes a task-oriented schema that is tailored to common BIM access patterns. The GraphQL interface encapsulates

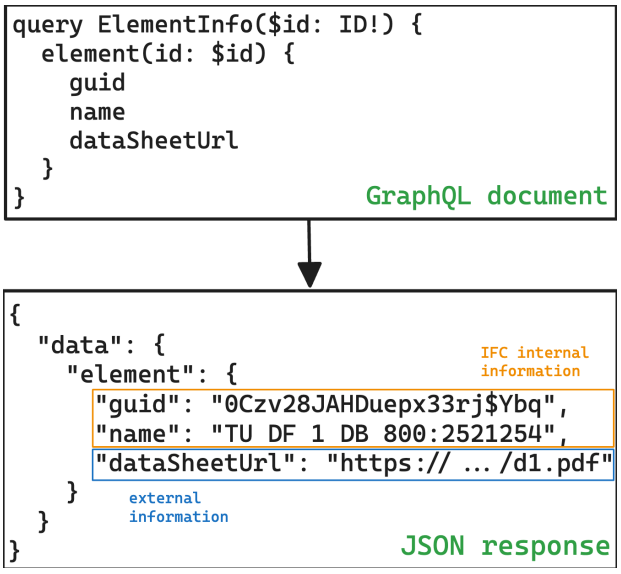

Figure 3: Query containing external information

complex graph traversal logic within resolver implementations, shifting complexity from the client to the server. At the same time, this abstraction comes at the cost of reduced direct access to the full underlying graph structure.

Scope and Limitations

The proposed API intentionally departs from a strict 1:1 mapping of the IFC schema in favor of a simplified data model. While this improves usability and query readability, it also implies that not all IFC semantics and modeling constructs are directly exposed at the API level.

The abstraction of geometry into atomic representations introduces additional limitations. Mesh-based exchange formats commonly used for visualization and data transfer, such as OBJ or glTF, do not preserve the full semantic and parametric structure of the original IFC geometry. Once converted, it is no longer possible to determine whether a shape was originally defined as BREP, CSG, or procedural description. It could be explored if extracting the geometry as a valid subset from the IFC model could be an alternative to typical geometry exchange formats.

Furthermore, certain geometric constructs cannot be represented exactly using mesh-based formats and require approximation. While these representations are sufficient for most visualization and downstream analysis tasks, they may lead to information loss in workflows that depend on higher-level modeling semantics. A detailed assessment of these trade-offs is provided in Wagner et al. (2020).

Several aspects did not fit the scope of this work and should be explored in future works.

First, the current implementation focuses on read-oriented access patterns. Future development should include support for GraphQL mutations to enable write operations, such as updating or creating (new) elements.

Second, the modular extension mechanism could be expanded to cover additional domain-specific use cases, for example quantity take-off, cost estimation, energy performance indicators, scheduling information, and sensor data integration.

Third, although the API design is resource-agnostic in principle, the current prototype only resolves data from IFC STEP files. Future work should extend the resolver implementations to support alternative IFC representations, such as graph databases, as well as native Linked Data representations.

Finally, this work does not address authentication, authorization, and access control mechanisms. Incorporating these aspects is essential for real-world deployment and represents an important direction for future research.

Conclusion

This paper presented a GraphQL-based API design for purpose-driven, fine-grained access to IFC building models. By moving away from a strict one-to-one mapping of the EXPRESS schema and instead adopting a flattened, modular interface inspired by Linked Building Data principles, the proposed approach reduces query complexity while supporting element-level, transactional access for read-oriented AECO workflows.

The presented schema design addresses two central challenges of IFC-based web access: verbose geometry retrieval and deeply nested property hierarchies. Treating geometry as an atomic, format-agnostic resource enables flexible integration of external and embedded representations, while flattened property access improves usability for common analysis and visualization workflows. In addition, the modular extension mechanism demonstrates how domain-specific information can be integrated dynamically without breaking existing clients or requiring API versioning.

The qualitative evaluation illustrates how GraphQL enables traversal of connected building information within a single request and supports the integration of external information through schema extensions. At the same time, the proposed design intentionally trades direct access to the full internal IFC structure for improved query readability and simpler client-side interaction. The resolver-based architecture further decouples the API schema from underlying data sources.

Overall, this work shows that GraphQL provides a practical and structurally explicit foundation for application-oriented access to building information models.

AN INFORMATION MANAGEMENT FRAMEWORK FOR MULTI-USE CASE BUILDING AND DISTRICT DIGITAL TWINS

Joao Patacas, Edgar Segovia, Xiang Xie, Phil James, and Mohamad Kassem
Newcastle University, United Kingdom

Abstract

Digital twins are increasingly being adopted in the built environment to support data-driven operations, optimisation, and lifecycle decision-making. However, most current implementations remain limited to single use cases and centralised architectures, constraining scalability and interoperability at building and district scales. This paper proposes a use-case-driven information management framework for multi-use case building and district digital twins. The framework combines a layered architecture with a dual semantic modelling strategy that separates stable, standards-aligned core models from flexible, use-case-specific extensions. Semantic alignment is demonstrated through a real pilot. The applicability of the framework to support multi-use case integration will be demonstrated in future work.

Introduction

Digital twin (DT) technologies are increasingly recognised as a cornerstone of digital transformation in the built environment, enabling data-driven operations, optimisation, and strategic decision-making across the lifecycle of buildings and districts (Boje et al., 2020; Opoku et al., 2021). By creating a dynamic digital representation of physical assets and systems that is continuously updated through data streams, digital twins extend traditional Building Information Modelling (BIM) approaches by enabling real-time analytics, which can be used to improve the performance of the physical twin (Grieves & Vickers, 2017; Lu et al., 2020). As a result, DTs are being actively explored for applications such as energy monitoring and optimisation, predictive maintenance, renovation planning, energy grid stability, and resilience assessment at both building and district scales.

Despite this growing interest, most existing building and district digital twin implementations remain focused on individual use cases or specific stakeholder needs. Many solutions are developed as isolated or BIM-centric systems, tightly coupled to particular data sources or software platforms, which limits scalability and reuse across the many use cases during the building lifecycle (Volk et al., 2014; Pärn et al., 2017). This fragmentation limits the ability of digital twins to support integrated decision-making across multiple domains and time scales.

These challenges are further exacerbated at district scale, where digital twins must integrate data and models from multiple buildings owned and operated by different stakeholders. Centralised data architectures raise concerns related to data sovereignty, privacy, and trust (Batty, 2018; Otto et al., 2021). Conversely, fully decentralised approaches often struggle to achieve semantic interoperability and do not support coordinated analytics.

This paper addresses these challenges by proposing an information management framework designed to support multi-use case digital twins operating across building and district scales. The framework adopts a use-case-driven design methodology, ensuring that information requirements are derived from specific operational and strategic needs rather than exclusively from technical considerations. It combines this with a layered and federated digital twin architecture aligned with emerging standards and data space principles (IDSA 2021, ISO/IEC 2023).

The proposed framework is grounded in the experience and results of the WILSON project, a European research initiative focused on distributed data modelling and federated digital twinning for the sustainable operation and management of buildings and districts. This paper provides four main contributions to the field of building and district digital twins: (i) development and analysis of multi-use case information requirements; (ii) definition of a layered information management framework; (iii) specification of a dual semantic modelling strategy enabling local and federated digital twins; and (iv) illustration of the approach through a real pilot implementation.

Background and Related Work

Digital Twins in the Built Environment

The concept of the digital twin originated in manufacturing and aerospace domains and has since been adopted in the built environment to support various asset management and operational optimisation activities during building and infrastructure lifecycle (Tao et al., 2018; Grieves & Vickers, 2017). In this context, digital twins are commonly defined as digital representations of physical buildings or infrastructure assets that are dynamically linked to their physical counterparts through data streams.

In contrast to BIM, which primarily supports design and construction through static information models, digital twins emphasise dynamic behaviour, continuous data integration, and the ability to support simulation, prediction, and control during operations (Volk et al., 2014; Lu et al., 2020). Building-level digital twins are typically applied to energy monitoring, fault detection, predictive maintenance, and indoor environmental quality management, while district- and urban-scale digital twins extend these capabilities to support aggregated analyses and coordination across multiple assets (Batty, 2018).

Multi-Use Case Challenges

A persistent limitation of many digital twin implementations in the construction and facilities management domains is their focus on single use cases or isolated lifecycle phases. Different applications often require different data resolutions, update frequencies, and semantic interpretations, making it difficult to reuse data and models across use cases (Pärn et al., 2017).

For example, real-time operational optimisation requires high-frequency sensor data and control interfaces, whereas renovation planning and investment analysis depend on aggregated historical data and scenario-based simulations. Without a coherent information management and semantic alignment strategy, there is a risk that these requirements are addressed through parallel, redundant data pipelines.

Semantic Interoperability and Alignment

Semantic interoperability has long been recognised as a key challenge in construction informatics. While standards such as IFC have significantly improved data exchange, they do not fully address the integration of heterogeneous operational data sources or the needs of analytics-driven digital twins (Beetz et al., 2009; Pauwels & Terkaj, 2016).

Ontology-based approaches and semantic web technologies have been proposed to enhance interoperability by providing machine-interpretable structures that unify BIM, sensor data, geospatial information, and external datasets, enabling better knowledge representation and facilitating reasoning (Karabulut et al 2024). However, many existing approaches rely on monolithic or overly complex models that are difficult to adapt and reuse to different project and operational requirements.

Methodological Approach

Multi Use-Case-Driven Framework Design

The framework presented in this paper adopts a multi use-case-driven design methodology. Rather than defining information models and architectures in isolation, the approach starts from defining use cases that capture the goals, actors, processes, and decision contexts relevant to building and district management. The use case methodology considers the input from domain experts, providing general ideas and functional requirements, while system experts detail these use cases down to a level that can be used to specify interfaces, dedicated functionalities, data and service model exchanges. This methodology ensures that the resulting digital twin infrastructure directly supports practical needs and avoids unnecessary complexity.

Within the WILSON project, use cases were developed through an iterative process involving technical partners, pilot site operators, and other stakeholders. This process combined action design research principles (Sein et al. 2011) with established use-case modelling standards (BSI 2020), resulting in a consistent set of use-case descriptions covering functional and non-functional requirements. Each stage in the Action Design Research (ADR) framework adopted in use case development is summarised in Table 1.

Table 1: Action design research for use case development

Stage 1 - Problem formulation	Use case scoping: Identification of UC leaders and stakeholders
Stage 2 - Building, intervention and evaluation - Use case development	• Initial development of use cases • Use case workshops (round 1) • Further development of use cases • Use case workshops (round 2)
Stage 3 - Reflection and learning - Developing detailed user requirements	Develop final version of use cases, and identification of main system functionalities
Stage 4 – Formalisation & Reporting	Reporting in project deliverables, scientific publications, etc.

From Use Cases to Information Requirements

Each use case was analysed to identify its information requirements, including actors, scenarios, functional and data requirements. These requirements were then abstracted to identify common information needs across multiple use cases, as well as specific extensions required for particular applications. This analysis provides the basis for defining a shared information management framework capable of supporting multiple use cases without duplication.

Use Cases and Information Requirements

Overview of Building and District Use Cases

The information management framework proposed in this paper is grounded in a comprehensive set of building- and district-level use cases that reflect operational and strategic needs in the built environment. Following structured stakeholder engagement and iterative analysis, use cases and their scope was defined (Table 2). The identified use cases illustrate the diversity of objectives, time horizons, and data requirements that the proposed information management framework must support.

Stakeholders and Decision Layers

The identified use cases (Table 2) involve a wide range of stakeholders, each interacting with the digital twin at different decision layers. Facility managers and building operators typically engage with the digital twin on a short-term operational basis, using real-time or near-real-time information to adjust control strategies, diagnose faults,

or respond to alerts. Their primary concern is maintaining efficient and reliable building operation while ensuring occupant comfort.

Table 2: Overview of identified use cases

Use case	Scope
Decentralised multi-source data management	Develop a federated DT approach, to achieve interoperability among diverse data sources scattered across various platforms and formats.
Energy monitoring and optimisation	Optimize energy management at building and district levels, allowing owners and other key actors to make data-driven decisions to enhance energy performance, comfort, and environmental sustainability.
Data-driven network asset management	Provide energy network operators with tools for optimising asset management, ensuring energy availability and network resilience.
Predictive maintenance	Enable proactive maintenance by predicting equipment failures and optimising maintenance schedules, reducing downtime and costs.
Risk, resilience and biodiversity nexus	Enable building owners to mitigate climate change hazards by identifying environmental risks at building and district levels.
Renovation planning and design	Apply LCA for planning and design of energy-efficient renovations and retrofitting projects.
Technoeconomic investment planning for property owners	Evaluation of energy improvement interventions and economic feasibility at building and community levels.
Boost of green energy investments by market actors	Enhancing green energy investments by leveraging DTs and network planning algorithms

Asset owners and portfolio managers operate at a medium- to long-term decision layer. They use digital twin outputs to support renovation planning, lifecycle cost analysis, and investment decision-making. For these stakeholders, historical data, performance trends, and scenario-based simulations are more important than real-time control.

At district level, additional stakeholders come into play, including energy service companies, distribution system operators, and public authorities. These actors are interested in aggregated performance indicators, flexibility potential, and compliance with regulatory or policy objectives. The coexistence of these diverse stakeholders highlights the need for an information management framework that can present different views of the same underlying data while enforcing appropriate access controls.

Information Requirements Analysis

Analysis of the use cases reveals a set of common information requirements that cut across applications and scales. Static information forms the foundation of the digital twin and includes building geometry, construction properties, system topology, and asset metadata. This information is often derived from BIM models and asset registers and changes infrequently over time.

Dynamic information consists primarily of time-series data from sensors, meters, and building management systems. These data streams capture the operational state of buildings and systems, such as energy consumption, temperatures, equipment status, and control signals. Depending on the use case, data may be required at different temporal resolutions, ranging from seconds or minutes for control-oriented applications to hourly or daily aggregates for reporting and analysis.

Contextual information provides essential background for interpreting building performance. Examples include weather data, occupancy schedules, energy tariffs, and grid conditions. Many analytical models rely on such contextual data to generate accurate predictions or recommendations.

In addition to raw data, use cases require access to derived information, such as key performance indicators (KPIs), alarms, forecasts, and optimisation results. Managing these different categories of information in a consistent and reusable manner is a central challenge addressed by the proposed information management framework.

Cross-Use-Case Synergies and Conflicts

A key finding of the use-case analysis is the significant potential for synergy through shared information resources. For example, the same sensor data streams can support energy optimisation, fault detection, and indoor comfort analysis. Similarly, building geometry and system topology information is relevant for both operational optimisation and long-term renovation planning.

However, conflicts may arise when different use cases impose competing objectives or constraints. Energy optimisation strategies that minimise consumption may negatively affect occupant comfort, while aggressive demand response actions may increase equipment wear. These conflicts cannot be resolved solely at the data level; they require explicit governance, prioritisation, and negotiation mechanisms embedded within the digital twin framework.

Proposed Information Management Framework

Framework Overview

The proposed information management framework is designed to address the complexity and diversity of multi-use case digital twins in the built environment. It adopts a multi-layer model inspired by Semantic Web principles

and DT reference architectures (CEN 2026, IDSA 2021, ISO 2021, Karabulut et al. 2024) that separates concerns while enabling strong integration across layers.

Heterogeneous data streams originating from BIM models, IoT sensors, legacy BMS systems, and operational platforms are transformed into semantically enriched and machine-interpretable representations, ensuring that local and federated DTs operate with shared meaning, supporting reasoning, analytics, and standardised data exchanges. By allowing data, models, and services to be shared across multiple applications, the framework enhances scalability, enabling the addition of new buildings, data sources, or use cases without fundamental redesign. The framework comprises the logical layers described below (Figure 1).

Acquisition Layer

The acquisition layer forms the interface between the physical world and the digital twin. It is responsible for ingesting heterogeneous data from a wide range of sources, including BIM repositories, building management systems, IoT devices, and external data services, while preserving essential metadata such as timestamps, sensor calibration, and spatial context. Data ingestion follows the principles of ISO/IEC 30141:2024 - Internet of Things (IoT) — Reference architecture (ISO/IEC 2024) and ISO 12006 for BIM-based information management (ISO 2022). By aligning data acquisition with these standards, it ensures consistent data quality and traceability across both building and district DTs, forming the foundation for accurate semantic mapping and analytics.

Integration Layer

Data Space connectors are implemented following the International Data Spaces (IDS) Reference Architecture (IDSA 2021) and Gaia-X Federation Services (Gaia-X 2022). This layer ensures data sovereignty and standardised access through policy-based usage control and authentication. Personalised Data Hubs (PDHs) provide APIs for tool access while enforcing local governance (Ramachandruni et al. 2025).

Semantic Layer

The semantic layer manages semantic mediation and ontology alignment between local data and the Core DT Model. This process follows ISO/IEC 21838 – Top-Level Ontologies for Interoperability (ISO/IEC 2021), to translate data into structured RDF or JSON-LD formats. The layer comprises two components:

- Semantic Mediation Gateways, which perform schema mapping and transformation from raw BIM, sensor, and energy datasets to standard ontologies such as BOT, SSN/SOSA, SAREF, and BRICK;
- Vocabulary Hub, which serves as a central ontology and vocabulary registry that provides shared concepts, mappings, and equivalence rules across DTs, ensuring alignment and semantic consistency (Ramachandruni et al. 2025).

Knowledge Layer

This layer structures the semantic building and district DTs following the dual-layer ontology model (i.e. core plus use-case specific extensions) to support reasoning and federated queries across DTs. The knowledge layer defines how entities, properties, and behaviours are modelled, enabling both static and dynamic aspects (geometry, operational parameters, behavioural trends, and contextual conditions) to be represented in an interoperable format. This layer provides the structural and semantic basis for the building-level and federated district-level DTs.

Applications Layer

The applications layer enables reasoning, analytics, and integration across Digital Twins tools and services. It aims to support cross-building insights and district-level use cases aligned with ISO 23247's composability and interoperability of DTs, ensuring that DTs can seamlessly exchange data and coordinate analyses across building (local) and district-level domains (ISO 2021).

Governance Layer

The governance layer underpins the entire framework by defining rules and mechanisms for data access, sharing, and usage. It addresses critical issues such as privacy,

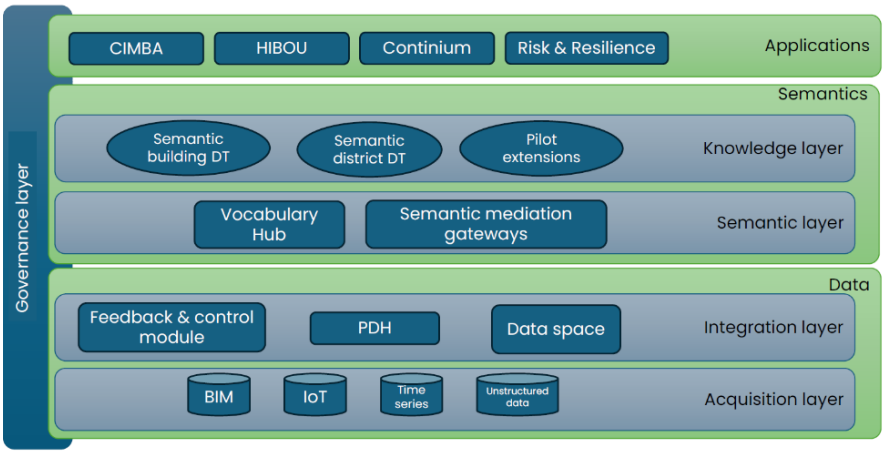

Figure 1 Proposed Information Management Framework

security, consent, and data sovereignty, to allow cross-building analytics and decision support while respecting organisational boundaries and regulatory constraints.

Semantic Local and Federated Digital Twins

Role of Semantic Alignment in Multi-Use Case Digital Twins

Semantic alignment is a central enabler of multi-use case digital twins, particularly in environments characterised by heterogeneous data sources, legacy systems, and multiple stakeholders. Without a shared semantic understanding, data originating from different buildings, systems, or domains cannot be meaningfully combined or reused across applications. This challenge becomes even greater when moving from building-level digital twins to federated district-level twins.

In the proposed framework, semantic alignment is treated as a continuous and systematic process embedded within the digital twin lifecycle. It provides the foundation for interoperability across data sources, analytical models, and services, enabling different use cases to operate concurrently on a shared information basis.

Dual-layer Modelling Strategy for Semantic Alignment

To balance interoperability, extensibility, and long-term maintainability, the framework adopts a dual-layer modelling strategy for semantic alignment. This strategy is particularly suited to construction and built-environment contexts, where stable reference models must coexist with project-specific, evolving information needs.

The core digital twin model captures fundamental concepts that are common across buildings, districts, and use cases. It includes the following entities: *District, Building, Space, System, Asset/Component, Sensor/Actuator, Observation*. The core model is intentionally kept compact, stable, and is aligned with internationally recognised standards and specifications used in construction and digital twin ecosystems. This alignment ensures long-term interoperability and supports integration with external platforms and systems (Table 3). Complementing the core model, context- and use-case-specific extension models are defined to represent additional concepts, attributes, or relationships required in specific use cases. These extensions may capture specialised system configurations, custom KPIs, domain-specific constraints, or locally relevant semantics that are not appropriate for inclusion in a generic core. Importantly, extensions are not isolated schemas: they are explicitly linked to the core model through well-defined semantic mappings. New use cases or data sources can be integrated by extending the model rather than modifying the core, reducing the risk of fragmentation and ensuring backward compatibility across the digital twin federation.

Table 3 – Alignment between DT core model entities and reference standards/ontologies

Core Entity	Reference Class / Standard Alignment	Description (ISO 2023, 2024, ETSI 2017, Brick 2023, W3C 2017, 2021)
District	CityObjectGroup	Represents an aggregation of multiple buildings and infrastructures (e.g. energy, mobility, environment) forming a district-level twin.
Building	bot:Building / IfcBuilding	Represents an individual physical building and its associated metadata such as ownership, use, and geolocation.
Space	bot:Space / IfcSpace	A physical or functional zone within a building (e.g. room, corridor, floor zone). Used to link spatial context with sensors and assets.
System	saref:DeviceGroup / brick:System/ IfcSystem	Represents technical systems such as HVAC, lighting, or electrical distribution that connect assets and sensors.
Asset / Component	saref:Device / brick:Equipment / IfcAsset	Represents components within a system (e.g. pump, fan, EV charger). Provide the link between physical equipment and their monitoring points.
Sensor / Actuator	sosa:Sensor/sosa: Actuator / IfcSensor/IfcActuator	Devices that capture observations or perform control actions on assets and systems.
Observation	sosa:Observation	A single measurement or data record generated by a sensor or actuator, including timestamp, unit, and value.

Semantic Alignment in Practice: Newcastle Helix

The Newcastle Helix innovation district is a mixed-use urban campus developed through a partnership between Newcastle University, Newcastle City Council and private stakeholders (Figure 2). Within the WILSON project, the pilot focuses on three representative buildings: Urban Sciences Building (USB), The Spark, and The Core. These three buildings provide a diversity of typologies and system maturities (higher education research facility, collaborative workspace, and commercial office respectively), which makes Helix an appropriate demonstrator for testing the semantic DT framework across heterogeneous operational contexts.

Figure 2 - Newcastle HELIX innovation district (UK)

The dual-layer approach to data modelling was applied to the Helix pilot considering:

- A core alignment layer, providing a common shared vocabulary and minimal schema.
- Pilot-specific extensions, representing Helix-specific concepts such as district heating nodes, site-wide EV infrastructure, and Urban Observatory (UO 2026) sensor feeds.

Figure 3 provides the UML diagram for the WILSON DT data model for Newcastle Helix pilot, highlighting the implementation of the proposed dual-layer modelling approach. The core model entities are represented in white, while pilot-specific extensions, representing Helix-specific concepts are highlighted in orange, represented as extensions (or inherited by) the core model.

The mapping of Helix datasets to the WILSON model follows these rules:

BIM data mapped to *Building / Space / Asset*. BIM models are mapped to the WILSON Building and Space classes. Asset registers (e.g. for AHUs, pumps, EV chargers) populate Asset entities with manufacturer and model metadata. The code snippet in TTL syntax in Listing 1 illustrates this example using existing ontologies:

Listing 1 - BIM data mapped to Building / Space / Asset

```
@prefix : <https://wilson-project.eu/helix/> .
@prefix bot: <https://w3id.org/bot#> .
@prefix schema: <https://schema.org/> .

    schema:name "Urban Sciences Building" ;
    bot:hasSpace :Some_USB_Lab ;
    bot:hasElement :USB_AHU_x .

:USB_Lab_2F  a bot:Space ;
    schema:name "Second Floor Lab" .

:USB_AHU_01  a schema:Product ;
    schema:manufacturer "Some Manufacturer" ;
    schema:model "Some model" .
```

BMS / IoT feeds mapped to *Sensor / Observation* (Timeseries). Real-time building management system (BMS) feeds, available at the USB and selected systems in other buildings, populate the Sensor and Observation entities. Where structured APIs are available (as in the Urban Observatory APIs (UO 2026)), the Entity–Feed–Timeseries chain is preserved to maintain semantic richness. Aggregated datasets (e.g. hourly averages) are represented as Observations, with metadata describing aggregation level and sampling frequency. The code snippet in TTL syntax in Listing 2 illustrates this example using existing ontologies:

```

The Helix pilot illustrates several benefits of the proposed semantic alignment approach. Shared core semantics enable the same underlying data to support multiple use cases, while pilot-specific extensions preserve the semantic richness required for detailed local analyses.
From a scalability perspective, the dual modelling strategy reduces integration effort when adding new buildings or data sources, as only mappings to the core model are required. Additionally, it enables selective exposure of information at district level, supporting data sovereignty and compliance with the organisational constraints of the Helix district.

Discussion

The primary contribution of this work lies in the integration of a dual semantic modelling strategy with a federated digital twin architecture, grounded in real multi-use case requirements. While semantic models, BIM standards, and digital twins have been extensively studied individually, their systematic combination to support multiple building- and district-level use cases remains limited. Unlike monolithic or purely BIM-centric approaches, the proposed framework:

- Treats semantics as a key architectural concern, not merely a data integration layer;
- Separates stable, standards-aligned semantics from evolving, use case-specific requirements;
- Aligns with emerging federated data and data space paradigms, which are increasingly relevant for cross-organisational construction ecosystems.

Limitations and Practical Considerations

Despite its advantages, the proposed approach also presents challenges. Establishing and maintaining high-quality semantic mappings requires upfront effort and domain expertise. Legacy systems and incomplete BIM models may limit the availability of structured information, necessitating incremental or hybrid integration strategies.

Furthermore, while the framework supports federation conceptually and architecturally, its effectiveness will depend on stakeholder willingness to adopt shared governance principles and semantic conventions. Addressing these factors is an important focus for future work, both during and beyond the duration of the WILSON project.

Conclusions and Future Work

This paper has presented an information management framework for multi-use case building and district digital twins. By combining a use-case-driven design methodology with a layered and federated architecture, the framework addresses the complexity inherent in supporting diverse applications and stakeholders across multiple spatial scales.

Future work will focus on the implementation and evaluation of the framework in real-world pilots, to demonstrate how shared information resources, model management, and governance mechanisms can enable scalable and reusable digital twin implementations to support use cases at the local (building) and district level.

AN IFC FRAMEWORK FOR INFORMATION AND DOCUMENT MANAGEMENT IN CONSTRUCTION PROCESSES

Beatrice Maria Toldo[1], Carlo Zanchetta[2]
[1]Department of Management and Engineering, University of Padua, 36100 Vicenza, Italy
[2]Department of Civil, Environmental and Architectural Engineering, University of Padua, 35131 Padua, Italy

Abstract

Information management of construction site documentation is crucial for cost control in construction companies. Currently, sites are often managed with traditional tools, leading to slow archiving processes and data inconsistencies. This highlights the need for a more efficient document-management system, where the IFC format can act as a standardized structure for organizing the data recorded in the documents. This paper proposes a conceptual framework and proof-of-concept implementation to optimize the use of site documentation by mapping and classifying key information. The structured extraction of data, as man-hours, enables integration with management control systems and BIM models, supporting more accurate evaluation of construction cost performance.

Introduction

The progressive digitalization of information flows represents a strategic cornerstone in the evolution of the construction sector toward Industry 4.0. The capability to collect data directly from construction sites and manage it efficiently is a fundamental requirement for the monitoring and control of contemporary projects, as well as a significant operational advantage. Effective information management enables the overcoming of traditional communication barriers and supports data-driven decision-making processes based on accurate and up-to-date information.

In recent years, the Building Information Modeling (BIM) methodology has significantly transformed the planning and monitoring of construction projects. Industry Foundation Classes (IFC) (EN ISO 16739-1:2024), an internationally recognized standard, constitute the principal open data schema for the representation and interoperable exchange of BIM information across heterogeneous software platforms and stakeholders, thereby enhancing collaboration and information consistency within the construction industry. A first stream of research focuses on the role of IFC as a standard for interoperability. The research highlights that, although the IFC provides a neutral framework for data sharing, its practical application is often hindered by inconsistent software implementations and potential data loss during data exchange. (Kone and Mahesh, 2025; Noardo et al., 2021). This becomes evident when maintaining consistency across multiple model versions or linking heterogeneous data, which often requires additional layers of data management or external databases to ensure reliable information management (Mastino et al., 2026; Pauwels et al., 2017). A second research area investigates the use of IFC for construction process modeling and project control. Recent studies have highlighted the importance of using IFC processes, such as *IfcTask*, *IfcProcedure*, and *IfcRelAssignsToProcess*, in bridging the gap between static product models and dynamic construction scheduling (Avogaro et al., 2024). Existing studies demonstrate that IFC-based models can facilitate the comparison between planned and actual progress. However, these approaches typically focus on predefined workflows, while the integration of site data, especially when derived from unstructured or semi-structured documents, remains a significant gap in the research (Avogaro and Zanchetta, 2025).

Despite the increasing adoption of BIM during the design phase, information management at the construction site level remains an area requiring further development, largely due to the high heterogeneity of data involved (Kerosuo et al., 2015).

At present, the management of temporal and economic progress on construction sites still relies predominantly on traditional, document-based project control approaches (e.g., PDF documents and spreadsheets). These are time-consuming and, if not properly managed within a centralized database, may lead to information loss (Dave et al., 2016). However, such approaches are inadequate for the dynamic nature of modern construction sites, which require a higher level of process digitalization. Labor costs account on average for between 30% and 50% of total project costs (Mohammed et al., 2024), while inefficient management of material resources can represent up to 70% of the overall project cost (Kasim et al., 2019). Current shortcomings in data collection and management systems arise from information fragmentation and manual reporting practices. Cost management, as well as the monitoring of construction progress over time, is often based on pre-existing documentation that frequently remains unused within company archives. This lack of integration between planning activities and on-site construction makes it difficult to assess project performance in real time, resulting in delayed reporting of schedule deviations and inaccurate evaluations of productivity.

To bridge this gap, the literature has proposed new field data collection systems that leverage emerging technologies (Deng et al., 2025), such as RFID for material tracking (Jain et al., 2024), or the use of tags for automated inventory identification via dedicated scanners. There are also examples of IoT sensors for the vertical tracking of materials on multi-story construction sites, which communicate via wireless protocols, ensuring the efficient transmission of field-collected data to a central platform (Gehring et al., 2025). Recent studies also explore Machine Learning and Natural Language Processing (NLP) to extract information from documents (Jafari et al., 2021; Singh et al., 2023). Although these approaches make it possible to transform vast amounts of unstructured digital data into actionable insights (Mahire et al., 2024), the research highlights that such approaches face persistent challenges related to the poor interpretability of models and the handling of linguistic ambiguity. In the specific context of the AEC sector, interoperability is further hindered by the fact that the IFC standard does not natively support dynamic data (time series) for systematically extracting and converting data from the site to Digital Twins (Du et al., 2024).

In this technological development context, BIM emerges as a data management tool capable of centralizing information from multiple stakeholders. In practice, it constitutes a single information database able to integrate not only physical quantities but also cost-related data for economic monitoring (Smith, 2014). To ensure interoperability and accurate information exchange among the various actors, IFC plays a central role. As a neutral and open data format, IFC enables interoperability across different platforms, allowing the storage and exchange of not only geometries but also complex metadata related to costs, schedules, and resources. The significance of IFC in project control lies in its hierarchical structure, which allows the association of specific properties (Property Sets) with each building entity, covering construction site documentation such as delivery notes, daily reports, and work progress status.

To address this gap, the paper investigates the following research questions:

RQ1: How can construction site documentation be semantically structured and integrated within the IFC schema?

RQ2: How can IFC entities be used to represent the relationships between documents, resources, activities, and time in construction processes?

This paper contributes to the existing body of knowledge by:

(i) proposing a semantic framework for integrating construction site documentation into the IFC schema;

(ii) formalizing the relationships between documents, activities, resources, and time within a standardized data model;

(iii) demonstrating the feasibility of using IFC as a process-oriented information system for construction management.

The novelty of the proposed approach lies in enabling the use of IFC as a process-oriented data infrastructure for integrating heterogeneous, document-based construction data into a unified and queryable information model.

Framework Overview

The proposed framework aims to support the document management of construction production and costs. The integration of documentation within the BIM environment, through the IFC standard, enables the transformation of documentary data into structured data. In this work, IFC4x3 ("IFC4.3.2.0 Documentation," 2024) has been used to implement the framework. Documentation is classified according to four categories of direct costs: materials, labor, equipment rentals, and subcontracting. From this perspective, site documentation is not regarded merely as a bureaucratic requirement, but as an informational input for the quantification of variable production costs. Each category is associated with specific types of site documents and corresponding IFC resource entities.

Although the framework is designed to be applicable to all cost categories, the present work focuses on labor-related documents for demonstration purposes. Labor is selected due to its significant impact on construction costs and the richness of information typically contained in daily site reports. The same methodological principles can be applied to the other categories within the proposed framework.

The framework developed in this study manages construction site documents by integrating the data they contain into the BIM model. The starting point is the analysis of labor data, historically the most complex cost item to monitor due to its dynamic nature. The framework identifies daily reports as the primary source of data.

Information relating to the document

In general, information relating to documents can be divided into information describing the document itself and information contained within the document. This division allows the relevant IFC classes to be identified, where the information can be entered. *IfcDocumentInformation* is the most suitable IFC class for collecting metadata relating to the document. This class is generic for any document. The actual content of the document is not defined in this specification, but its location is managed via the *Location* attribute. In this field, it is possible to transcribe the URL of the document, thus generating an external link to the database. The IFC file does not directly contain the document, thus avoiding becoming excessively large in terms of MB. Instead, the IFC file maintains a reference to the document. The standard provides several other attributes that allow the association and description of the information related to a document. Among the main ones are *Identification*, which enables to assign a unique identifier to the document, *CreationDate*, useful for indicating the date of creation, and *Name*, which allows to assign a name or a short description of the content.

The *IfcDocumentInformation* element can be linked to model elements via the *IfcRelAssociatesDocument* relationship, which allows a document to be associated with one or more subtypes of IfcObject. In this way, a single document can refer to several model objects at the same time, ensuring centralised and consistent information management.

This feature is particularly significant in complex operational scenarios, where a single document may contain data relevant to multiple components of the model. For example, in the context of labor management, documents such as daily report can record activities related to different tasks in the schedule, involving multiple construction elements and the resources associated with them. The ability to link a document to multiple objects ensures integrated and up-to-date traceability of information, improving data consistency and coordination between the various figures involved in the design and construction process.

Information contained in the document: resources

Regarding the information contained in the documents, the IFC standard provides a clear framework for mapping using specific entities related to tasks, resources and costs. Regarding labor resources, the main documents produced are daily reports and timesheets. The latter, which is mandatory for public works, is also widely used in private projects. These documents contain detailed information on the work carried out, the personnel involved, the hours worked and, where relevant, the equipment and materials used. In many cases, information regarding the labor of subcontractors can also be included.

Within the IFC model, this information is stored in resource-specific entities provided by the standard, including *IfcConstructionMaterialResource* for material resources, *IfcConstructionProductResource* for products, *IfcLaborResource* for labor, *IfcConstructionEquipmentResource* for equipment, and *IfcSubContractResource* for subcontracted work. All these entities are subtypes of *IfcConstructionResource*, from which they inherit common attributes useful for resource management.

The handling of activities performed is treated separately within the *IfcTask* class, which represents a unit of work within the project schedule. This structure allows for a conceptual link between the resources (labor, equipment, materials) and the actual task executed.

IfcLaborResource

Hours worked are associated with *IfcLaborResource* entities, enabling detailed and consistent tracking of work performed. The standard provides the Property Set *Pset_ConstructionResource*, which includes properties of relevance for reporting purposes. Among these, *ActualWorkTime* allows the recording of actual hours worked through an *IfcTimeSeries*, which defines time intervals associated with measurements. As a time series, *ActualWorkTime* can contain multiple values, effectively constituting a real-time record stored within the information model.

The *IfcIrregularTimeSeries* class, a subclass of *IfcTimeSeries*, is used to record data that varies over time. Although the recording of hours worked may generally be considered regular, variations in recording intervals can occur due to factors such as weather conditions, holidays, or unforeseen events on site. Using the *Values* attribute, a list of recorded values can be reported, each associated with its corresponding date of measurement. In practice, activities involving human resources often span multiple days or time intervals. As a result, several reports are typically produced to document the ongoing execution of the same task by the same personnel over successive days.

In this context, within the IFC standard, an *IfcIrregularTimeSeries* contains multiple *IfcIrregularTimeSeriesValue* entities, each corresponding to a measurement taken on a different day and including the total man-hours expended on the specific activity during the relevant period. Since this data originates from separate documentation, the *IfcLaborResource* entity is linked to multiple instances of *IfcDocumentInformation*, one for each report from which the information is derived. Figure 1 presents a representative example of this data structure. This approach enables hours worked to be associated with each resource in a structured and dynamic manner, ensuring transparency, traceability, and continuous updating of information within the Common Data Environment.

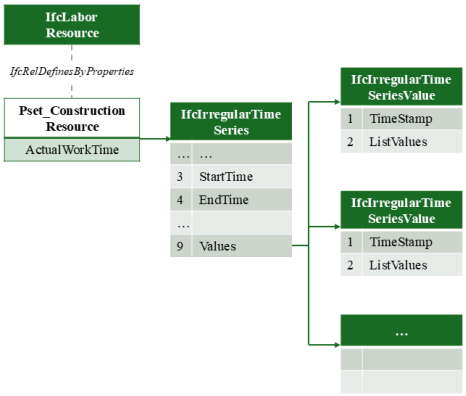

Figure 1: Mapping of temporal properties for an IfcLaborResource entity

IfcSubContractResource

Daily site reports also document the hours worked by subcontracted labor. In such cases, within the IFC standard, the reference class for the structured storage of this information is *IfcSubContractResource*, which represents the subcontractor responsible for the execution of the activities. The *IfcSubContractResource* entity is not used directly to record working hours, but serves as a reference organizational entity. For the purpose of capturing labor hours, one or more instances of the *IfcLaborResource* class are created, each linked to the corresponding *IfcSubContractResource* entity. In this way, human resources employed by the subcontractor are modeled similarly to those within the main contractor,

while maintaining a clear distinction from a contractual and organizational perspective.

Each subcontractor present on site is therefore represented by a dedicated *IfcSubContractResource* instance, to which the relative labor resources are linked through corresponding *IfcLaborResource* entities. This structure enables a clear distinction between the different companies involved, facilitating financial reporting as well as control, verification, and comparison of what is contractually agreed versus what is actually performed.
All resources employed in a construction site activity are, in addition to being linked to the relevant reference document or drawing, directly associated with the operational task to which they contribute. This approach ensures full traceability between planning, documentation, and the activities actually carried out on site.

IfcConstructionEquipmentResource

In most construction site daily reports, the equipment used to perform the work is also typically recorded. The IFC standard defines the *IfcConstructionEquipmentResource* entity to represent each machine or tool on site. Similar to labor, equipment usage can be tracked through the *Pset_ConstructionResource* property set, using *ActualWorkTime* and an *IfcIrregularTimeSeries* instance. This approach enables the documentation of actual usage time, links it to site reports, and associates it with the relevant operational activities.

Relationship between IfcResource and IfcTask

Within the IFC model, the *IfcTask* entity represents a project work unit and serves as the fundamental element for activity management. It can describe both high-level activities and more detailed operations, thanks to the possibility of instantiating additional *IfcTask* entities within it, thereby enabling a hierarchical structure of the work program (work breakdown structure). The association between activities and the resources employed is established through the *IfcRelAssignsToResource* relationship, which allows different resource types, such as labor, materials, and equipment, to be linked to the corresponding activity. This relationship makes it possible to specify which resources are used for a given task, facilitating the control of costs, quantities, and operational utilization. Moreover, *IfcTask* allows the recording of temporal parameters through the *IfcTaskTime* object, which collects all information related to the time dimension of the task. In particular, it is possible to define the scheduled start and finish dates and times of the activity (*ScheduleStart* and *ScheduleFinish*), as well as the corresponding actual values (*ActualStart* and *ActualFinish*), enabling a comparison between planned and actual work progress. These temporal values can also be determined and updated based on the time and availability information associated with the resources involved (Figure 2).

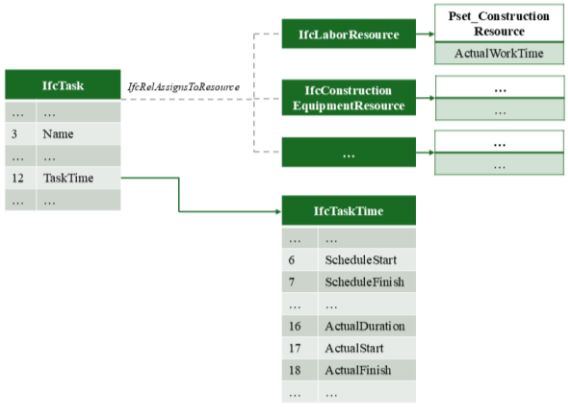

Figure 2: Relationship schema between IfcTask project activities and resource allocation

Relationship between IfcDocumentInformation and IfcTask

The above discussion addresses the organization and management of information contained within a single document. However, in the real context of a construction site, the situation is generally much more complex: numerous activities must be carried out over time, and the resources involved frequently interact, participating in multiple processes and operational phases. Consequently, it is essential to understand how to correctly manage the links between activities, resources, and documentation in such a complex and dynamic environment.

Specifically, regarding labor reporting, an operational document such as a site report may include information relating to work performed over several days. This information is therefore distributed across multiple separate documents, each corresponding to a specific date or period. In this scenario, the same *IfcTask* entity, representing a specific activity or process, can be linked to multiple documents, each documenting a portion of its progress or a particular time phase. Similarly, the same *IfcLaborResource* entity, representing a human resource, may be associated with multiple documents, as the same resource may contribute to different activities over multiple days (Figure 3).

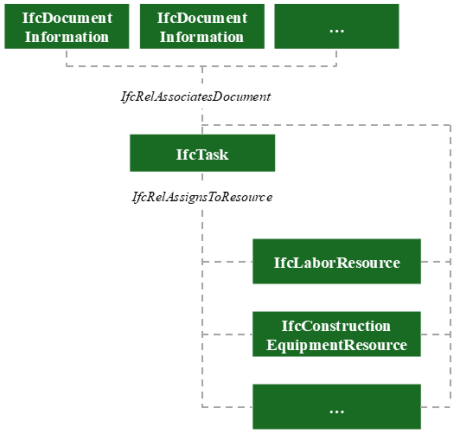

Figure 3: IfcLaborResource entity associated with multiple documents

The opposite situation can also occur: multiple activities are performed on the same working day and are consequently documented within a single reporting document. In this case, the single document is linked to multiple *IfcTask* entities, each representing a distinct task carried out during the same period (Figure 4). This configuration highlights a many-to-many relationship between documents and activities, which must be carefully managed to ensure the consistency and completeness of the information.

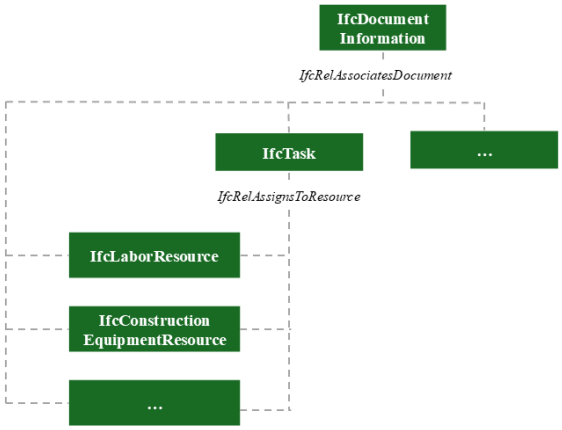

Figure 4: IfcDocumentInformation entity associated with multiple tasks

Results

This section presents the results of the study and provides a technical validation of the framework through a Proof-of-Concept (PoC), showing how the IFC standard enables the integration of different document-based data into a unified information structure. It was evaluated to verify the consistency and completeness of the proposed data mapping. In particular, the validation focused on the ability to correctly represent the relationships between documents, activities, and resources, as well as on the completeness of the mapping of information derived from the documents into IFC entities. It is assumed that two daily reports are available containing the following information. Table 1 presents the data for Daily Report No. 37, while Table 2 shows the data for Daily Report No. 38.

Table 1: Information contained in Daily Report No. 37

Task	Labor Resource hour	IfcConstruction EquipmentResource hour
Placement of formwork for first-floor columns	General construction worker (4 h)	Cold rental of electric saw (4 h)
Laying of bricks for construction of first-floor partition walls	Skilled construction worker (8 h)	Hoist rental with operator (8 h)

Table 2: Information contained in Daily Report No. 38

Task	Labor Resource hour	IfcConstruction EquipmentResource hour
Reinforcement for first-floor columns	General construction worker (6 h) Skilled construction worker (8 h)	wet rental of mobile crane (8 h)
Laying of bricks for construction of first-floor partition walls	Skilled construction worker (8 h)	Hoist rental with operator (8 h)

The figure available at the following link (Mapping) illustrates the resulting IFC schema after the mapping process. Each document is linked to the corresponding resources and tasks, which represent the activities carried out on site. A task is shared by both reports since it is carried out over both working days; therefore, the *IfcTask* entity is not duplicated, but linked twice. In this scenario, the information related to the resources connected to the task pertains to both document 37 and document 38. The resources involved are *IfcLaborResource* and *IfcConstructionEquipmentResource*. In both time series within the *Pset_ConstructionResource*, two values are recorded:

- In orange, the data from document 37 is shown, indicating 8 hours of work on 2025-09-10, with 8 hours of equipment usage.
- In purple, the data from document 38 is shown, indicating 8 hours of work on 2025-09-11, with 8 hours of equipment usage.

When the first *IfcIrregularTimeSeriesValue* for a specific activity is recorded, it corresponds to the *ActualStart* attribute of *IfcTaskTime* (number 17). If the activity is completed, the end date is recorded in the *ActualFinish* attribute (number 18). This allows a later comparison between planned and actual progress. In this case, the activity is assumed not to be completed yet, so the end parameter is not filled in. These temporal data can be compared with the project data contained in *IfcTaskTime* to monitor the progress of the activity. Additionally, *ActualStart* and *ActualFinish* can also be recorded for individual resources via *IfcResourceTime*, allowing the monitoring of each resource's specific duration.

In cases where different types of labor are used for the same activity, for example skilled workers and general laborers, two *IfcLaborResource* entities are created, one for each qualification, to which the worked hours are then assigned. This approach allows for more accurate resource management and ensures a consistent allocation of hourly costs at a later stage. In the upper part of the figure, this scenario can be observed. For the task "Reinforcement for first-floor columns", two *IfcLaborResource* entities are created, each containing the hours worked by the corresponding labor group.

Discussions

Based on the previously identified IFC classes and explained hierarchies, it is possible to develop an operational workflow for data integration. Although this research does not focus on tools for automatic data collection from documents, the framework serves as a technical proof of concept for automated BIM-based project control. The possible stages are: Data digitization (key information is extracted from documents); Mapping to IFC; Output for management control (once populated, the IFC model functions as a database for monitoring actual costs). This paper proposes a computational framework for integrating construction site documentation into BIM models based on the IFC standard, with particular emphasis on labor management. The current results should therefore be interpreted as a proof of concept rather than a comprehensive empirical validation, highlighting the need for further testing on real-world projects. This approach enables a structured mapping between unstructured documents and IFC entities, ensuring consistency in data representation. Although the framework does not currently rely on machine learning techniques, it provides a robust semantic structure that addresses the fragmented nature of traditional reporting.

Construction site documentation collected during operational activities, particularly daily reports, is often characterized by unstructured or manually compiled documents. The framework addresses the unstructured nature of construction site documentation, such as daily reports, by enabling their integration into a standardized BIM environment. Documents remain stored externally (e.g., within Common Data Environments), while relevant information is structured within the IFC model and linked through references. This approach supports interoperability across different information systems and maintains synchronization between BIM models and external data sources. Another significant outcome of this work concerns the management of labor and hours worked within the IFC model, closely aligned with the document and operational management structure described above. Human resources are modeled using the *IfcLaborResource* entity, while the recording and calculation of hours worked are managed through the Property Set *Pset_ConstructionResource*, in combination with the use of *IfcIrregularTimeSeries*. This configuration enables the representation of discontinuous and variable time trends, which are typical of construction site activities, while maintaining a consistent and formalized data structure for monitoring labor hours and costs. Once the actual hours are recorded in the *ActualWorkTime* parameter through the time series, a cost calculation system can be established based on the assignment of specific hourly rates for each resource, derived from company price lists or subcontracting contracts. This allows for the determination of variable production costs in real time by multiplying the unit cost by the hours worked directly within the IFC model. Such an approach overcomes the limitations of manual and fragmented reporting typical of traditional tools, such as spreadsheets.

At the same time, the association between *IfcTask* and *IfcTaskTime* enables a direct link to be established between planned activities and temporal data, facilitating integration with planning and scheduling systems. This connection allows the IFC model to be synchronized with external work planning tools, enabling a comparison between the theoretical schedule, the actual hours worked, and the site documentation, which remains archived in external systems via IFC references as described above.

The work presented shifts the focus from the automatic classification of documents to their informational integration into the BIM model. Unlike many existing approaches, which rely on text mining, machine learning, or natural language processing techniques applied to documents, the proposed methodology emphasizes the importance of mapping data onto standardized entities and relationships.

In this context, the theoretical contribution of the study lies in formalizing a semantic correspondence between construction site documentation and the IFC schema, explicitly linking documents, activities, resources, and time. The IFC model is thus not used solely as a geometric exchange format, but as a computational infrastructure for the management of process-related data.

Thanks to this integration, with all information contained within a single data model, it becomes possible to monitor construction site progress in real time, not only in terms of activity scheduling but also regarding the resources used and the associated costs. Although the research does not focus specifically on labor resource documents, the framework is applicable to any type of documentation, thereby providing a comprehensive and consistent view of the construction site, capable of supporting informed decision-making and integrated management strategies.

Furthermore, the centralized management of documents within the IFC model helps prevent the loss of critical information, which is typically associated with paper-based records or unstructured archives, ensuring that all information resources are stored, accessible, and correctly linked to the operational entities of the construction site. This approach significantly enhances data traceability, security, and continuity, promoting more effective and reliable management of the entire construction process.

Mapping and associating documentation with resources and activities modelled in the BIM model allows for significantly more detailed management of construction site progress. Thanks to this integration, the company can constantly monitor the actual status of the work and compare actual data with that planned in the project, thus obtaining an accurate view of the correspondence between planning and operational progress. This level of detail is particularly useful for more accurate management control, as it allows for the timely identification of any deviations from plans and targeted intervention to correct delays, optimise the use of resources or rebalance workloads. The methodology also provides a clear view of the costs incurred and resources used, not only at a global level, but also for each individual activity or planned work phase. Thanks to this granularity, it is

possible to carry out specific and targeted analyses, for example by evaluating the productivity of a team, comparing the hours worked with those scheduled, or analysing the impact of operational choices on overall costs. In this way, the integrated BIM model becomes a powerful decision-making tool, capable of supporting the strategic and operational management of the construction site, increasing transparency, reducing margins of error, and promoting a proactive approach to planning and controlling activities.

The proposed method prioritizes semantic structuring over automated extraction, distinguishing it from ML and NLP approaches. While these techniques efficiently process large amounts of unstructured data, they may struggle to ensure consistent and standardized outputs. In contrast, the IFC-based approach enhances semantic consistency and interoperability but requires more structured input and greater manual effort. For this reason, the two approaches should be seen as complementary rather than competing. Future research should focus on integrating their respective strengths.

Although the framework demonstrates the feasibility of integrating site documentation into the IFC schema, further research is needed to validate its robustness, scalability, and applicability in different contexts. Future studies should assess data completeness and consistency, as well as their effectiveness in supporting cost control and progress monitoring. In addition, integrating NLP techniques could enable automated extraction of information from unstructured documents. Finally, further developments should explore interoperability with external systems (e.g., CDEs, ERPs, planning tools) and extend the framework to include additional construction data, such as materials, equipment, and subcontracting.

Moreover, the integration of real-time data sources, such as IoT sensors and tracking systems, offers significant potential to develop dynamic, continuously updated BIM-based control systems aligned with actual site conditions.

Conclusions

This research defines a conceptual framework for document management and the integration of data derived from documentation within BIM models, in accordance with the IFC standard. The research demonstrates how IFC entities can act as structured data containers to support management control. The main objective is to move beyond the traditional approach based on mere document archiving, instead enhancing their value as a structured source of information useful for monitoring project performance. Analysis of the construction site documentation led to the identification of the relevant IFC classes, highlighting how the standard can operate as an environment for collecting, organizing and correlating information relating to resources, activities and time.

In particular, the combined use of the *IfcDocumentInformation*, *IfcTask*, and *IfcLaborResource* entities, together with *IfcIrregularTimeSeries*, enables a consistent representation of labor reporting while maintaining a direct link to the original documents stored in the Common Data Environment. These entities are complemented by additional resource classes dedicated to the management of materials, rentals, and subcontracts, such as *IfcConstructionMaterialResource*, *IfcConstructionProductResource*, *IfcConstructionEquipmentResource*, and *IfcSubContractResource*.

Within the context of this research, the IFC standard is not employed solely as a tool for geometric representation, but as a genuine information database for the management of construction processes. Although the proposed framework is demonstrated using labor as an example, it can be extended to other main categories of direct costs including materials, rentals, and subcontracts by applying the same principles of classification, mapping, and document association. This makes the approach suitable for integrated and comprehensive construction site management. Standardization of data also enhances information traceability and enables systematic comparisons between planned and actual outcomes, supporting more timely and accurate management control. While the proposed framework successfully maps construction site data into the IFC4x3 schema, it faces challenges regarding data stability and interoperability. Native GUIDs and custom properties are often subject to changes during model re-exports, potentially breaking semantic links. To mitigate this risk, it is advisable to use stable, user-defined identifiers, such as WBS codes or persistent project parameters. Furthermore, although this paper advocates for a rigid semantic structure to ensure the high data fidelity required for cost control, this inherently entails a high level of manual intervention and mapping effort. The first area for future research concerns the empirical validation of the framework through real case studies. Applying the methodology to projects of varying scale and complexity would allow for an assessment of the robustness of the proposed IFC mapping, as well as the completeness and reliability of the data supporting management control. At the same time, extending the approach to different types of documents could reveal critical issues related to format variability and the diverse operational practices adopted by companies. To reduce the burden of manual input, future developments may focus on the identification of automated tools for data extraction and their correct assignment to the corresponding IFC entities. Integrating ML and NLP algorithms could combine automation in data extraction with the semantic precision of IFC, merging operational efficiency and structured control. In this context, methods for verifying the accuracy of information mapping should be investigated. The adoption of models for text and document structure recognition could further reduce manual intervention and minimize the risk of errors. Finally, another area of development concerns integration with IoT technologies, allowing the inclusion of information directly obtained from the field and not contained in static documents.

Abstract

Design changes during construction remain a challenge, as late-stage modifications to complex MEP systems impact cost and schedule. While BIM enables documentation of design evolution through versioned IFC files, existing tools focus on retrospective change detection rather than forward-looking stability assessment. This study introduces two metrics, Change Intensity (CI) and Stability Index (SI), to track MEP design evolution across IFC versions. CI aggregates the proportion of elements changed, while SI applies a logistic function to translate CI into an interpretable stability score. Eleven IFCs from a real project demonstrate the framework's ability to identify disruption events and track design convergence.

Introduction

Design instability during the construction phase remains a critical challenge in construction project management. Studies have shown that site managers spend more time due to design modifications and rework. This extra time can result in up to 5 to 40% cost overrun (Aslam et al., 2019). Notably, changes made to MEP systems near the completion of the project can be costly, as often these systems must be rerouted around previously installed structural or architectural components.

Last-minute modifications, particularly in MEP design, are affected by numerous circumstances. The prevailing belief among contractors is that MEP design can be modified nearly up to the commencement of installation without substantial detriment to the installation process (Valkonen et al., 2025). The selected installation method significantly impacts this; the typically low level of prefabrication allows contractors to alter plans nearly up to the commencement of installation (Valkonen et al., 2025). The late involvement of the MEP contractor, often used in many countries for business and legal reasons, creates pressure to make changes after the MEP contract has been secured (Valkonen et al., 2025). One of the main causes for delayed design changes is the postponement in approval of changes to the architectural design and its subsequent effect on the MEP design, which follows later in the sequence (Tillmann, 2020).

Leveraging BIM now allows detailed documentation of the evolution of the design through versioned modelling files. Additionally, several commercial software packages can assist users in identifying the changes that occurred between model versions through comparison of either element property or geometry (Bockstael and Issa, 2016). These capabilities provide transparency into how a design has evolved over time.

However, for design managers, simply knowing the number of changes does not provide a reliable and actionable insight. The conventional method of tracking changes and reacting to them does not inherently yield enough reliable and useful insights (Juszczyk et al., 2016). There is a need to understand whether the design is converging toward stability or if there are more impactful changes still expected. Scholars have suggested that if the design change management practices are improved, including predicting or forecasting change impacts, it can enhance overall project performance, reduce negative impact on cost and schedule, and help in coordination decisions (Wang et al., 2022, Motawa et al., 2007).

Despite recent advances in BIM-based change management, a gap remains in that the existing BIM comparison tools detect what changed between model versions, but are limited in assessing design maturity or distinguishing meaningful design changes from metadata updates (Lin et al., 2019). Furthermore, only a limited number of metrics exist to quantify the rate at which a design approaches stability or when convergence will occur.

The current research addresses this gap by proposing two complementary metrics, which are Change Intensity (CI) and Stability Index (SI), to track MEP design evolution across consecutive IFC versions. CI measures the percentage of elements added, removed, or changed from each updated version of a design, and then uses that information to apply a logistic function and compute an interpretable stability score (SI). The resulting CI/SI framework, combined with smoothing and trend analysis techniques, allows the management to analyse the historical patterns of design evolution as well as make predictions about the future stability of designs going forward.

The objective of this study is to develop a simple framework that tracks MEP design evolution across IFC versions and provides interpretable metrics for assessing design stabilisation, enabling project teams to make informed decisions about coordination timing and construction readiness.

Literature review

The detection of design changes within BIM has evolved significantly over the past decade. Lee et al. (2011) developed foundational metrics to quantify the similarities and differences between IFC files. Their research proposed five key metrics, which are similarity rate, matching rate, globally unique identifier (GUID) preservation rate, missing rate, and addition rate. They performed the analysis on 88 IFC files and demonstrated the potential for automated comparison methods in tracking design evolution across project versions. Building upon this foundation, various commercial tools provided clash detection and model coordination mechanisms (Bockstael and Issa, 2016). However, the focus of these tools is primarily on identifying what changed between model versions, and they do not assess design progression or predict stabilisation patterns (Abdulfattah et al., 2023).

Concurrently, the concept of digital twins has advanced from physical asset monitoring to evolve design process management. Boje et al. (2020) proposed directions for the semantic construction of digital twins that emphasises on the real-time data integration throughout the building lifecycle. To complement the design-based data integration, Dai et al. (2024) proposed digital twin modelling methods, which are based on IFC standards. In addition, the integration of BIM with lean principles has further demonstrated benefits, including waste reduction and enhanced visualisation (Sacks et al., 2010). However, these approaches typically address process management rather than quantitative design stability assessment.

Despite these advances, a critical gap persists in the literature. The existing methods focus on retrospective change identification rather than forward-looking stability assessment. For example, Abdulfattah et al. (2023) concluded that no established framework exists for quantifying design maturity progression across multiple model versions. Furthermore, the current comparison methods do not adequately distinguish between meaningful design changes, as indicated by Lee et al. (2011) who acknowledged that automated identification of modified versus newly generated information remains an unsolved challenge. Moreover, the methods for predicting design stabilisation timing are notably absent. While Saoud et al. (2017) proposed Design Structure Matrix approaches for change propagation prediction and subsequently, Chen and Whyte (2022) developed digital-twin-driven DSM methods; these approaches address change impact propagation rather than overall design convergence assessment.

More recently, researchers have explored approaches to managing time-evolving BIM data at the object level. Esser et al. (2022) proposed a graph-based version control method that represents IFC object networks as formal property graphs and describes model changes through graph transformations, enabling object-level synchronization rather than whole-file comparison. Their subsequent work extended this to event-driven collaboration environments for asynchronous BIM workflows (Esser et al., 2023). While these contributions advance the technical infrastructure for detecting granular changes between model versions, they focus on the mechanics of change detection rather than interpreting change patterns in terms of design stability. The present study complements this work by providing interpretable metrics that translate detected changes into actionable stability assessments.

Recent studies emphasize that artificial intelligence applications in construction should support practical decision-making (Pan and Zhang, 2021), yet current implementations prioritise technical sophistication over accessibility. This gap indicates an opportunity for frameworks that could convert the complex change data into actionable metrics for design managers and project stakeholders.

To address these gaps, this study introduces a framework comprising two complementary metrics, which are CI and SI. These metrics are designed to track MEP design evolution across consecutive IFC versions. The following section details the methodology for calculating these metrics and their application in assessing design maturity progression.

Methodology

The research was conducted using the Design Science Research Methodology as proposed by Peffers et al. (2007). The research process is structured into six sequential activities: problem identification, definition of objectives, artefact development, demonstration, evaluation, and communication, as shown in Figure 1.

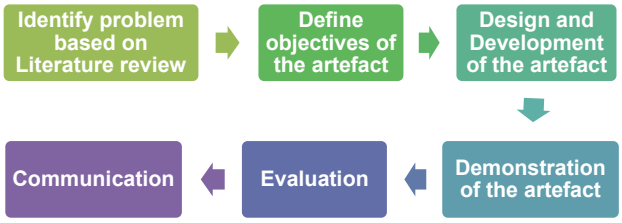

Figure 1. Research Method

The research addresses the problem that the existing BIM model comparison tools detect changes but do not assess whether the design is stabilising over time or not. To address this gap, a BIM-based analytical artefact was developed to quantify design change behaviour and assess stabilisation trends across model versions.

The artefact was iteratively developed and refined using a case study consisting of eleven consecutive IFC versions of a sprinkler system spanning approximately five months of design development. The sprinkler system was chosen because the changes made by architects and clients to the suspended ceiling and interior finishes cause design alterations in sprinkler systems, which make them one of the critical systems in MEP systems. This system is suitable for the demonstration of the problem. The Iterative refinement was guided by sensitivity analysis and empirical behaviour observed in the case study, consistent with DSR principles of relevance, rigor, and utility.

A positive side of this research approach is that it does not require extensive data sets like complex machine learning approaches, which need extensive training data, the CI and SI metrics. The current approach offers immediate interpretability with simple computation. The logistic transformation used in SI calculation provides an intuitive scale that facilitates communication among project stakeholders and supports decision-making in construction management.

Change Intensity (CI)

Design changes between consecutive IFC files are quantified using a CI metric, which captures the proportion of elements affected by different types of changes. CI is defined as (1):

$$CI = A + R + G + P \quad (1)$$

Where:

A = Percentage of added elements

R = Percentage of removed elements

G = Percentage of elements with geometric changes

P = Percentage of elements with property changes

The formulation provides a normalised measure of design activity between versions. CI reflects how much the model has changed without yet interpreting whether those changes indicate convergence or instability.

Stability Index (SI)

To interpret CI in terms of design stabilisation, SI was introduced. The SI transforms CI values into an interpretable stability signal using a two-step process:

Step 1: Raw Stability Index (Logistic Mapping)

A logistic function is used to map CI values to a bounded stability scale [0, 100], shown as (2):

$$SI_{raw} = \frac{100}{1+e^{\frac{CI-\theta}{s}}} \quad (2)$$

Where:

θ is the stability threshold,

S controls the steepness of the transition around the threshold

The logistic function was selected because design stabilisation is non-linear, i.e., small increases in CI near the threshold can significantly reduce confidence, while very low CI values rapidly increase perceived stability. Earlier studies have used logistic growth models as part of forecasting model comparisons to evaluate trend-based cost predictions (Narbaev and De Marco, 2014a).

Step 2: Smoothed Stability Index (Moving Average)

Single version stability measurements may be sensitive to isolated events such as bulk geometry updates or metadata changes. To reduce this sensitivity and reveal underlying stabilisation trends, a moving average is applied to the raw SI values, shown in (3):

$$SI_{smoothed} = \frac{1}{n}\sum_{j=i-n+1}^{i} SI_{raw,j} \quad (3)$$

where n is the window size.

In this study, n-3, meaning that stability is evaluated based on the three most recent versions. The moving average smooths short-term fluctuations and supports the interpretation of sustained convergence behaviour, which is more relevant for design management decisions than single version stability. Multiple practical descriptions show moving averages are widely applied in fields like finance, forecasting, business, and economics (smoothing trends, forecasting) (Hansun, 2013, Hyndman, 2025).

Trend-Based Prediction Logic

Rather than predicting absolute future design stability, the artefact supports trend-based anticipation of stability behaviour. A simple first-order extrapolation (2) is used to estimate near-term change intensity:

$$CI_{predicted} = CI_i + (CI_i - CI_{i-1}) \quad (4)$$

The predicted CI is then transformed using the same logistic mapping to obtain a predicted raw stability value. Final anticipated stability is expressed as a moving average combining recent and predicted values, shown in (5):

$$SI_{predicted} = moving\ average\ of\ (SI_{raw,recent} + SI_{raw,predicted}) \quad (5)$$

This mechanism does not claim deterministic forecasting but provides early warning signals indicating whether the design process is converging, persisting, or diverging.

Artefact Iteration

The artefact parameters were iteratively calibrated through sensitivity analysis:

- For Threshold and Steepness, twelve parameter combinations were tested (θ = 5-20%, s = 2-5). The final values θ = 10% and s = 3 were selected as they provided the most interpretable separation between stable and unstable design phases
- For the moving average window, sizes of n = 2, 3, 4, 5 were evaluated. A three-version window was selected as it balanced responsiveness with robustness against isolated spikes.

These iterations ensured that the artefact remains sensitive to meaningful design changes while avoiding overreaction to short-term anomalies.

Demonstration

The artefact was demonstrated on a real-world case study involving a sprinkler system from a Finnish under-construction sports arena project. The gross area of the building was 15000 sqm with eight storeys. The dataset consisted of eleven consecutive IFC versions spanning approximately five months of design development. The initial version of the dataset contained approximately

15,800 MEP elements, enabling analysis of stabilisation over time.

Evaluation

To assess the extent to which the artefact met its intended purpose, an evaluation process was carried out. Evaluation focused on the ability to identify convergence and divergence trends against updated design changes, and the interpretability of CI and SI metrics for design management decisions. This paper details the evaluation results along with the final design of the artefact and how those results were used to provide a practical BIM-based tool for evaluating the stabilisation of the MEP design phase/preliminary designs using open IFC data.

While the by Peffers et al. (2007) framework guided the sequential process of this research, from problem identification through communication, Hevner et al. (2008) provide a complementary set of guidelines for evaluating the rigour and relevance of design science outputs. Table 1 maps these guidelines to the current study to demonstrate that the developed artefact satisfies established quality criteria for design science research.

Table 1. Mapping of DSR guidelines to the study

DSR Guideline	Application in this study
Guideline 1: Design as an Artifact	The CI/SI framework is a purposeful artifact developed to quantify and track BIM design stability.
Guideline 2: Problem Relevance	Addresses the critical gap where existing BIM tools lack stability assessment for project management.
Guideline 3: Design Evaluation	The framework was demonstrated and evaluated on 11 real-world IFC versions to ensure empirical validity.
Guideline 4: Research Contribution	Provides novel interpretable metrics (CI and SI) that offer a new way to measure and visualize design stabilization.
Guideline 5: Research Rigor	Rigor is maintained through sensitivity analysis and the iterative calibration of threshold and steepness parameters.
Guideline 6: Design as a Search Process	The "search" involved testing 12 parameter combinations and evaluating various moving average window sizes to find the optimal configuration.
Guideline 7: Communication of Research	Findings are presented to both technical and management audiences through the detailed documentation in this paper.

Results

Change Intensity across IFC versions

Change Intensity was calculated for ten consecutive version transitions from 1 March 8 March to 15 July 26 July by aggregating added, removed, geometry-changed, and property-changed elements as shown in Figure 2.

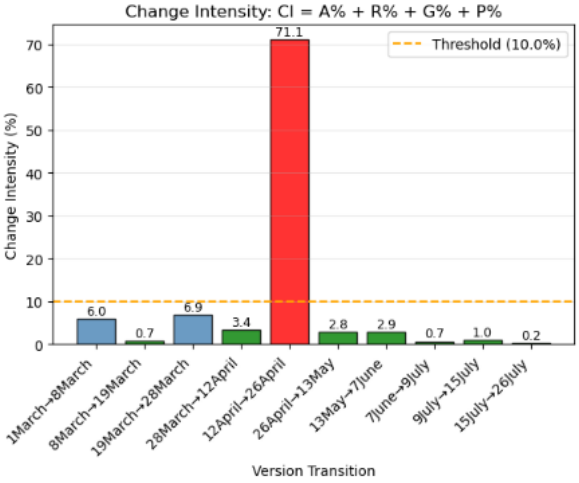

Figure 2. Change Intensity over revisions

A clear exception occurred during the 12 April → 26 April transition, where CI spiked sharply to approximately 71%. This spike was primarily driven by many elements undergoing property changes, indicating a bulk update event rather than gradual design development. Such behaviour reflects a disruptive intervention in the design process, for example, late requirement changes, system reconfiguration, or data restructuring. After this event of instability, CI values dropped rapidly and consistently, reaching near-zero levels by 15 July → 26 July, signalling a return to stable and controlled design changes.

Stability Index Behaviour

The raw SI, computed using the logistic function, responded sensitively to CI fluctuations as shown in Figure 3.

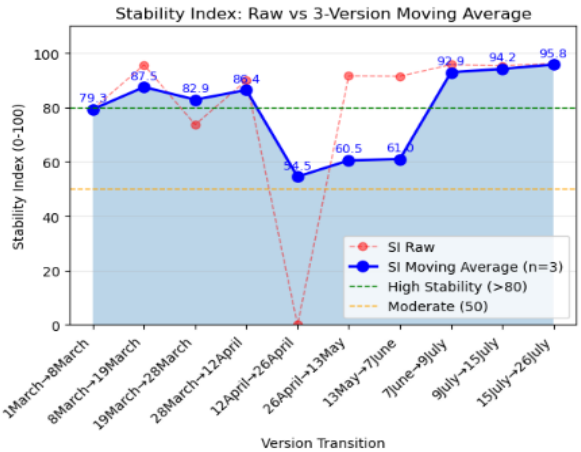

Figure 3. Stability Index

During early revisions, raw SI values remained mostly in the high-stability range (>80), reflecting low change intensity and increasing design stability. On 12 April 26 April, the extreme CI spike caused the raw SI to collapse to near zero, demonstrating the model's ability to

correctly penalise disruptive design behaviour. However, this sharp drop also illustrates the volatility of raw SI when isolated bulk changes occur.

To address this, a 3-versions moving average was applied. The smoothened SI successfully dampened abrupt fluctuations while preserving the overall trend. Following the disturbance on 12 April → 26 April, the smoothed SI gradually recovered, crossing back into the high-stability zone and reaching 95.8 on 15 July → 26 July. This progression reflects a transition from unstable redesign back to controlled convergence.

Stability Trend Prediction and Evaluation

As described earlier, there were eleven versions of IFCs that were used in the demonstration. Nine versions were used to calculate the stability trends, and the last two were used for the prediction of the stability index. Figure 4 indicates the trend analysis, which shows a positive SI trend (+1.6) combined with a negative CI trend (−0.7%) in the most recent versions. Based on linear extrapolation of CI and the smoothed SI trajectory, the predicted next version indicates continued stability.

Evaluating the trends based on the results shown in Table 2, it was noticed that the predicted stability points align with the raw/actual stability value of the last two versions, i.e., 9 Jul → 15 Jul difference is 1.1, and 15 Jul → 26 Jul difference is 0.5. The predicted SI for the last two versions remains within the high-stability regime, corresponding to an estimated ~80% stability confidence.

The results show different phases of design evolution that validate the framework's effectiveness. During initial revisions from 1 March to 12 April, CI values remained between 0.73% and 6.92% with raw SI exceeding 73%, which indicates controlled incremental development consistent. The versions from 12 April to 26 April represented a significant disruption event, with CI spiking to 71.06% and raw SI collapsing to zero, which was caused by bulk property updates or late requirement changes rather than gradual evolution. The 3-version moving average effectively reduced this instability, dropping gradually to 54.5 while maintaining trend visibility. After this abrupt disturbance, the design showed gradual stabilisation. CI decreased constantly from 2.84% to 0.23%, while smooth SI recovered from 60.5 to 95.8 by the final alteration. The positive SI trend (+1.6) combined with the negative CI trend (−0.7%) in recent versions demonstrates the framework's capacity to differentiate between normal iteration, disruptive interventions, and stabilisation patterns.

Table 2. Results of Raw and Predicted Stability Index

Version	CI (%)	SI_raw	SI_avg	Window
1 Mar → 8 Mar	5.96	79.3	79.3	[1..1]
8 Mar → 19 Mar	0.73	95.6	87.5	[1..2]
19 Mar → 28 Mar	6.92	73.6	82.9	[1..3]
28 Mar → 12 Apr	3.43	89.9	86.4	[2..4]
12 Apr → 26 Apr	71.06	0.0	54.5	[3..5]
26 Apr → 13 May	2.84	91.6	60.5	[4..6]
13 May → 7 Jun	2.88	91.5	61.0	[5..7]
7 Jun → 9 Jul	0.66	95.8	92.9	[6..8]
9 Jul → 15 Jul	0.96	95.3	94.2	[7..9]
15 Jul → 26 Jul	0.23	96.3	95.8	[8..10]

Discussion

The proposed research framework builds upon existing literature in the collaboration and coordination of BIM-based projects by integrating temporal analysis of multiple sequential versions of an IFC, rather than a single-instance comparison. While the commercial tools used to identify conflicts and clashes between elements of a built project are well known (e.g., Hasannejad et al. (2023)), the question of whether the design is stabilising or not has not been addressed within the academic literature. This distinction could influence decisions made by design managers regarding project coordination, timeliness of projects, and construction readiness. To

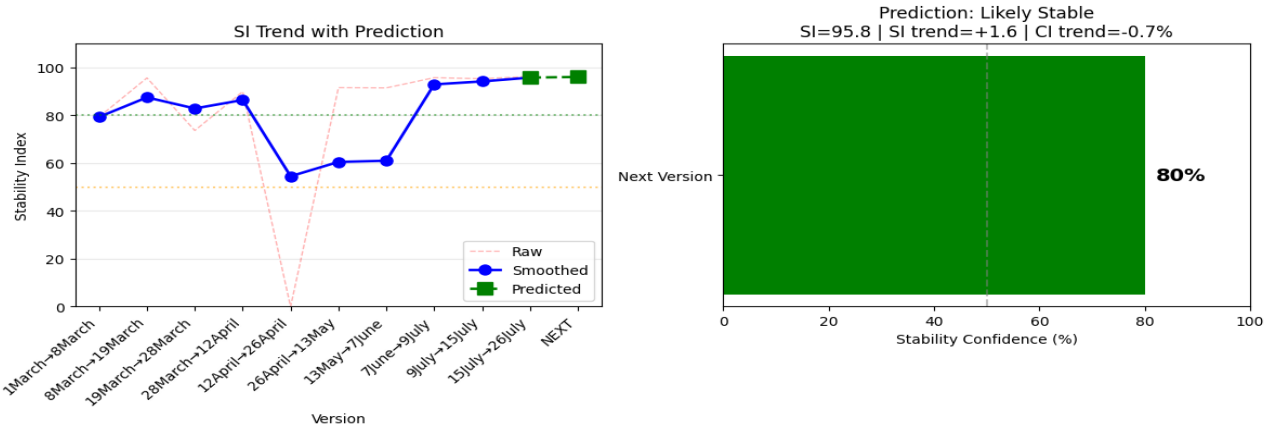

Figure 4. Stability Index trend with prediction

address this gap in the building and construction industry, 2 interpretable project metrics, CI and SI, are proposed with a demonstration of the framework.

The CI and SI metrics have been developed to be easily understood by project managers without requiring a statistical background to understand how the results are represented. For example, if a project manager sees a CI value of 15%, they know 15% of elements have changed; or if they see an SI value of 85%, they know that all project elements are in a stable condition. This transparency is not merely convenient, but it is essential for adoption in practice, where stakeholders need to trust and understand the basis for recommendations. The proposed metrics also do not rely on complex machine learning algorithms (Abdulfattah et al., 2023, Pan and Zhang, 2021) to determine how an element will behave in the future based on its previous history; therefore, no statistical expertise is required to understand the CI and SI metrics.

The study supports the existing research by extending element-based two-version IFCs comparison to an analysis of a series of consecutive IFC versions. Most of the change detection studies only catalogue differences between two versions (Moayeri et al., 2015), which provides valuable data and information, but provides limited information to reveal patterns of design evolution over time. This research demonstrates through tracking CI and SI over 11 versions of IFCs that the design process follows recognisable patterns of design. These patterns include controlled incremental refinement during initial phases, possible disruption events that produce temporary instability, and eventual convergence towards stability as a design develops.

This finding of this research aligns with the established understanding of iterative design processes in BIM-enabled projects, where coordination activities gradually resolve conflicts until the design reaches a sufficient level of maturity for execution (Ahmad et al., 2017). In complex project management, coordination noise is experienced during an iterative information flow. To address this noise, moving average filters are utilised. This approach is complemented by logistic growth models, which have been validated in previous literature for forecasting the progression of design stability (Largani et al., 2026, Narbaev and De Marco, 2014b). This prediction mechanism provides a potential solution for the challenges in construction readiness due to design changes, mentioned in recent researches (Radzi et al., 2025).

Limitations and Future Research

This study is based on one project only and focuses on fire sprinkler systems, which limits the generalizability of the results. The selected thresholds and weighting factors, while suitable and effective in this case, may require calibration for different project types and levels of model granularity. Additionally, the current CI formulation treats all geometric changes and all property changes as equally weighted. In practice, repositioning an element carries different design implications than modifying a pipe cross-section, yet both are captured identically as geometric changes. Similarly, updating a critical performance parameter such as a flow rate differs in significance from a metadata update such as a naming convention change.

To address these limitations, future studies can investigate weighted sub-categorisation of change types based on their functional relevance to the design intent. Furthermore, future research can apply the framework across multiple projects and building systems to validate its robustness and explore adaptive or learning-based threshold selection

Practical Implications

The framework provides a practical way for design managers to optimise coordination, timing, and resource allocation. A construction site with complete situation awareness of upcoming design changes can perform better than traditional sites in terms of rework reduction and cost overrun. The 10% CI threshold provides a simple decision rule, which is that if the transitions exceed this threshold warrant investigation into root causes and potential downstream impacts. This alertness helps the site manager to stay aware of the design change situation. The smoothed SI trend enables actionable scheduling of design reviews, and positive trends suggest approaching stability. While negative trends indicate continued volatility, requiring additional coordination meetings to stabilise the design. For this case project, the framework would have flagged the April disruption event in real-time and enabled the managers to inspect the cause and assess the impact before implementation. This approach aligns with research demonstrating that early conflict identification through BIM reduces costly on-site modifications (Khanzode et al., 2008). The prediction capability mentioned in the results of the case study estimates 80% stability confidence for subsequent versions. This stability confidence has the potential to support decisions regarding construction release timing and trade coordination scheduling.

Conclusions

This study presented a BIM-based framework for tracking MEP design development leveraging CI and SI metrics. CI quantifies element-level modifications across consecutive IFC versions, while SI applies a logistic transformation to produce a bounded stability score from 0 to 100%. The demonstration of eleven IFC versions from a real project demonstrated that the framework successfully identifies disruption events, tracks design convergence, and supports trend-based prediction of stabilisation. The approach addresses a critical gap in existing tools, which focus on retrospective clash

detection rather than forward-looking stability assessment, providing project managers with interpretable metrics for coordination timing and construction readiness decisions. Proposed future work can extend validation across multiple projects and building systems, integrate with scheduling tools, and explore adaptive thresholds for different project contexts.

Acknowledgement and Fundings

This research was conducted as part of the Research to Business (R2B) project BIMSpect. The authors gratefully acknowledge the financial support provided by Aalto University and Business Finland, which made this work possible. The authors also wish to thank all members of this R2B project, including industry piloting partners, practitioners, and team members, for their valuable contributions and collaboration. This work was partially supported by the Research Council of Finland, grant number 357307.

DIGITAL TWIN VALUE CREATION AS A DYNAMIC SYSTEM: A CAUSAL LOOP DIAGRAM APPROACH

J Omar Abbas, Nicola Moretti, and Tim Broyd
University College London, London, United Kingdom

Abstract

Digital Twins (DTs) are promoted as a transformative paradigm for the built Environment, yet their value is articulated through benefit propositions that lack cost integration. This study proposes a new conceptualisation of DTs value creation for asset owners, based on System Dynamics (SD). DT costs and benefits are identified first and modelled as variables of four subsystems representing operational, human, financial and market mechanisms across the asset lifecycle. The results reveal different feedback loops of how value is realised. The contribution is a general system-level explanation of DT value that supports more informed investment decisions.

Introduction

Digital Twins (DTs) are increasingly positioned as a transformative paradigm for the Architecture, Engineering, Construction and Operation (AECO) industry, promising to enhance decision-making, performance, and value creation across the asset lifecycle. DTs integrate multiple digital technologies to enable continuous data exchange between physical assets and their digital representations, allowing organisations to monitor, analyse, and predict asset behaviour over time (Iqbal & Mirzabeigi, 2025). Despite growing interest and increasing experimentation, the value of DTs remains difficult to articulate and justify in practice (Opoku et al., 2023). Much of the existing discourse emphasises expected or potential benefits, often presented in static or descriptive terms, while providing limited insight into how benefits relate to incurred costs or how these elements interact over time and across organisational functions (Abbas et al., 2024).

The AECO industry has struggled to translate digital technological advances into productivity and performance improvements (Berlak et al., 2021). These challenges stem from inherent industry characteristics, including high uncertainty with work processes that are often unpredictable and difficult to standardise (Oesterreich & Teuteberg, 2016). Against this setting, Industry 4.0 principles have stimulated interest in digital technologies capable of addressing productivity and decision-making challenges in the AECO industry. Technologies such as Building Information Modelling (BIM), Artificial Intelligence (AI), and the Internet of Things (IoT), have been identified as key drivers of digital transformation in the AECO industry (Moshood et al., 2024). DTs have emerged as a prominent concept within this broader set of digital technologies, integrating many of them to support lifecycle-oriented asset management.

Problem statement and research gap

A central challenge lies in the lack of a clear and shared understanding of DT value. As a result, organisations often struggle to justify the additional investment burden associated with DT development and implementation (Opoku et al., 2023). Furthermore, there is no established framework or taxonomy that articulates the full spectrum of DT value delivered to different stakeholders across the asset lifecycle, leaving their true value largely undefined (Pregnolato et al., 2022).

Existing research has focused on describing value propositions or potential benefits of DTs, without empirical validation or explicit consideration of associated costs. For instance, in their formulation of ontological dimensions for DTs during the construction phase, Sacks et al. (2020) presented some benefits and described them as potential or expected. These benefits were not examined in terms of how they interact with costs within organisational settings. This highlights a gap in both research and practice which is the absence of a system-level explanation that links DT-enabled benefits and costs through explicit cause/effect mechanisms within organisational settings. This gap underscores the need for approaches that move beyond static representations of DT benefits and instead provide a systemic explanation of how DT value is created over time.

Research aim, questions, and objectives

This study adopts Causal Loop Diagrams (CLDs) within System Dynamics (SD) to move beyond the static definition of DT benefits and costs. The aim of this study is to develop a system-level conceptual model that represents how value from DTs emerge over time through the interaction of operational, human, financial and market mechanisms across the asset lifecycle, from an asset owner perspective. Guided by this perspective, the study addresses two Research Questions (RQs) and identifies four related Research Objectives (ROs) (see Table 1).

Table 1: Research Questions and Objectives of this study.

Research Questions	Related Research Objectives
RQ1: What DT benefits and costs are relevant for representing value creation from an asset owner perspective across the asset lifecycle?	**RO1**: to identify and synthesise the benefits and costs of DTs that are relevant to asset owners across the planning, delivery, operation and end-of-life phases.
	RO2: to structure these benefits and costs into an integrated system encompassing operational processes, labour dynamics, financial performance, and market outcomes, and to classify performance-related variables using Balanced Scorecard (BSC) perspectives (financial, customer, internal business, and innovation and learning).
RQ2: How do these benefits and costs interact through causal relationships and feedback mechanisms?	**RO3**: to develop a CLD that represents the causal relationships between DT capabilities and performance metrics, under the assumed case of active and consistent DT use across the asset lifecycle.
	RO4: to identify and describe the dominant feedback loops that shape how DT value evolves over time.

The remainder of this paper is structured as follows. The Related work section reviews DT literature in the built environment, focusing on how benefits and costs have been conceptualised. The Materials and methods outline the identification and synthesis of DT value elements, the CLD approach, and the asset owner system boundary and subsystems. The Results and discussion present and interpret the CLD and its dominant feedback mechanisms, with implications for asset owners' decision-making. The paper concludes by summarising the main contributions and outlining directions for future research.

Related work

The ISO/IEC 30173:2023 defines a DT as a "digital representation […] of a target entity […] with data connections that enable convergence between the physical and digital states at an appropriate rate of synchronization" (ISO, 2023: p. 6). There is also a broad agreement on three fundamental DT building blocks: the physical asset, its digital representation, and the data exchange linking both (Korenhof et al., 2021). While there is no technology stack prescribed for developing a DT, DTs could be characterised as a collection of technologies (Wei et al., 2022). Alongside BIM, which is widely regarded as a core modelling element of DTs (Revolti et al., 2024), key enabling technologies include IoT, AI, Cloud Computing and Extended Reality (XR) which encompasses Augmented Reality (AR), Virtual Reality (VR) and Mixed Reality (MR) (Attaran & Celik, 2023).

In their review of DT applications in the built environment, Kookalani et al. (2026) mapped use cases across lifecycle phases and sectors. During design and construction, applications include lifecycle planning, progress monitoring, and resource management, while in operation and maintenance they include fault detection, energy optimisation, and predictive maintenance. Across sectors, applications span infrastructure projects, buildings and urban development contexts, among others. The different applications are what ultimately lead to value creation, which has been identified as a fundamental property of DTs (Bolton et al., 2018). In the literature, the concept of value is frequently invoked but often used inconsistently, sometimes interchangeably with benefits only (Laursen & Svejvig, 2016). Value is instead understood as a relationship between benefits and costs, consistent with definitions that conceptualise value as benefits realised minus costs incurred (Morris, 2013).

Prior research has proposed several ways of classifying benefits. For example, they have been categorised according to strategic, tactical, and operational levels (Irani & Love, 2002), where strategic benefits are often intangible and difficult to quantify, and operational benefits are typically more tangible and measurable. Bradley (2010) further distinguishes between intermediate benefits and end benefits, arguing that end benefits are often realised only after a sequence of intermediate benefits has occurred. It was further delineated that enablers are inputs that make benefits possible, and in the context of this study, implementing a DT could be considered as such.

With respect to costs, studies have distinguished between capital expenditure (CapEx) and operational expenditure (OpEx) of DTs, identifying sensors, computing infrastructure, and software licensing as CapEx, and maintenance and server-related expenses as OpEx (McClenaghan et al., 2023). This study, however, was largely based on experimental settings and did not provide a comprehensive account of DT costs across the asset lifecycle. Oesterreich and Teuteberg (2018a) identified the costs of developing and utilising BIM from earlier Information Science domain studies, distinguishing between indirect costs, and direct costs. In this framing, direct costs are those directly attributable to operating the digital system (e.g., hardware and software costs), whereas indirect costs include human inputs (e.g., training, and human resource costs) and organisational costs associated with shifting to new workflows and practices (Love et al., 2013). More recently, Su et al. (2025) proposed a methodology for estimating DT costs in the manufacturing domain. While this study provides useful insights, it focuses exclusively on the development phase of a DT and is limited to a prototype-scale implementation in the manufacturing domain.

Overall, the literature reveals a strong emphasis on DT benefits, often presented as value propositions without empirical evidence, alongside a comparatively limited and fragmented treatment of costs (Abbas et al., 2024).

Moreover, existing studies did not provide system-level explanations that link benefits and costs or account for how these elements interact and evolve over time.

Materials and methods

This study adopts a qualitative multi-method approach. It builds on a previously published Systematic Literature Review (SLR) (Abbas et al., 2024), which identifies the benefits and costs of digital twins and informs the development of the CLD model presented in this paper. The model is used to explain how value emerges over time. The research schema is shown in Figure 1.

Identification and synthesis of benefits and costs

Additional studies were incorporated to expand and consolidate the list of benefits of DTs identified in Abbas et al. (2024), including cost-benefit analysis (CBA) models using SD for BIM (Oesterreich & Teuteberg, 2018a) and AR in the built environment (Oesterreich & Teuteberg, 2018b). Both BIM and AR are widely recognised as integral components of DT systems (Attaran & Celik, 2023). Incorporating these studies therefore allowed the synthesis to capture benefits that are either explicitly attributed to DTs or implicitly enabled through DT-related technologies. The synthesised benefits are illustrated in Table 2. Cost identification drew on DT cost studies (Oettl et al., 2023; Su et al., 2025), and BIM cost classifications (Oesterreich & Teuteberg, 2018a).

System Dynamics modelling

CLDs form a core component of the SD methodology and are commonly used as an initial step in modelling system behaviour. They provide a qualitative representation of a system by depicting variables and the causal relationships between them, including the polarity of each relationship and the presence of reinforcing or balancing feedback loops (Sterman, 2000). Variables can be either exogenous (external inputs that influence the system but are not influenced by it) or endogenous (internal system variables whose behaviour is determined by interactions with other variables) (Ford, 2019). Costs and benefits in this study are modelled as variables of the overall DT SD model. Vensim[1] was used to create the CLD.

The modelling approach in this study followed the first two stages of the SD process outlined by Sterman (2000). The first stage, problem articulation, is addressed through the definition of the research problem and the adoption of an asset owner perspective. The asset owner is defined as the long-term beneficiary of the asset's financial value, responsible for governing asset management policy and whole-life performance requirements (The Institute of Asset Management, 2024). This boundary is assumed to encompass facility management functions and the client/investment role. Delivery organisations such as designers, contractors, and operators may be outsourced, but their contributions are treated within the boundary because the asset owner remains ultimately accountable for lifecycle value outcomes. Occupiers/tenants are included as stakeholders within the boundary. For conceptual clarity, the model assumes a single asset owner and does not explicitly represent ownership transitions or split ownership. The boundary spans the asset lifecycle from initial DT investment through operation and end-of-life, with financial performance represented up to Earnings Before Interest and Taxes (EBIT) and excluding external macroeconomic factors outside organisational control such as inflation or interest rates.

The overall system is structured into four interacting subsystems adapted from earlier SD models of organisational performance (Clark & Augustine, 1992) and subsequent applications in the construction domain (Oesterreich & Teuteberg, 2018a; Oesterreich & Teuteberg, 2018b). The subsystems used in this study are:

1. Processes & Data (Information, data, systems, execution),
2. Personnel & Labour (People, skills, time),
3. Sales & Market (Output, quality, demand),
4. Finance & Accounting (Cost aggregation, profits).

Each variable was assigned to one of the four Balanced Scorecard (BSC) perspectives proposed by Kaplan and Norton (1992): financial (e,g., profitability and cost-related measures) customer (e.g., customer satisfaction, retention, and market share), internal business (e.g., operational efficiency), and innovation and learning (e.g., workforce development, and innovation capability). Using BSC with SD modelling has been used in prior work, for example to group performance metrics into performance drivers and outcome metrics before mapping

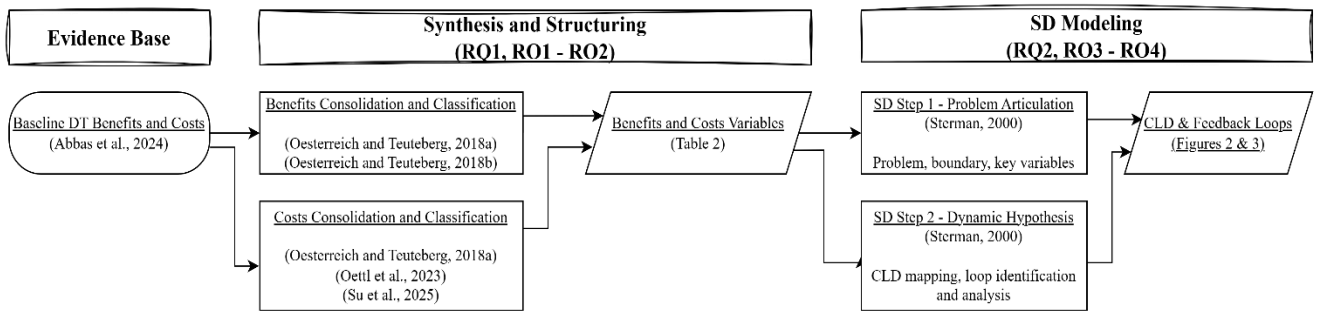

Figure 1: Flowchart illustrating the research schema.

[1] https://vensim.com/software/

their links in a CLD (Hristov et al., 2024). Utilising BSC classification at the CLD stage improves the model's relevance and interpretability for asset owners (and other stakeholders within this organisational boundary). Although these metrics are not quantified at this stage, the BSC grouping supports selection of quantifiable indicators for translating the CLD into a Stock and Flow Diagram (SFD), consistent with standard SD practice (Sterman, 2000).

The second stage, formulation of a dynamic hypothesis, involves identifying the key endogenous variables and feedback structures that are hypothesised to drive system behaviour over time and it is operationalised through the development of the CLD. To select the feedback loops for analysis, the Shortest Independent Loop Set (SILS) method is applied to identify a set of shortest, non-redundant loops that account for system behaviour (Oliva, 2004).

Results and discussion

Consolidation of DT value elements

To address RO1 & RO2, Table 2 summarises the variables included in the model, indicating their associated subsystem, endogenous or exogenous status, and Performance metric/perspective, along with the consolidated benefits from literature.

Consistent with the benefit realisation perspective (Bradley, 2010), some benefits could be interpreted as DT-based organisational enablers (depicted as DT capabilities thereafter), reflecting improved capabilities in monitoring, coordination, risk control, and asset management as examples. Other benefits are represented as internal business outcomes, including reduced execution time, reduced rework and error incidence, and improved output quality and output volume. Customer performance metrics reflect the organisation's relative position in the market, including reputation and market share, while innovation and growth performance metrics show employee and organisational growth.

Most financial variables, as illustrated in Table 2 and Figure 2, were derived from the literature. Additional elements were introduced to improve system-level representation, including cost aggregation (direct, overhead and indirect costs), and depreciation to derive EBIT. Cost variables represent both initial and ongoing investment expenditures, as well as costs that arise endogenously from system behaviour, such as staffing, training, and injury compensation costs. Costs are represented as both exogenous and endogenous variables, depending on their role in the system. Baseline investment and operational costs associated with DT deployment are treated as exogenous, while costs arising from workforce dynamics, business processes, and organisational change are modelled as endogenous.

System-level CLD and cross-subsystem integration

To address RO3, the CLD, illustrated in Figure 2, illustrates how DT capabilities influence different performance perspectives through interacting feedback loops across the asset lifecycle. These capabilities are represented as exogenous variables, and they are highlighted using dotted green boxes to distinguish them from other variables. The CLD indicates that DT value is not produced directly by technology deployment but emerges through the interaction of DT capabilities with operational, workforce, financial and market mechanisms. In the model, DT capabilities shape endogenous behaviour primarily through internal business metrics such as execution time, rework and error incidence, and output quality.

The *Process and Data subsystem* captures the primary pathways which DT capabilities affect internal business processes. For instance, capabilities related to information management, forecasting, coordination, and asset performance (exogenous capabilities) influence execution time, rework and error incidence, and output quality (internal business performance metric). For example, information and documentation quality, and site coordination effectiveness reduce rework and error incidence by limiting coordination errors, and this in turn improves output quality. Progress monitoring capability, and supply chain reliability reduce schedule slippage and execution time by enabling earlier detection of deviations. Asset performance and efficiency improve operational continuity by reducing downtime, thereby improving labour productivity. Several of the internal business performance variables are highly interconnected, reflecting the central role of operational performance as a mediator between DT and downstream customer and financial outcomes. Within this subsystem, execution time and rework and error incidence emerge as especially central, given their multiple connections to other performance metrics. In terms of cross-subsystem interactions, the Processes and Data variables receive incoming influences from only three variables in the Personnel and Labour subsystem: experience accumulation, labour productivity, and workforce skills.

The *Personnel and Labour subsystem* captures workforce-related mechanisms through which DT capabilities and internal business metrics affect productivity, safety, workforce stability and associated costs. Safety monitoring and prevention capability appears as a native variable of this subsystem, and it is the only DT capability in this subsystem reflecting its primary influence on workforce outcomes. This capability reduces accident frequency, and this improves labour productivity and enhances organisational reputation. Labour productivity is a highly central variable within this subsystem, linking workforce skills, safety outcomes, and staffing requirements. This position reflects its function linking workforce dynamics to financial outcomes.

The *Sales and Market subsystem* represents how internal business performance translates into customer outcomes over time. For example, improved output quality and reduced rework increase customer satisfaction, which supports order volume and strengthens organisational reputation. This in turn improves the firm's competitive position and market share. Environmental management

capability is the only DT capability in this subsystem, and it is shown to positively influence customer satisfaction.

Finally, *the Finance and Accounting subsystem* captures the cost and revenue consequences of DT development and implementation. Exogenous financial variables represent DT deployment and operation costs, such as data acquisition, software and platform, and security and data protection, and organisational and change management costs. Endogenous cost variables arise from internal system behaviour, including injury and compensation costs, hiring and recruitment costs, training costs, human resource costs. Direct costs, and overheads and indirect costs act as aggregation points capturing the cumulative effects of operational activities. Revenue is driven jointly by output volume and order volume. EBIT emerges from the interaction of revenue generation and cost accumulation.

Key feedback loops

To address RO4, applying the SILS method identified four reinforcing feedback loops, illustrated in Figure 3. Loop 1 (order volume - experience accumulation - output quality - customer satisfaction - order volume) is reinforcing: as demand increases, experience accumulates, which improves output quality and customer satisfaction, supporting further demand growth. This implies that DT value can compound over time when organisational learning is sustained.

Loop 2 (accident frequency - organisational reputation - employer attractiveness - staff turnover rate - experience accumulation - workforce skills - accident frequency) is also reinforcing and describes how safety retains and improves organisational reputation. Here, the exogenous safety monitoring and prevention capability acts as a lever that reduces accident frequency. This loop shows the

Table 2: Variables used in the CLD and corresponding Subsystem. Financial or cost items that are aggregated into direct costs, or overhead and indirect costs are excluded from the table and presented in Figure 2.

Subsystem	CLD Variable	Endogenous/ Exogenous	Performance metric/perspective	Syntehsised benefit from literature
Processes and Data	Information and documentation quality	Exogenous	DT capability	Improved information and documentation management
	Progress monitoring capability	Exogenous	DT capability	
	Forecasting and scenario capability	Exogenous	DT capability	Improved forecasting and scenario analysis
	Risk management capability	Exogenous	DT capability	Better risk management
	Site coordination effectiveness	Exogenous	DT capability	Improved site management
	Asset performance and efficiency	Exogenous	DT capability	Improved maintenance
	Supply chain reliability	Exogenous	DT capability	Improved supply chain management
	Resource allocation efficiency	Exogenous	DT capability	Better resource management
	Emergency response capability	Exogenous	DT capability	Better emergency and crisis management

significance of safety outcomes, and how they could shape a strategic organisational reputation.

Loop 3 (organisational reputation - competitive position and market share - order volume - experience accumulation - workforce skills - accident frequency - organisational reputation) caputres how market-facing outcomes intereact with safety and capability accumulation. This loop shows how organisational reputation can translate into competitive positioning and demand, while improving safety outcomes.

Loop 4 (organisational reputation - employer attractiveness - staff turnover rate - experience accumulation - workforce skills - accident frequency - organisational reputation) is also reinforcing and reflects a workforce stability mechanism along with improved safety outcomes. The loop also shows how organisational reputation can lead to capability accumulation by improving employer attractiveness.

Reflection and limitations

Given the limited evidence on realised DT value, this model was adapted from the SD-based CBA models developed by Oesterreich and Teuteberg (2018a) for BIM and Oesterreich and Teuteberg (2018b) for AR. Accordingly, this model should be interpreted as a conceptual hypothesis that organises the available evidence, rather than a definitive representation of DT value elements. It is presented as an initial gauging step to support progression to subsequent SD modelling stages.

Structurally, the three models differ in boundary choices and the explicit representation of technology capabilities. The BIM model is organised across three domains (Personnel and Labour; Customer and Market; Finance and Accounting), whereas the DT model adopts four subsystems, by introducing processes and data subsystem, to make DT capabilities clearer. The AR model also adopts four subsystems by introducing a Processes subsystem, which is comparable to the DT model's Processes and Data subsystem, although AR capabilities are not explicitly distinguished in the same way.

Across the market-facing domain, the DT model and the BIM model share comparable causal pathways. In the BIM model, environmental performance influences output quality and customer satisfaction, which then propagate to demand outcomes through customer base and orders. A similar mechanism appears in the DT model, where environmental management capability influences output quality and customer satisfaction, which then increases order volume. In the Personnel and Labour subsystem, the models also align in broad terms. Both BIM and AR models highlight safety-related mechanisms and their influence on productivity, and the BIM model

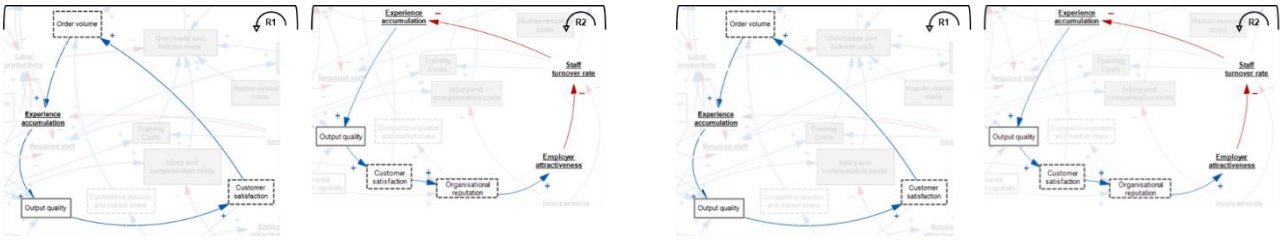

Figure 3: Four dominant feedback loops.

links injuries and accidents to corporate image and employer attractiveness. The DT model expresses a closely related pathway by linking accident frequency to organisational reputation and employer attractiveness.

The financial boundary and level of accounting detail differ across the models. The BIM model incorporates a more detailed financial structure extending beyond operating profit, whereas the present DT model adopts a simpler boundary with financial performance represented up to EBIT. The AR model applies a relatively simple financial structure as well and is therefore closer in scope to the DT model in its reliance on revenue, direct costs, and overheads and indirect costs. Despite differences in granularity, all three models share the same basic accounting logic in which value outcomes depend on revenue generation and cost accumulation across direct and indirect categories.

Unlike the other models, the DT model used BSC perspectives to structure the variables into recognisable performance domains, improving interpretability and clarifying how DT capabilities influence internal business processes and propagate to customer and financial outcomes. This could also provide a practical basis for subsequent quantification when translating the CLD into a SFD.

Regarding the limitations of this study, the benefits and costs were derived solely from secondary sources and may therefore not yet be comprehensive. The CLD built on earlier SD models developed for DT-enabling technologies, reflecting the limited availability of comparable SD studies. Third, this study only developed a CLD without progressing to later SD stages such as simulation, testing, or policy evaluation (Sterman, 2000), and within the CLD, the feedback loops analysed were not exhaustive. Furthermore, the financial boundary was limited to EBIT (rather than net profit), and the asset owner boundary excluded external macroeconomic factors such as inflation and interest rates, and this may affect realised value in practice.

Conclusion and future research

This study developed a CLD that explained how DT value evolves through interactions between operational, human, financial and market mechanisms across the asset lifecycle, from an asset owner perspective. In response to the literature gap identified, this study moves beyond itemised representations of DT benefits and costs by providing a system-level explanation (Sterman, 2000). In response to RQ1, the study identified and synthesised DT benefits and costs relevant to asset owners and structured them into an integrated system spanning four subsystems. For RQ2, the study developed the CLD structure linking DT capabilities to BSC perspective. The dominant feedback loops were also illustrated.

The study has implications for both research and practice. For academia, the model provides a conceptual basis for future empirical work on DT value mechanisms. The identified variables and CLD can be used in subsequent studies to test and validate these mechanisms for asset owners in the AECO industry. For practitioners, including asset owners and other stakeholders interacting with them, the CLD provides a tool for structuring investment decision-making while supporting more realistic expectations of value realisation over time. For policymakers, the results reinforce the importance of supporting not only technology deployment but also organisational capability building, to accelerate the realisation of value in DT systems.

Future work will initially ensure the completeness of benefits and costs of DTs by interviewing experts. Subsequently, the CLD will be tested and validated through stakeholder interviews and focus groups and then develop a SFD for quantitative simulation and scenario testing (Sterman, 2000). This will also include widening the financial boundary beyond EBIT and test sensitivity to external factors.

Abstract

Residential prosumer buildings with PV and high-load subsystems exhibit irregular demand, yet current residential digital-twin and baselining studies rarely address missing-data realism and causal deployment constraints. This paper presents a monitoring-oriented operation-phase digital twin analytics pipeline for an instrumented villa in Segrate, Italy, linking whole-building demand, PV output, pool-circuit power, and outdoor air temperature to a one-hour-ahead baseline task. A fixed Random Forest is evaluated across eight dataset configurations against persistence and Multiple Linear Regression. Under deployment-realistic causal conditions, the best configuration achieves RMSE 576.5 W, demonstrating the value of a traceable leakage-safe baselining workflow for residential prosumer settings.

Introduction

Digital twins, which were initially developed as models for the design phase, are now being used as effective tools to monitor and manage building operations (Oulefki et al., 2025; Mengual Torres et al., 2022). In this setting, data-driven energy baselining has emerged as a method to generate short-horizon reference predictions of building demand, supporting fault detection, performance tracking, and measurement and verification (Xie et al., 2023).

In the residential sector, smart home automation and IoT monitoring have been extensively studied, but residential digital twins are still less prevalent compared to their use in commercial facility management (Mengual Torres et al., 2022). Many existing residential studies concentrate on basic monitoring dashboards or the optimisation of specific components like batteries or heat pumps, lacking a robust and traceable connection between sub-metered devices and operational building-level representations (Xie et al., 2023). Residential prosumer buildings are also more difficult to model than conventional offices due to more stochastic occupancy patterns and the presence of onsite generation and high-load amenities, such as rooftop photovoltaics and swimming pools, which lead to non-linear and intermittent demand profiles necessitating comparison against both persistence and linear benchmark models to isolate the value of complex learners (Ghaemi et al., 2024). In the absence of a dependable short-horizon baseline that reflects these factors, building owners and facility managers do not have a clear reference point for detecting anomalies or assessing system upgrades (Ghaemi et al., 2024; Xie et al., 2023).

This gap is addressed in this paper using an instrumented residential villa in Segrate (Milan, Italy) as a documented operational-phase digital-twin testbed, linking heterogeneous IoT telemetry (whole-building electrical demand, PV production, swimming-pool circulation pump load, and outdoor air temperature) into a traceable data-processing pipeline that enforces domain constraints and prevents time leakage. This paper investigates a monitoring-oriented operation-phase digital twin analytics pipeline and documented residential testbed for causally consistent short-horizon baselining, addressing a gap narrower than a general digital-twin one: few residential prosumer studies jointly examine one-hour-ahead operational baselining, sub-metered telemetry, explicit missing-data policy, causal versus non-causal imputation, and comparison against persistence and linear regression within a leakage-safe design (Krishnan et al., 2024). Here, digital twin denotes a traceable operational representation linking telemetry, subsystem context, and analytics; it does not imply bidirectional control or formal BIM integration (Xie et al., 2023).

The one-hour-ahead horizon is chosen because the baseline serves as an operational reference for residual-based anomaly screening rather than long-range forecasting. At this horizon the baseline can support near-real-time fault detection in subsystems such as the pool circulation pump or the PV array, and it can provide building owners or facility managers with a timely reference for detecting deviations before they propagate into larger energy waste or equipment damage. The research question is whether adding sub-metered telemetry improves one-hour-ahead residential demand baselines over demand-only models and how that benefit varies across dataset configurations that differ in imputation strategy and missing-data policy.

Related work

Operation-phase monitoring pipelines and metadata traceability in residential digital twins

Operation-phase digital twin applications rely on robust data integration and metadata management to connect time-series data to building context (Xie et al., 2023). Recurring challenges in metadata consistency for smart-

building analytics motivate digital twin architectures that incorporate a traceable data integration layer linking building entities to operational data streams through curated metadata configurations (Balaji et al., 2018; Oulefki et al., 2025).

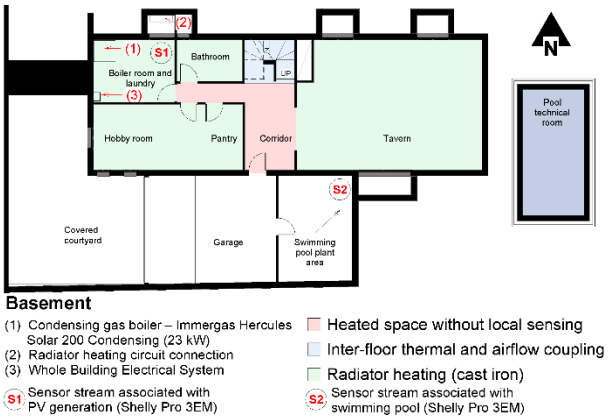
Data-driven energy prediction for occupied buildings

Building energy prediction has been extensively examined through three primary modelling paradigms: physics-based ("white-box"), data-driven ("black-box"), and hybrid ("grey-box") approaches. Reviews commonly observe that white-box models offer interpretability, but demand detailed and precise building parameters along with significant calibration efforts. In contrast, data-driven approaches are generally easier to implement when historical operational data are accessible and can deliver strong forecasting performance (Krishnan et al., 2024).

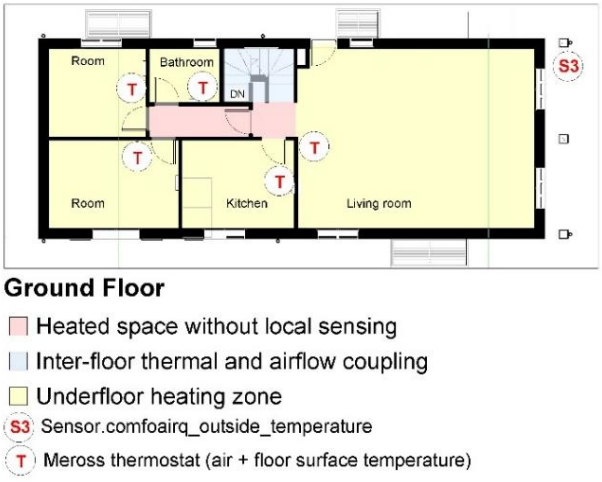
For operation-phase baselining and short-horizon forecasting, data-driven methods are frequently adopted as practical predictors, provided that issues such as data quality, missing values, and non-stationary operation (e.g., discontinuities from in-use residential operation) are appropriately addressed during preprocessing and evaluation (Krishnan et al., 2024). Within this framework, the methodological significance of baseline construction lies not only in final accuracy but also in how the inclusion of explanatory operational features, such as weather data, subsystem telemetry, and temporal context, contributes to the reliability and interpretability of predictive references relative to naïve benchmarks (Zhou, Yang & Wang, 2024). However, many studies still treat data handling and deployment constraints as secondary implementation aspects rather than as central methodological considerations (Krishnan et al., 2024; Xie et al., 2023).

The prosumer challenge and subsystem variability

Operation-phase analytics is more complex in residential prosumer contexts, where onsite generation and flexible or high-load subsystems lead to intermittent and non-linear demand patterns (Ghaemi et al., 2024). Recent peer-reviewed surveys on AI-enabled digital twins and data-driven energy management in buildings indicate that scalable applications such as forecasting and operational analytics require reliable data pipelines and consistent contextual information. Despite this, many residential studies continue to focus on component-level optimization, such as PV self-consumption, often without addressing the construction of a causally consistent whole-building operational baseline (compared against persistence and linear regression reference models) supported by sub-metered data (Xie et al., 2023).



Recent residential short-term forecasting studies provide the closest benchmark context for this deployment-oriented case study. Kychkin & Chasparis (2025) conduct a broad comparative analysis of hourly and day-ahead load forecasting models for a small residential energy community, demonstrating that computationally efficient persistence-based and autoregressive models can match or outperform more complex deep learning approaches on aggregate community load. Popławski, Dudzik & Szeląg (2023) apply LASSO regression and Random Forest to forecast the net electricity balance of a single prosumer household with rooftop PV, using short training windows and both endogenous and exogenous scenarios. Neither study jointly addresses sub-metered high-load subsystem telemetry, explicit causal versus non-causal imputation policy, or a leakage-safe multi-configuration evaluation design under deployment-realistic missing-data conditions. The gap addressed here is therefore narrower than a general residential forecasting gap: this study examines one-hour-ahead operational baselining with sub-metered pool-circuit and PV telemetry under systematically varied imputation strategies and a chronologically enforced train/test split designed to reflect realistic deployment constraints.



Methodology

This study implements a monitoring-oriented operation-phase digital twin analytics pipeline for operational energy baselining in a residential prosumer context following a three-stage empirical approach: characterising the case study, deploying the data integration and analytics architecture, and constructing and evaluating the operational baseline (Krishnan et al., 2024).

Case study apparatus: the monitored villa

The testbed is a detached residential villa situated in Segrate (Milan), Italy. It consists of three floors and has numerous sensors installed throughout (Fig. 1). Built in 1993, it falls under climatic zone E, with a heating season from 15 October to 15 April and 2404 degree days. The building envelope has been upgraded to comply with contemporary efficiency standards, with a calculated design heating load $Q_{H,des}$ of ~12.9 kW (approx. 44 W/m^2) according to its last Energy Performance Certificate (EPC). In the renovated sections, the transmittance of opaque envelope elements reaches values as low as 0.18 $W/(m^2K)$, reflecting a high level of thermal insulation. The net useful floor area is 291.5 m^2, spread across three levels (underground 105.8 m², ground floor 95.9 m^2, first floor 89.8 m^2). The heated gross volume is 1087 m^3, with a heat losing area/heated volume $S/V = 0.61\ m^{-1}$. In contrast to typical residential datasets that consider the building as a black box, this facility operates as a documented micro energy system with detailed information on both the building envelope and technical systems. A swimming pool and PV array complete the site (Fig. 2).

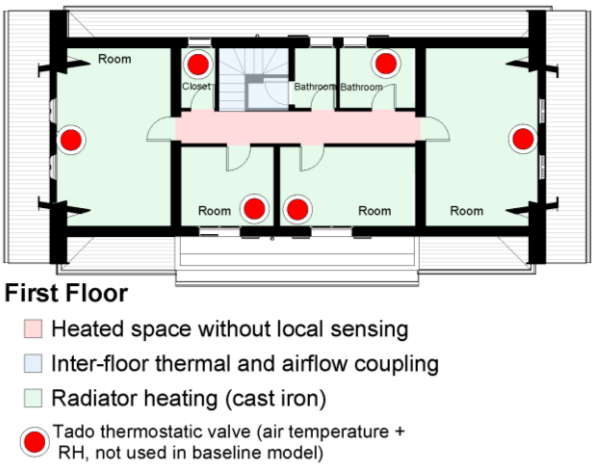


Figure 1. Villa floor plans

The outdoor swimming pool (approximately 50 m³) has a significant electrical load due to circulation and filtration. Ground-floor heating is provided by a 7-kW air-to-water heat pump with low-temperature hydronic underfloor heating, while the underground and first floors use a 23-kW condensing gas boiler with cast-iron radiators. The building also includes smart thermostatic control and a Zehnder ComfoAir Q heat-recovery ventilation unit.

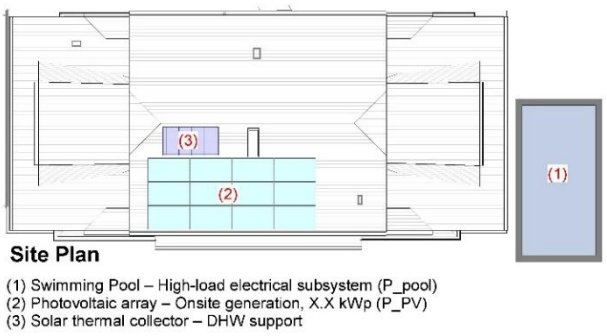

Figure 2. Villa site plan

Instrumentation consists of a heterogeneous IoT network including Shelly Pro 3EM energy meters, smart thermostats, and MVHR telemetry. The operational boundary is defined by four telemetry streams accessed through the *Home Assistant* platform: whole-villa electrical power *P_villa*, PV electrical power *P_PV*, pool circuit electrical power *P_pool*, and outdoor air temperature *T_outdoor*. Streams were retrieved as historical exports and processed in Python over a one-year period from 18 January 2025 to 18 January 2026, resampled to $\Delta t = 60$ minutes. Telemetry includes discontinuities and missing periods consistent with in-use residential operation, motivating explicit missing-data handling in the analytics pipeline.

Operation-phase digital twin architecture

Figure 3 shows the implemented architecture, in which Shelly and Zehnder sensors are integrated via the Home Assistant gateway and processed through a Python analytics pipeline. Sensor-to-subsystem association is maintained through a curated metadata configuration table that maps sensor identifiers to physical subsystems. The implemented architecture links the villa's IoT telemetry streams to a curated subsystem mapping within the analytics layer, enabling traceable association between sensor streams and operational building subsystems. This architecture supports traceable monitoring and baseline construction only; it does not implement bidirectional control, online actuation, or formal BIM-linked semantic integration.

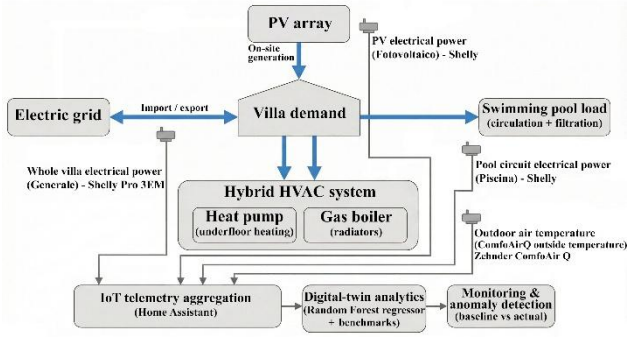

Figure 3. Energy system architecture and data pipeline integrating onsite generation, high-load subsystems, and hybrid HVAC operation with an IoT aggregation layer (Home Assistant) and a baseline-analytics module.

The data processing pipeline aligns asynchronous PV and whole-villa measurements to the nearest hourly timestamp, constructs datasets in multiple configurations based on feature availability (Table 1), imputes data using the noted missing-data policy, and generates engineered features to capture daily and seasonal patterns related to occupancy and solar exposure. For demand-only configurations, the feature set comprises the current demand reading, 1h, 24h, and 168h lags of demand, cyclic hour encodings (sine and cosine), day of week, month, weekend and public holiday indicators, a grid-export flag, and an imputation flag for the demand stream. For telemetry configurations, the feature set additionally includes the current readings and 1h, 24h, and 168h lags of P_PV, P_pool, and T_outdoor, together with per-stream imputation flags, yielding a feature vector of 28 variables for keep-imputed telemetry configurations and a reduced set for clean-only configurations where imputation flags are excluded.

The two missing data policies are as follows. For the first Ax series (causal imputation): missing values are imputed using only information available up to time t (bounded forward-fill plus signal-specific fallbacks):

$$\tilde{x}_t = x_t \quad (1)$$

if observed; otherwise

$$\tilde{x}_t = \tilde{x}_{t-1} \quad (2)$$

when the gap length $\leq H$, else

$$\tilde{x}_t = g(x,signal) \quad (3)$$

For example, PV approaches zero at night and the temperature was set based on an existing climate database. Signal-specific forward-fill bounds H were applied to each stream based on its physical rate of change. For P_villa, P_PV, and P_pool, H was set to 6 hours, reflecting the operational volatility of electrical signals where longer imputation would introduce implausible values. For T_outdoor, H was set to 24 hours, where temperature varies slowly enough that a longer fill window remains physically reasonable. Gaps exceeding these bounds fall back to the signal-specific default g(x, signal) defined in Eq. 3.

For the second Bx series (offline interpolation upper bound): for gaps up to 2 h, missing points are filled by linear interpolation between the nearest available samples x_a and x_b:

$$\tilde{x}_t = x_a + \frac{t-a}{b-a}(x_b - x_a) \quad (4)$$

with

$$b - a \leq 2 \text{ h} \quad (5)$$

Gap-filling and interpolation are applied separately within the training and test partitions to prevent test-period information from influencing the training data. In addition, both keep-imputed and clean-only data selection policies are considered to distinguish realistic deployment conditions from an upper performance bound.

Because interpolation uses both the past and the future endpoint within a gap, Bx represents an offline upper bound; Ax uses past-only information and therefore better approximates conditions where only information available up to time t is used (no future data).

Table 1: Data Treatments

Dataset	Imputation Pipeline	Missing Data Policy	Feature Set
A1	Pipeline A: causal-fill	Keep-imputed	Demand-only
A2	Pipeline A: causal-fill	Clean-only	Demand-only
A3	Pipeline A: causal-fill	Keep-imputed	Demand + telemetry
A4	Pipeline A: causal-fill	Clean-only	Demand + telemetry
B1	Pipeline B: time-based interpolation	Keep-imputed	Demand-only
B2	Pipeline B: time-based interpolation	Clean-only	Demand-only
B3	Pipeline B: time-based interpolation	Keep-imputed	Demand + telemetry
B4	Pipeline B: time-based interpolation	Clean-only	Demand + telemetry

The analytics layer accesses the processed feature vectors and constructs short-horizon operational energy baselines using a fixed Random Forest regressor (Krishnan et al., 2024).

Energy baseline prediction strategy

The analytics function seeks to develop a dynamic energy baseline model that estimates what the building's total consumption should be under current conditions based on historical behaviour. This is framed as a short-horizon baseline construction task (Krishnan et al., 2024). Let y_t denote the total electrical demand at time t. The baseline function f predicts the demand one hour ahead as:

$$\hat{y}_{t+1} = f(X_t) \quad (6)$$

Following the pipeline design, eight dataset configurations are constructed by combining feature availability (demand-only vs. demand augmented with PV, pool, and temperature telemetry), missing-data policy (keep-imputed vs. clean-only), and imputation strategy (Pipeline A: causal fill vs. Pipeline B: time-based interpolation). Imputation strategies are critical to ensure that missing data points or sensor errors do not introduce gaps that could adversely affect the predictive performance of the digital twin (Xie et al., 2023).

A data quality assessment of A1, the causal-fill, keep-imputed, demand-only dataset, indicates substantial operational missingness (e.g., demand missing/imputed 15.9%, PV missing 27.2%, and on-site temperature sensor missing 56.3%), leaving 38.4% fully clean rows; this motivates the explicit keep-imputed vs. clean-only policies and the imputation ablations.

These missingness rates should be understood as a property of an in-use residential monitoring environment rather than as a laboratory-grade sensing setup. In this case study, discontinuities are consistent with intermittent subsystem activity, telemetry or gateway interruptions, sensor outages, and periods in which parts of the monitoring pathway were unavailable. For the outdoor temperature stream specifically, the on-site sensor was

unreliable throughout the monitoring period, and the pipeline substituted values from a meteorological database where available; the reported 56.3% missingness rate reflects the combined proportion of rows where neither source provided a valid observation. For the PV stream, missingness appears as scattered individual hours consistent with intermittent gateway synchronisation rather than extended outage periods. This level of missingness is unusually high for a continuously monitored residential system, but it provides a challenging test of deployment-oriented baseline construction. From a deployment perspective, this means that a practically useful baseline cannot assume fully clean streams and must remain interpretable under missing and reconstructed observations. For this reason, missing-data handling is treated here as a first-order design variable rather than as a secondary preprocessing detail.

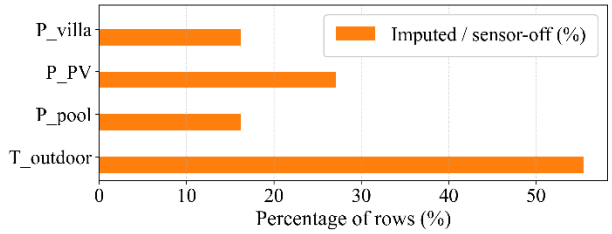

Figure 4. Missingness proxy by signal for dataset A3, expressed as the percentage of rows flagged as Imputed or sensor-off.

Pipeline A constitutes the primary deployable dataset family used for reporting results, while Pipeline B is included only as an offline upper-bound diagnostic that quantifies the performance cost of enforcing causal imputation under otherwise matched conditions; it is not presented as an independent contribution and its near-identical performance relative to Pipeline A is an expected and interpretable outcome rather than a redundancy. Data are split chronologically into 70% training and 30% testing to preserve temporal order and avoid look-ahead bias. To evaluate performance, we compare the Random Forest regressor against two benchmark models: (i) a naïve persistence model, which assumes that next-hour demand equals the current hour's demand (Eq. 7), and (ii) a Multiple Linear Regression (MLR) model trained on the same feature set to test whether simple linear relations are sufficient for short-horizon baselining.

$$\hat{y}_{t+1} = y_t \tag{7}$$

Together, these establish a minimum performance floor that must be exceeded to demonstrate predictive value (Zhou et al., 2024). A Random Forest regressor is used as a fixed learner to capture non-linear interactions between weather, prosumer subsystems, and temporal patterns (Krishnan et al., 2024). We keep the model class fixed (Random Forest) across all experiments to isolate dataset effects. Hyperparameters were tuned on training data only using *RandomizedSearchCV* with *30 iterations* and negative RMSE as the scoring metric, applied via *TimeSeriesSplit* with four folds to avoid look-ahead bias. The search space *covered n_estimators* in the range *300–1100*, *max_depth {None, 10, 20, 40, 60}*, *min_samples_split 2–30*, and *min_samples_leaf 1–20*. The resulting best hyperparameters were frozen per dataset configuration, and the test set was used only once for final evaluation.

Algorithm selection and validation

The Random Forest regressor is adopted as the primary learner because it can capture non-linear relationships in medium-sized tabular time-series data and remains robust with one year of operational observations. The learner is kept fixed across dataset variants to isolate the effect of dataset construction rather than algorithm choice. Feature importances are reported using impurity-based importance, defined as the normalized total reduction in split criterion across trees as implemented in scikit-learn (Pedregosa et al., 2011); these values should not be interpreted as equivalent to Pearson correlation. Performance is evaluated using Mean Absolute Error (MAE) and Root Mean Squared Error (RMSE). Tree-based ensembles are widely reported as strong baselines for tabular prediction under irregular target behaviour (Grinsztajn, Oyallon & Varoquaux, 2022).

Results

The Random Forest regressor was benchmarked against both persistence and MLR on the chronological test set, achieving an 8.4% RMSE reduction versus persistence (629.26 W → 576.50 W) and a 5.9% reduction versus MLR (612.0 W → 576.5 W) on A3. Feature importance analysis revealed that sub-metered PV and pool data were the most influential predictors. These findings demonstrate the practical utility of the monitored villa testbed and the proposed pipeline for short-horizon operational baselining in this residential prosumer case study.

Direct RMSE comparison across residential forecasting studies should be interpreted cautiously because buildings, climates, target ranges, horizons, and feature availability differ substantially; for this reason, the present study is positioned as a deployment-oriented case study rather than as a universal benchmark. The full one-year time series of all four input signals alongside whole-building demand is not shown here due to space constraints; signal quality, missingness patterns, and the operational range of each stream are characterised in the Methodology section and summarised in Fig. 4.

Fig. 5 presents the Pearson correlation heatmaps of the hourly processed datasets under causal fill, time-based interpolation, and clean-only selection, focusing on the relationships between subsystem telemetry and whole-villa electricity demand.

PV generation shows the strongest negative linear association with whole-building demand, which is expected because it reflects onsite generation rather than demand-side consumption. Outdoor temperature also shows a negative association consistent with seasonal heating behaviour. Pool-circuit power exhibits a weaker linear correlation, but this does not imply low predictive value because pool operation is intermittent and state-like rather than smoothly linear.

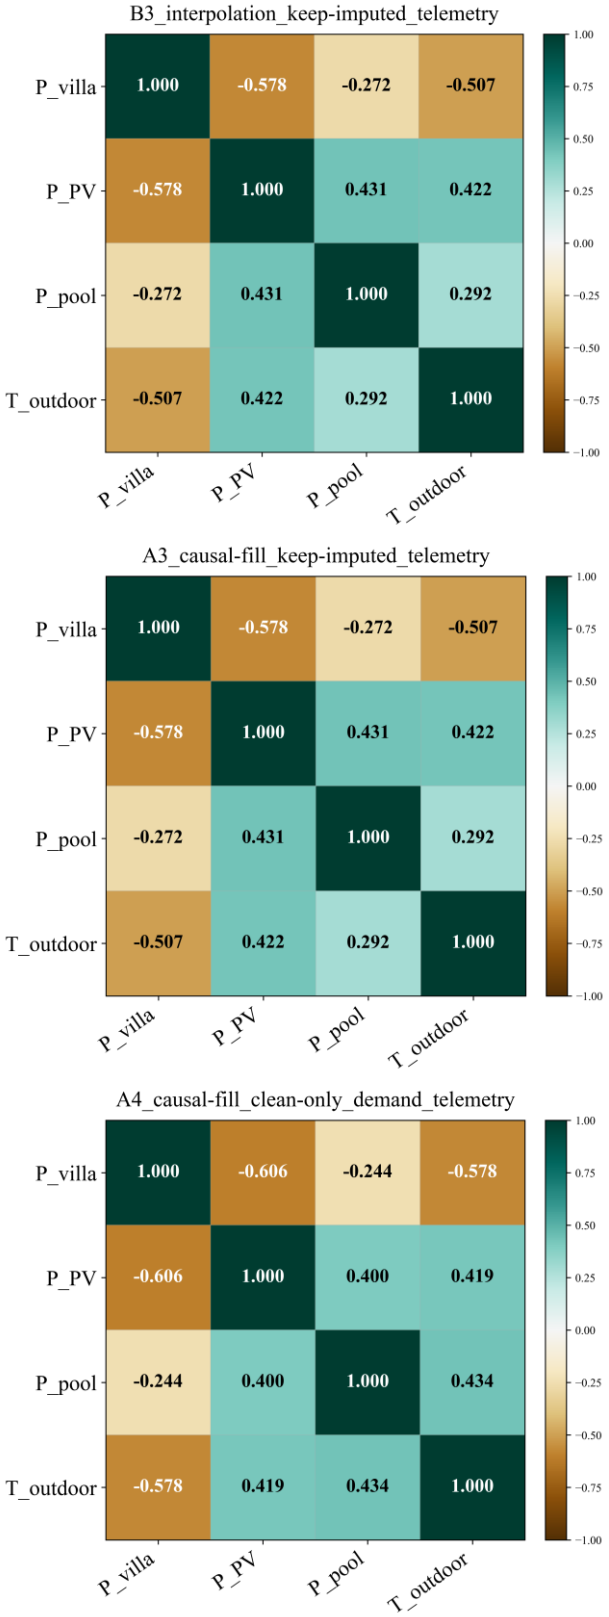

Figure 5. Pearson correlation heatmaps for selected processed datasets: B3 (top), A3 (middle), and A4 (bottom).

For this reason, feature-importance results and Pearson correlation should be interpreted as complementary rather than equivalent diagnostics. The near-identical correlation matrices for A3 and B3 are expected: in both configurations missing values are retained through imputation rather than removed, so the underlying observed data structure is identical and only the imputed segments differ; since these segments are small relative to the full dataset and consistent with the surrounding trend, the global linear association structure remains effectively unchanged. In contrast, the A4 and B4 configurations show noticeably different correlation values because clean-only filtering removes imputed rows and thereby alters the sample composition and temporal coverage. The maintained metadata mapping is used only to preserve subsystem traceability within the analytics layer. Correlation patterns are broadly similar across the compared datasets, while any differences introduced by clean-only filtering should be interpreted cautiously because dataset coverage and evaluated timestamps change across configurations.

Operational baseline model performance

Table 2 summarises model performance on the chronological test set (30% of the available data; 2529 samples for keep-imputed datasets) and reports Random Forest RMSE alongside those from the persistence and MLR benchmarks, showing that the datasets using the "Keep-imputed" data policy alongside "Demand + telemetry" features outperformed the others. Note that A4 and B4 have substantially lower usable hours than the other datasets, as reflected in the test-row counts reported in Tables 2 and 3, partially accounting for their decreased performance. This reduction in usable hours is not only a sample-size issue. Clean-only filtering also changes which operating regimes remain in the evaluated subset and therefore changes the task itself. In A4 and B4, the retained rows no longer represent the same full operational variability as the keep-imputed datasets. As a result, the predictive advantage of the richer feature set and the non-linear flexibility of Random Forest can be reduced, while a simpler model such as MLR may become comparatively more competitive on the filtered subset. This regime shift also accounts for the MAE results in Table 3, where RF underperforms MLR in A4 and B4; on a filtered subset with reduced operational variability, the non-linear flexibility of Random Forest provides no advantage over a linear model and the smaller sample size limits effective hyperparameter tuning. The eight configurations test three directional hypotheses embedded in the pipeline design. Keep-imputed configurations should outperform clean-only counterparts by preserving operational variability that filtering removes. Telemetry configurations should outperform demand-only configurations by providing subsystem-level predictive signal that demand history alone cannot capture. Pipeline A and B should converge under keep-imputed conditions because the imputation method has limited influence on the global data structure when imputed values are retained. Tables 2 and 3 confirm all three patterns.

Table 2: Summary of results – RMSE

Dataset	Test rows	RF RMSE (kW)	Persistence RMSE (kW)	MLR RMSE (kW)
A1	2529	0.597	0.629	0.634
A2	2118	0.652	0.681	0.655
A3	2529	**0.576**	0.629	0.612
A4	939	0.831	0.859	0.804
B1	2529	0.596	0.629	0.634
B2	2118	0.652	0.681	0.655
B3	2529	**0.573**	0.629	0.612
B4	939	0.831	0.859	0.804

We additionally report MAE (Table 3) to indicate typical behaviour error, while the RMSE values indicate the model sensitivity to extreme conditions.

Table 3: Summary of results – Mean Absolute Error

Dataset	Test rows	RF MAE (kW)	Persistence MAE (kW)	MLR MAE (kW)
A1	2529	0.366	0.378	0.426
A2	2118	0.431	0.440	0.473
A3	2529	**0.362**	0.378	0.409
A4	939	0.633	0.618	0.620
B1	2529	0.365	0.378	0.426
B2	2118	0.431	0.440	0.473
B3	2529	**0.361**	0.378	0.409
B4	939	0.633	0.618	0.620

The Random Forest regressor trained on A3 achieved MAE = 0.362 kW and RMSE = 0.576 kW, representing the best trade-off between accuracy and deployment realism among the tested configurations, since B3 achieves marginally lower error but relies on non-causal interpolation that is not available at deployment time. The building exhibits a skewed demand distribution with a median of 0.76 kW and a mean of 1.04 kW driven by occasional high-load and PV export events, making the RMSE of 0.576 kW a substantial fraction of typical instantaneous demand. This indicates that the baseline is suited to detecting large residual deviations consistent with equipment faults or sustained anomalous consumption but may not meet the accuracy requirements of fine-grained measurement and verification applications. In this paper, the baseline is intended as an operational reference for residual-based monitoring and measurement-oriented comparison, not as a full physical emulator of building behaviour. Its practical value lies in improving over persistence and MLR under leakage-safe and deployment-realistic conditions.

Adding telemetry (A3 vs A1) reduces RMSE by ~3.5%, while RF improves over persistence and MLR by 8.4% and 5.9%, respectively, quantifying the practical benefit of subsystem instrumentation under deployment-like constraints.

A3 and B3 show nearly identical results (RMSE ≤ 0.5%). The cost of enforcing deployable causality is therefore modest in this case study. Across all keep-imputed configurations, the Random Forest regressor outperforms the persistence benchmark, confirming predictive value beyond trivial extrapolation. Feature importance analysis ranks P_pool (32%), recent demand history (28%), P_PV (19%), and T_outdoor (12%) as the dominant explanatory variables, with temporal features making up the balance across all keep-imputed configurations. These rankings are consistent across all keep-imputed configurations; demand-only configurations assign full importance to demand history and temporal features by construction. The prominence of pool-circuit telemetry in impurity-based feature importance, despite its weaker Pearson correlation with demand, is plausible in this setting because the pool signal acts as a regime marker for intermittent switching behaviour and interacts non-linearly with other predictors. In other words, a feature can contribute strongly to tree-based prediction even when its standalone linear association with the target is modest. It should also be noted that impurity-based importance is known to inflate scores for intermittent or high-variance signals because such features create frequent and uneven splits across trees; the reported importance values should therefore be interpreted as indicative of predictive relevance within this specific Random Forest configuration rather than as absolute measures of physical influence.

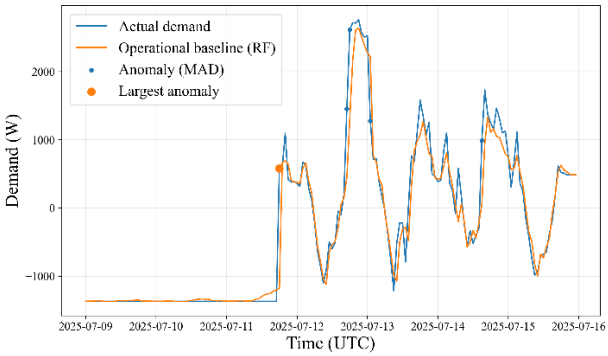

Figure 6. Sample week showing actual demand vs operational baseline (RF with A3 data configuration)

Fig. 6 illustrates a representative week of measured demand, and the one-hour-ahead operational baseline produced by the best-performing A3 configuration using Random Forest. The baseline reproduces daily structure and prosumer-specific effects such as PV self-consumption periods and pool-pump cycling. A prominent deviation is consistent with a documented circulation-pump fault due to voltage instability (resolved by installing a stabiliser in July 2025); such episodes are detected from the baseline residual using the MAD-based threshold defined in Eq. 9 and are flagged for separate post-hoc analysis. They are not removed from the test set used for RMSE and MAE

computation, and the current study does not implement an online retraining loop in which flagged anomalies are used to update the fitted baseline.

Anomalies are detected from the baseline residual rather than from raw demand. Let

$$r_{t+1} = y_{t+1} - \hat{y}_{t+1} \quad (8)$$

where y_{t+1} is the measured demand and $\hat{y}_{t+1}$ is the Random Forest baseline prediction. We compute the median residual $m = \text{median}(r)$ and $MAD = \text{median}(|\, r - m \,|)$, and flag time step $t + 1$ as anomalous if

$$|\, r_{t+1} - m \,| > K \cdot MAD \quad (9)$$

In this study we use $K = 9$, selected via a threshold sweep to reduce spurious detections during stable operation.

Conclusions

This study demonstrates that deployment-realistic missing-data handling and sub-metered subsystem telemetry are first-order determinants of operational baseline quality in residential prosumer buildings. The monitored villa testbed and the eight-configuration ablation show that imputation strategy and data policy shape predictive performance as much as feature selection, and that the cost of enforcing causal deployability is modest when imputed values are retained.

Key findings

Sub-metered subsystem telemetry, especially PV and pool-circuit power, improves predictive baselines when used within a controlled and leakage-safe dataset design. Baseline quality is strongly shaped by feature availability and missing-data policy rather than algorithm choice alone. Under keep-imputed causal conditions, A3 achieved the lowest deployable RMSE (0.576 kW). The A3 baseline residuals successfully flagged the documented circulation-pump fault in July 2025, confirming practical anomaly screening capability under in-use conditions.

Limitations and future work

Occupancy is not directly measured, so the current feature set relies on temporal proxies and may not distinguish between unoccupied and low-activity conditions. The present study is limited to monitoring and baseline construction on a single residential testbed. Accordingly, the current implementation remains an analytics-oriented operational representation rather than a closed-loop control system or a formally BIM-integrated workflow. Future work should validate the approach across multiple residential buildings, enrich behavioural and occupancy context, and extend the current offline pipeline toward continuous deployment, supervisory diagnostics, and optional richer semantic alignment were justified by the monitoring objective.

A DECENTRALIZED DIGITAL TWINNING APPROACH FOR ASSESSING CIVIL ENGINEERING STRUCTURES

Kosmas Dragos, Thamer Al-Zuriqat, and Kay Smarsly
Institute of Digital and Autonomous Technology, Hamburg University of Technology,
Blohmstraße 15, 21079 Hamburg, Germany

Abstract

In wireless structural health monitoring (SHM), the focus is usually placed on reducing the power-consuming data transmission for preserving the limited resources of wireless sensor nodes. In this direction, embedded computing has been leveraged for distributing SHM data analysis tasks to the sensor nodes instead of transmitting raw data to centralized servers. This paper reports on decentralizing SHM tasks using reduced-order numerical models of structures, embedded into wireless sensor nodes as decentralized digital twins that use sensor data to assess the structural condition. The applicability of the proposed approach is demonstrated via laboratory validation tests.

Introduction

The traction that wireless structural health monitoring (SHM) has been gaining in structural maintenance since the end of the 20th century has mainly been attributed to the drawbacks of cable-based technologies for SHM, in terms of labor installation and cabling (Çelebi, 2002). Notwithstanding the significant benefits of wireless technologies, non-negligible drawbacks have been recognized already from early wireless SHM approaches, related to low transmission reliability and limited power autonomy (Lynch and Loh, 2006). The recent growing trends towards digitalization, fostering state-of-the-art technological concepts, such as Internet-of-Things systems (Al-Zuriqat et al., 2025), has brought wireless SHM once again to the forefront, frequently placed within the framework of emerging computing paradigms, such as embedded systems design and edge computing (Buckley et al., 2021).

Considerable research effort has been invested in tackling the weakest point of wireless SHM systems: The reliance on batteries, which limits the power autonomy. In this direction, the main schools of thought have focused on either integrating hardware components capable of generating power or reducing in-network wireless transmission both among wireless sensor nodes and between wireless sensor nodes and centralized servers. The former school of thought promotes the installation of energy harvesters for converting energy from ambient sources (solar, wind) to power, or – in some cases – exploiting the very vibration of structures for charging wireless sensor nodes (Park et al., 2008). Nevertheless, energy harvesting does not impose fundamental changes in the design and operation of wireless SHM systems. The latter school of thought builds upon embedded (or edge) computing, which aims to convert wireless sensor nodes from mere data collection devices to quasi-independent platforms capable of autonomously executing SHM tasks (Dragos and Smarsly, 2015). In this context, embedded/edge computing effects a decisive change on the design of wireless SHM systems, as well as on the overall SHM strategies.

Embedded computing in wireless SHM has been studied extensively over the last three decades. Seminal work proving the superiority of embedded computing in SHM over centralized approaches, in terms of energy efficiency, dates back to the beginning of the millennium with the works of Mitchel et al. (2000), Spencer Jr. et al. (2003), Lynch et al. (2004) and Wang et al. (2007), paving the way for introducing a plethora of embedded computing approaches, mostly from 2008 onwards. Common ground among most embedded computing approaches has been the extraction of features from sensor data (e.g. structural response data or environmental data) indicative of a “system state” (essentially, structural condition), which enables either identifying structural parameters or detecting structural damage. Examples include the extraction and tracking of modal parameters, reported by Zimmerman et al. (2008), the estimation of the damage location vector, introduced by Nagayama et al. (2009), and the computation of the transmissibility function between mobile sensor nodes, presented by Yi et al. (2010). In recent work, Quqa et al. (2021) have applied embedded damage detection based on the interpolation error when approximating deflection shapes using smooth functions. Other approaches for extracting features from sensor data have been based on the random decrement method (Friedmann et al., 2010), auto-regressive modeling (Kijewski-Correa and Su, 2009), and on cable-force estimation (Spencer Jr. and Cho, 2011). A special class of embedded computing approaches for wireless SHM has centered around machine learning, employed for system identification (Peckens et al., 2011), damage detection (Avci et al., 2018) and for fault diagnosis in the time domain (Smarsly and Law, 2014), in the frequency domain (Dragos et al., 2016) and in the coupled time-frequency domain (Fritz et al., 2022). Finally, embedded computing has been leveraged for eliminating synchronization errors, as part of on-board estimation of modal parameters (Dragos et al., 2018).

The literature review on embedded computing for wireless SHM reveals a trend in adopting data-driven analysis methods for on-board computations. However informative, data-driven analysis methods exhibit inherently limited information potential, due to only implicitly considering the physics dominating the structural behavior. In other words, the outcomes of data-driven analysis methods are essentially mathematical quantities, whose physical meaning cannot always be guaranteed. In this context, this paper reports on an embedded computing approach aiming to render on-board analysis "physics-informed". In particular, drawing from the state-of-the-art paradigm of digital twinning, the proposed approach focuses on decentralizing digital twins in an attempt to enable wireless sensor nodes to conduct complex SHM tasks on board with enhanced decision-making capabilities. Preliminary work on employing physics-based modeling for embedded computing has been conducted by the authors (Dragos and Smarsly, 2017; Dragos and Smarsly, 2024). Capitalizing on the preliminary work, the decentralized digital twinning approach builds upon embedding physics-based models that are computationally manageable and amenable to independent analysis on each wireless sensor node. The proposed approach is validated in laboratory tests on a shear-frame structure, demonstrating the capabilities of the decentralized digital twins in identifying structural damage.

The remainder of the paper starts with a description of the decentralized digital twinning approach, followed by the implementation and the laboratory validation test. The paper ends with the summary and conclusions, as well as with a brief discussion on potential future research.

Decentralized digital twinning

The decentralized digital twinning approach is presented in this section. First, the two steps towards producing physics-based models suitable for embedment into wireless sensor nodes (model-order reduction and model segmentation) are illuminated. Next, the overview of the approach is described.

Model-order reduction

The limited computational resources of wireless sensor nodes render the embedment of physics-based models, frequently used in structural engineering (mostly, finite element models), prohibitive. In an attempt to alleviate the computational burden of finite element (FE) models, model-order reduction (MOR) is employed. In civil engineering, the reduction usually involves representing physical structures through features, capable of capturing the structural behavior. The features are estimated either by transforming elaborate FE models, e.g., from the physical domain to the modal domain (representing a physical structure via its modal parameters) or by transforming structural response data, collected from a physical structure, from the time domain to the frequency domain (representing the structural behavior in terms of dominant frequency components, instead of raw structural response data). However, most MOR methods are associated with transforms that result in reduced-order models hardly representable in physical-coordinate systems. Consequently, coupling such reduced-order models with structural response data, corresponding to degrees of freedom with physical coordinates, is challenging.

To tackle the aforementioned challenge, the decentralized digital twinning approach, presented in this paper, employs a MOR method that partially retains representability in physical coordinates. Specifically, the dynamic condensation method is applied, which has been widely used in case studies of component mode synthesis (Bathe and Dong, 2014). Considering a physical structure, represented by a FE model of N degrees of freedom, the starting point for the dynamic condensation is the formulation of the equation of motion as follows:

$$\mathbf{M}^{N\times N}\ddot{\mathbf{x}}^{N\times 1}(t)+\mathbf{C}^{N\times N}\dot{\mathbf{x}}^{N\times 1}(t)+\mathbf{K}^{N\times N}\mathbf{x}^{N\times 1}(t)=\mathbf{p}^{N\times 1}(t). \quad (1)$$

The quantities $\mathbf{M}$, $\mathbf{C}$ and $\mathbf{K}$, represent the mass, damping, and stiffness matrices, respectively. The vectors $\ddot{\mathbf{x}}$, $\dot{\mathbf{x}}$ and $\mathbf{x}$, hold the acceleration, velocity, and displacement response data, the variable t denotes time, and $\mathbf{p}$ is the load vector. The N degrees of freedom are partitioned into two sets, the "retained" (r set) and the "condensed" (c set) degrees of freedom. Since the goal of MOR is to produce reduced-order models intuitive for SHM, the r set contains degrees of freedom measured by the SHM system, and the c set contains the rest of the degrees of freedom of the FE model. Thereupon, each of the matrices $\mathbf{A}$ in Equation 1 (with $\mathbf{A}$ = {$\mathbf{M}$, $\mathbf{C}$, $\mathbf{K}$}) and each of the vectors $\mathbf{a}$ (with $\mathbf{a}$ = {$\ddot{\mathbf{x}}$, $\dot{\mathbf{x}}$, $\mathbf{x}$}) are rearranged as shown below:

$$\mathbf{A}=\left[\begin{array}{c|c}\mathbf{A}_{cc} & \mathbf{A}_{cr}\\ \hline \mathbf{A}_{rc} & \mathbf{A}_{rr}\end{array}\right] \quad \mathbf{a}=\left\{\begin{array}{c}\mathbf{a}_c\\ \hline \mathbf{a}_r\end{array}\right\}. \quad (2)$$

Next, the submatrices of the c set are used for computing (i) the static-constraint modes $\mathbf{\Psi}_{cr}=(-\mathbf{K}_{cc})^{-1}\mathbf{K}_{cr}\mathbf{I}_{rr}$ and (ii) the eigenmodes $\mathbf{\Phi}_{cv}=[\boldsymbol{\varphi}_{cj}]$ ($j=1...v$) of the eigenproblem $\mathbf{K}_{cc}\boldsymbol{\varphi}_{cj}=\lambda_j\mathbf{M}_{cc}\boldsymbol{\varphi}_{cj}$, which together form the following transformation matrix $\mathbf{\Psi}_r$:

$$\mathbf{\Psi}_r=\begin{bmatrix}\mathbf{\Phi}_{cv} & \mathbf{\Psi}_{cr}\\ \mathbf{0}_{rv} & \mathbf{I}_{rr}\end{bmatrix}. \quad (3)$$

Finally, the transformation matrix is used for computing the reduced-order $r\times r$ model matrices, $\mathbf{K}_{red}$ and $\mathbf{M}_{red}$, as shown in Equation 4.

$$\mathbf{K}_{red}=\mathbf{\Psi}_r^T\mathbf{K}\mathbf{\Psi}_r \qquad \mathbf{M}_{red}=\mathbf{\Psi}_r^T\mathbf{M}\mathbf{\Psi}_r \quad (4)$$

As regards the damping matrix, due to the generally low vibration excitation of typical SHM applications, the Rayleigh-damping approximation is adopted, which is frequently applied in civil engineering. As a result, the damping matrix is considered proportional to the stiffness matrix ($\mathbf{C}_{red}=\beta\mathbf{K}_{red}$) with β representing the Rayleigh coefficient. Proportionality with the mass matrix, also applied in civil engineering, is not considered, in this case, for simplicity. Upon completing MOR, the reduced-order model is segmented to enable its use on board the wireless sensor nodes, as will be shown in the next subsection.

Model segmentation

The dynamic condensation produces matrices of the following layout:

$$\mathbf{M}_{red} = \left[\begin{array}{c|c} \mathbf{M}_{rr} & \mathbf{M}_{rv} \\ \hline \mathbf{M}_{vr} & \mathbf{I}_{vv} \end{array}\right], \quad \mathbf{K}_{red} = \left[\begin{array}{c|c} \mathbf{K}_{rr} & \mathbf{0}_{rv} \\ \hline \mathbf{0}_{vr} & \mathbf{\Lambda}_{vv} \end{array}\right]. \quad (5)$$

In Equation 5, $\mathbf{I}$ is the unitary matrix, $\mathbf{0}$ is a zero matrix, and $\mathbf{\Lambda}$ is a diagonal matrix holding the v eigenvalues from the eigenproblem, previously shown. Moreover, the vectors assume the form $\mathbf{x}_{red} = [\mathbf{x}_c, \mathbf{q}_v]^T$, where $\mathbf{q}$ is the vector of the generalized coordinates, corresponding to the v eigenvalues. By substituting the matrices and vectors of the reduced-order model into Equation 1 and by recasting the matrix-form equation as a set of two equations, the following formulation is obtained:

$$\begin{aligned} &\mathbf{M}_{rr}\ddot{\mathbf{x}}_r + \mathbf{M}_{rv}\ddot{\mathbf{q}}_v + \mathbf{K}_{rr}\left(\mathbf{x}_r + \beta\dot{\mathbf{x}}_r\right) = \mathbf{p}_r \\ &\mathbf{M}_{vr}\ddot{\mathbf{x}}_r + \ddot{\mathbf{q}}_v + \mathbf{\Lambda}_{vv}\left(\mathbf{q}_v + \beta\dot{\mathbf{q}}_v\right) = \mathbf{p}_v \end{aligned} \quad (6)$$

Since the top equation contains structural response data from the r set of degrees of freedom, this equation forms the basis for the rest of the computations. The first step towards model segmentation involves eliminating terms from the equation that are unknown. For example, in typical vibration-based SHM practices, acceleration response data is collected, while measuring velocities and displacements is relatively rare. Furthermore, estimating velocities and displacements via double integration is hardly accurate, due to the inevitable contamination of acceleration response data with noise and measurement errors. To remove the "unknown" velocities and displacements, the top part of Equation 6 is transformed into the frequency domain via the fast Fourier transform (FFT):

$$\mathbf{M}_{rr}\ddot{\mathbf{X}}_r + \mathbf{M}_{rv}\ddot{\mathbf{Q}}_v + \mathbf{K}_{rr}\left(\mathbf{X}_r + \beta\dot{\mathbf{X}}_r\right) = \mathbf{P}_r. \quad (6)$$

The FFT representations of acceleration, velocity and displacement response data are denoted as $\ddot{\mathbf{X}}$, $\dot{\mathbf{X}}$, and $\mathbf{X}$, respectively. The following equivalences between the FFT representations for each frequency component f, with respect to the natural frequency ω ($\omega = 2\pi f$), are considered:

$$\dot{\mathbf{X}}_r = \frac{\ddot{\mathbf{X}}_r}{\omega \mathrm{i}} + \varepsilon_1, \qquad \mathbf{X}_r = -\frac{\ddot{\mathbf{X}}_r}{\omega^2} + \varepsilon_2. \quad (7)$$

In Equation 7, ε_1 and ε_2 are error functions of the natural frequency, accounting for the inaccuracies stemming from the approximative character of the FFT and the effects of incomplete sampling, spectral leakage, and noise. Using Equation 7, Equation 6 is converted as follows:

$$\left[\mathbf{M}_{rr} + \left(\frac{\beta}{\omega \mathrm{i}} - \frac{1}{\omega^2}\right)\mathbf{K}_{rr}\right]\ddot{\mathbf{X}}_r = \mathbf{P}_r. \quad (8)$$

Representing an extension to the approach presented in Dragos and Smarsly (2024), MOR in this paper is applied in a pair-wise manner, i.e. in pairs of degrees of freedom, corresponding to locations measured by the SHM system, designating a "master" (w) and a "slave" (o) degree of freedom (DOF) in each pair (r = 2). The purpose of applying pair-wise MOR is to produce reduced-order models as lightweight as possible, while minimizing in-network communication. In fact, each reduced-order model is designed to be embedded into the wireless sensor node measuring the master DOF, and use the model with locally collected acceleration response data, as well as with data collected from the slave-DOF (typically, neighboring) sensor node. As a result, the matrices $\mathbf{M}_{rr}$ and $\mathbf{K}_{rr}$ are 2×2 with the layout shown below:

$$\mathbf{M}_{rr} = \left[\begin{array}{c|c} m_{ww} & m_{wo} \\ \hline m_{ow} & m_{oo} \end{array}\right], \quad \mathbf{K}_{rr} = \left[\begin{array}{c|c} k_{ww} & k_{wo} \\ \hline k_{ow} & k_{oo} \end{array}\right]. \quad (9)$$

By substituting the expressions of Equation 9 into Equation 6, and by performing some mathematical manipulations, the top part of the 2×2 matrix-form equation of motion assumes the following form:

$$\begin{aligned} &a_{ww} \cdot \ddot{X}_w + a_{wo} \cdot \ddot{X}_o = h_w \\ &a_{ij} = \left[m_{ij} + \left(\frac{\beta}{\omega \mathrm{i}} - \frac{1}{\omega^2}\right)k_{ij}\right]. \end{aligned} \quad (10)$$

In Equation 10, h_w denotes an error term, including the quantities: $h_w = P_w - (\mathbf{m}_{wv})^T\,\ddot{\mathbf{Q}}_v - (\beta\varepsilon_1 + \varepsilon_2)\cdot(k_{ww} + k_{wo})$. Each wireless sensor node is assigned the task to use the reduced-order model and locally collected acceleration response data $\ddot{X}_w$ to estimate the slave-DOF acceleration response data ($\ddot{X}_o$), by solving Equation 10 as:

$$\ddot{X}_o = \frac{h_w - \left[m_{ww} + \left(\frac{\beta}{\omega \mathrm{i}} - \frac{1}{\omega^2}\right)k_{ww}\right]\cdot \ddot{X}_w}{\left[m_{wo} + \left(\frac{\beta}{\omega \mathrm{i}} - \frac{1}{\omega^2}\right)k_{wo}\right]}. \quad (11)$$

Equation 11 represents a "segmented" reduced-order model, capable of being implemented into an independently operating wireless sensor node.

Following up on the previous discussion, the decentralized digital twinning approach is summarized in Figure 1. The starting point for applying the approach on each wireless sensor node involves the formulation, calibration and dynamic condensation (to master-slave DOF pairs) of a FE model representing the initial condition of the structure being monitored ("undamaged" structure). The calibration is achieved using preliminary acceleration response data from all degrees of freedom measured and by applying FE model updating. Then, a family of L FE model variants, corresponding to damage scenarios, are created by perturbing a set of structural parameters $\boldsymbol{\theta}$ and reduced, following the same condensation as in the undamaged structure. Finally, using newly collected acceleration response data, Equation 11 is applied for several FE model variants.

The error term h_w in Equation 11 is generally unknown, hindering the estimation of the slave-DOF responses. To overcome the computation difficulty, the term h_w is assumed to be random Gaussian, the acceleration response data is segmented into n time windows, and Equation 11 is applied to each time window separately to statistically limit the effect of the term h_w. As a result, a vector of slave-DOF response estimates is obtained

$\tilde{\mathbf{X}}_o = [\tilde{X}_{o1}, \tilde{X}_{o2}, ..., \tilde{X}_{on}]^T$ deviating from the respective acceleration response data $\ddot{\mathbf{X}}_o = [\ddot{X}_{o1}, \ddot{X}_{o2},..., \ddot{X}_{on}]^T$ by the error terms $\mathbf{h}_w = [h_{w1}, h_{w2},...,h_{wn}]$. The fitness of each model variant is determined upon the proximity between the vector $\tilde{\mathbf{X}}_o$ to the vector $\ddot{\mathbf{X}}_o$, computed by the coefficient of determination R^2, shown below, summed over a range Ω of frequency components, separately for the real and imaginary parts of the complex-valued $\tilde{\mathbf{X}}_o$ and $\ddot{\mathbf{X}}_o$:

$$R^2 = 1 - \frac{\sum_{j=1}^{n}\left(\ddot{X}_o - \tilde{X}_o\right)^2}{\sum_{j=1}^{n}\left(\ddot{X}_o - \bar{X}_o\right)^2}. \qquad (12)$$

In Equation 12, $\bar{X}_o$ is the mean slave-DOF response from the vector $\ddot{\mathbf{X}}_o$. The decentralized digital twinning approach is implemented in a prototype wireless SHM system and validated in a laboratory test, presented in the next section.

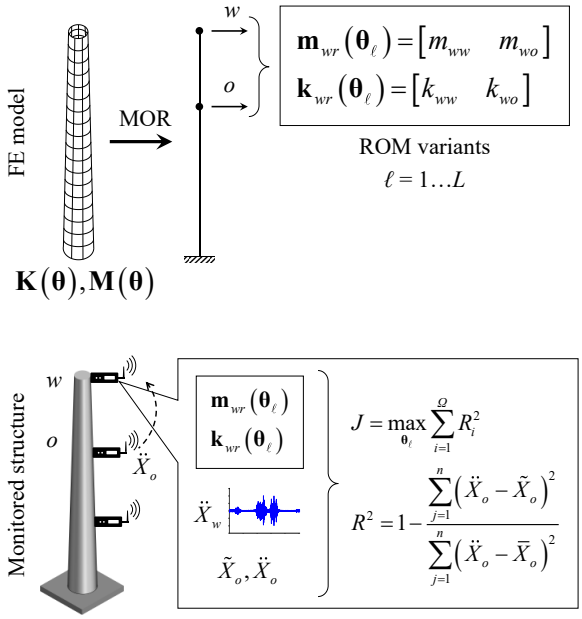

Figure 1: Overview of the decentralized digital twinning approach.

Implementation and validation

The prototypical implementation of the decentralized digital twinning approach involves the design of a relatively simple wireless SHM system, equipped with embedded physics-based models. In this section, first, the implementation details are illuminated, with emphasis on the software designed for the microcontrollers of the wireless sensor nodes. Thereupon, a small-scale laboratory test is presented, serving as proof of concept of the capability of the embedded physics-based models in identifying the structural condition.

Implementation in a prototype wireless SHM system

A key benefit of the decentralized digital twinning approach is the application of MOR in pairs of degrees of freedom, which allows a relatively minimal SHM system design, in terms of hardware. In fact, the proposed approach can be implemented even in SHM systems comprising only two wireless sensor nodes, one base station and one on-site computer (functioning as a server), as shown in Figure 2. The role of the base station and the on-site computer is secondary: The on-site computer is used for SHM system management (e.g. initialization, coordination) and data storage, and the base station acts as gateway node, enabling communication between the on-site computer and the wireless sensor nodes. Nevertheless, the wireless sensor nodes operate in a quasi-independent fashion, and the communication with the on-site computer is only performed when needed for system management and for transmitting data including results of the on-board computations for storage.

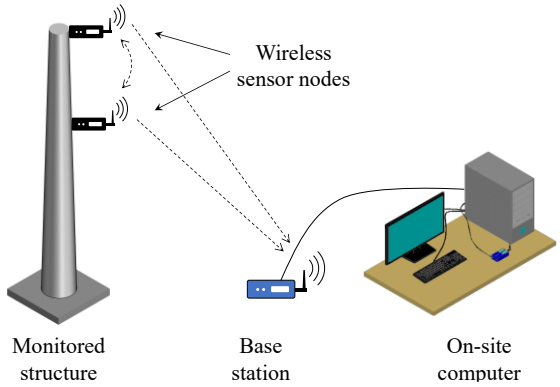

Figure 2: Layout of the prototype wireless structural health monitoring system.

Regarding the software implementation, embedded software for applying Equations 11 and 12 on board the wireless sensor nodes is exemplarily written in the Java programming language. The complexity of the software architecture is kept deliberately low to (i) preserve the limited computational resources of the sensor nodes and (ii) to facilitate the reproducibility of the code in other programming languages. An extract of the embedded software is shown in Figure 3.

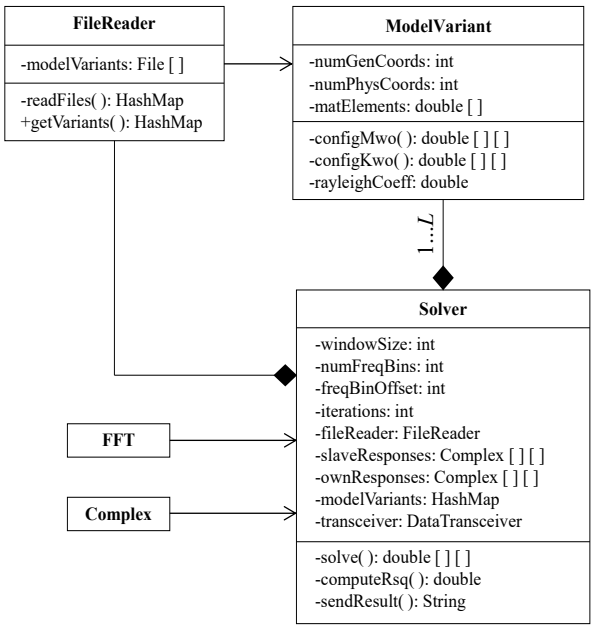

Figure 3: Extract of the embedded software.

The class `ModelVariant` realizes every reduced-order model variant, representing a damage scenario, the specifications of which are read as input streams by the `FileReader` class. Upon retrieving the responses $\ddot{\mathbf{X}}_w$ (`ownResponses` attribute) and the slave-DOF acceleration response data $\ddot{\mathbf{X}}_o$, the class `Solver` computes the estimates $\tilde{\mathbf{X}}_o$, using the method "`solve`" and the coefficient of determination for each model variant using the method "`computeRsq`". The outcome of the `Solver` class is communicated to the base station by invoking the method "`sendResult`". Finally, the FFT transform and the mathematical operations involving complex numbers are handled by the helper classes `FFT` and `Complex`, respectively. The prototype wireless SHM system is validated in a laboratory test, shown in the next subsection.

Validation test

The laboratory structure used for the validation test is shown in Figure 4. A 3-story shear-frame structure is employed, consisting of high-density-fiber (HDF) plates supported by aluminum columns. The density of the materials is assumed equal to 0.634 t/m^3 for the HDF and 2.70 t/m^3 for the aluminum, respectively. The elastic moduli are assumed equal to 3 MPa for the HDF and 70 MPa for the aluminum. Plate-to-column connections are fixed using two M3 screws per column. The dimensions of each plate are 300×200 (mm) (length × width) with a thickness of 18 mm and vertical inter-story spacing of 245 mm. The nominal cross-section dimensions of the columns are equal to 20×1.8 (mm) (width × thickness); however, the thickness of the columns is selected as "uncertain parameter" with high sensitivity and is used for calibrating the FE model. The column thicknesses, computed via model updating and used for MOR, are t_{z1} = 1.64 mm, t_{z2} = 1.79 mm and t_{z3} = 1.88 mm, for the first, second, and third story, respectively. At the base, the shear-frame structure is fixed on a 20-mm thick steel plate, which secures adequate clamping.

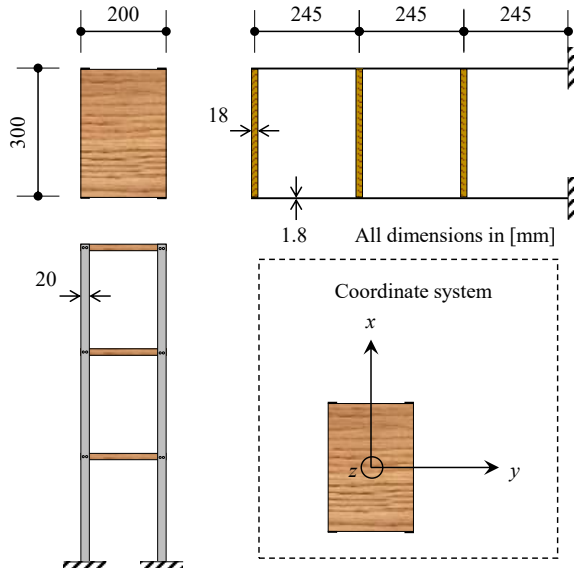

Figure 4: Laboratory shear-frame structure.

Two wireless sensor nodes are placed on the structure of type Oracle SunSPOT (Oracle Corp., 2010), featuring Java-based microcontrollers that enable the straightforward embedment of user-defined code. The software, presented in the previous subsection is embedded in the wireless sensor nodes, which are equipped with 3-axial accelerometers, capable of collecting acceleration response data at a sampling rate of 125 Hz, digitized with 8-bit resolution for a measurement range of ±2g. Despite the user-friendly interface of the SunSPOT wireless sensor nodes for embedding software, preliminary tests have revealed measurement inaccuracies, due to the low resolution of the accelerometer and the relatively high noise floor. To overcome the measurement inaccuracies, while leveraging the embedment capabilities of the SunSPOT sensor nodes, external measurement datasets are collected for each test case using high-accuracy wireless sensor nodes of type Lord Microstrain G-Link-200 (Parker Hannifin Microstrain Sensing, 2020). The external measurement datasets are subsequently deployed to the SunSPOT sensor nodes and used for applying the decentralized digital twinning approach.

The two wireless sensor nodes are placed on the first and second story, respectively, i.e. at heights of z_1 = 245 mm and z_2 = 450 mm. The sampling rate for the external measurement datasets is set equal to f_s = 128 Hz, and the measurement duration is 300 s for each test case. A window size of 2048 measurements is selected, resulting in n = 36 time windows with 50% overlap. Three test cases are considered: (i) undamaged ("intact") structure, (ii) minor damage, and (iii) major damage. For inflicting damage on the structure, the screws at the base of one column are loosened (one screw for "minor" damage and both screws for "major" damage). A family of L = 9 FE model variants are considered, including one FE model for the undamaged structure and 8 FE model variants, representing 4 different levels of damage per story for the bottom two stories. It should be noted that damage scenarios at the top story are not considered in this study, due to the negligible effect of top-story stiffness changes on the MOR of the FE model to the degrees of freedom of the bottom two stories. Following typical assumptions for shear-frame structure, the laboratory structure is modeled as a multi-DOF oscillator with one translational DOF per story in the x-axis direction. The translation in the y-axis direction is neglected due to the relatively high stiffness. Damage is simulated as stiffness reduction factors (0.9, 0.8, 0.7, 0.6) multiplied by the collective story stiffness ($4 \cdot k_c$, where k_c is the column stiffness). For selecting the range Ω of frequency components, the highest peaks in the FFT amplitude spectrum are located in each set of external measurements, and an offset of ±1 Hz is considered around each peak. The FFT amplitude spectra for the test cases (i) and (iii) are exemplarily illustrated in Figures 5 and 6. As can be seen in the FFT amplitude spectra, the effect of damage is relatively small in the second and third peak, leading to the conclusion that extending the range to include these peaks may be hardly sensitive to the damage scenario considered and are, therefore, excluded from Ω. All test cases are conducted by hammer-induced excitation. The results are summarized in Table 1.

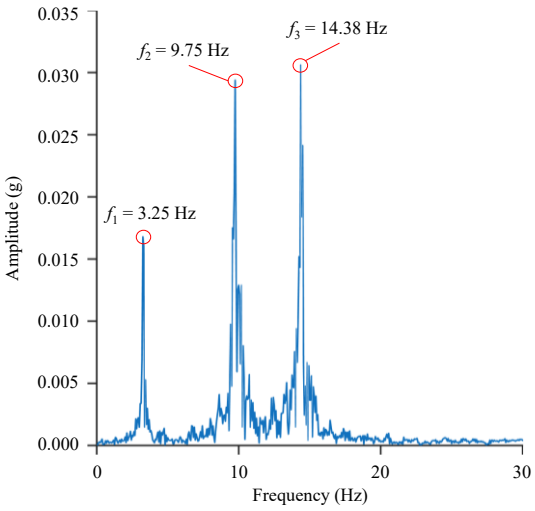

Figure 5: FFT amplitude spectrum for test case (i) (intact structure).

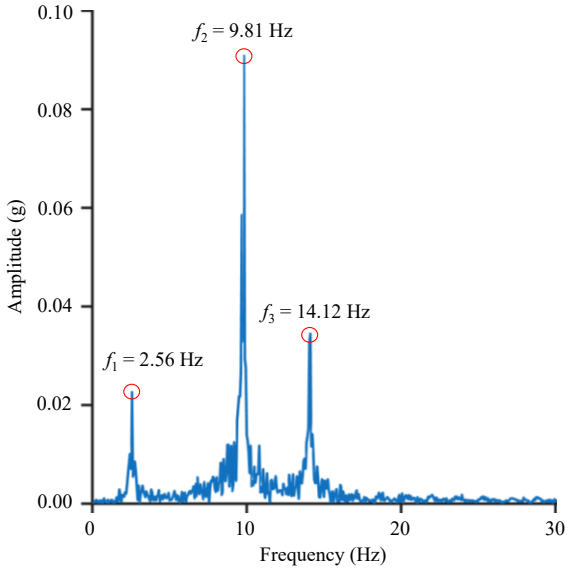

Figure 6: FFT amplitude spectrum for test case (iii) (major damage).

Table 1: $\sum R^2$ for all test cases and all model variants.

Model variant	Stiffness reduction factor	Test case		
		(i)	(ii)	(iii)
Intact	N/A	**58.86**	56.33	53.00
Damage on 1st story	0.9	58.67	56.79	54.71
	0.8	58.20	**56.91**	55.96
	0.7	57.46	56.69	56.77
	0.6	56.43	56.12	**57.13**
Damage on 2nd story	0.9	58.77	55.63	51.27
	0.8	58.37	54.41	48.64
	0.7	57.37	52.27	44.53
	0.6	55.23	48.40	37.75

The test results clearly show that the decentralized digital twinning approach yields the fittest model variant most compatible with the test case considered. In test case (i), the "intact" model variant receives the highest R^2 value, although the proximity with model variants representing minor damage is close, indicating the sensitivity of the approach to measurement inaccuracies. The fittest model variant for test case (ii) is the model with reduction factor 0.8 at the first story, which is expected, since the damage inflicted is minor. By contrast, the fitness of the significant-damage model variant with reduction factor 0.6 is prominent in test case (iii), where damage is indeed major. Nevertheless, the applicability of the decentralized digital twinning approach needs to be investigated in large-scale experiments, which will be covered in future work.

Summary and conclusions

Embedded computing has been employed in wireless structural health monitoring as a means of reducing the power-consuming transmission of large sets of structural response data. However, most embedded computing approaches rely on data-driven analysis, which yields limited information on the structural condition, due to the implicit consideration of the physics dominating the structural behavior. This paper has reported on embedding physics-based models for conducting SHM tasks directly on wireless sensor nodes, realized as decentralized digital twins. The proposed decentralized digital twinning approach relies on model-order reduction (to render the physics-based models – in practice, finite element models – computationally manageable by the sensor nodes) and model segmentation (to enable wireless sensor nodes to use the models quasi-independently). The decentralized digital twinning approach has been implemented in a prototype wireless SHM system and validated in a small-scale laboratory test, serving as proof of concept for the capability of the approach to correctly identify structural damage. Future work will focus on investigating the applicability limits of the decentralized digital twinning approach, via large-scale tests on real-world structures.

DEEP LEARNING AND REALITY CAPTURE FOR AUTOMATED RAILWAY BRIDGE INSPECTION WITH BIM ENRICHMENT

Rafael Cabral[1,2], Ricardo Santos[1,2], Diogo Ribeiro[1,2]
[1] iBuilt, School of Engineering, Polytechnic of Porto, Portugal
[2] CONSTRUCT, Faculty of Engineering, University of Porto, Porto, Portugal

Abstract

Manual inspection remains subjective and poorly integrated with digital workflows. Although computer vision enables automated damage detection, most approaches fail to translate observations into parametric Building Information Modelling (BIM). For bridges, this limitation persists within Bridge Information Modelling (BrIM), where geometry, semantics, and lifecycle information must align. This paper addresses the gap through a four-stage framework: optimal reality modelling, hybrid damage perception, automated Scan-to-BIM, and semantic enrichment via IFC objects. Validated on operational railway bridges, the method achieves a damage-detection mAP50 of 0.621 and geometric deviations under 23 mm, enabling BrIM generation directly from visual data.

Introduction

Railway bridges are critical infrastructure assets whose safety and serviceability depend on regular condition assessment. This requirement is becoming increasingly pressing as the European railway network ages; currently, more than 35% of railway bridges in the European Union are over 100 years old, with many approaching the end of their design service life (Tomor, 2013). Current inspection practice relies predominantly on manual visual surveys, which are inherently subjective, difficult to reproduce, and constrained by access, safety, and time limitations. Large-scale studies have demonstrated substantial inter-inspector variability in condition ratings, directly affecting the reliability of bridge management systems (BMS) and long-term maintenance planning (Moore et al., 2001).

To address these limitations, recent progress in reality capture technologies, specifically Unmanned Aerial Vehicles (UAVs), Terrestrial Laser Scanning (TLS), and Mobile Laser Scanning (MLS), has enabled the rapid acquisition of high-resolution geometric and visual data (Rakoczy et al., 2025, Olaszek et al., 2024). In parallel, deep learning techniques have achieved remarkable performance in detecting and segmenting structural damage from imagery (Ribeiro et al., 2025). However, a significant discontinuity remains between detection and digitalization.

Recent reviews on Digital Twin implementation (Nichols et al., 2025) indicate that while visual data is abundant, it is rarely used to update the engineering models serving as basis for structural analysis. Most inspection pipelines end at the level of 2D images or unstructured point clouds, failing to translate perception results into structured, parametric, and computable Building Information Modelling (BIM) representations (Yang et al., 2025). Within the bridge domain, this paradigm is referred to as Bridge Information Modelling (BrIM), extending BIM principles to infrastructure assets. This gap limits BrIM adoption for automated Operation and Maintenance (O&M), as current Scan-to-BIM approaches struggle to generalize across complex typologies without substantial manual intervention (Patil and Kalantari, 2025).

Unlike prior works that focus on isolated tasks, this work presents an end-to-end methodology for generating "as-damaged" BIM models directly from multimodal reality capture data. The framework is validated by a reinforced concrete railway bridge study located in Porto, Portugal.

Related works

Bridge inspection has traditionally relied on manual visual surveys that are time-consuming, subjective, and difficult to standardize (Kruachottikul et al., 2021). Recent research focuses on using reality capture, deep learning, and BIM/BrIM to improve efficiency and data quality along different parts of the inspection workflow.

UAV photogrammetry and terrestrial laser scanning (TLS) are widely used to generate accurate 3D as-is models of bridges, often by combining multiple sensors to overcome occlusions and access limitations (Mirzazade et al., 2023). For railway bridges, multimodal TLS–UAV fusion -has been applied to create precise 3D as-is models and compare them to as-designed models for geometric deviation assessment (Cabral et al., 2023). Other studies use 3D point clouds for automatic bridge component recognition to support Scan-to-BIM of existing bridges (Xu et al., 2026).

Numerous works propose CNN-based systems to detect, segment, and classify multiple defect types in bridge images, including cracks, corrosion, rust, spalling, and other surface damage . Advanced networks such as BridgeNet for multiclass damage segmentation (Huang et al., 2024), BGInet for bi-task bolt and rust detection from UAV imagery (Xu et al., 2025), and attention-enhanced YOLO variants for RC bridges (Ruggieri et al., 2025) achieve high detection accuracy and real-time

performance. Several frameworks also address defect quantification, for example mapping image pixels to real-world dimensions or using orthophotos for crack measurements (Xu et al., 2025, Ayele et al., 2020).

A growing body of work links inspection data with BIM or digital twins to support asset management. Some studies integrate corrosion or surface defect measurements into BIM models to manage long-span or RC bridges more efficiently (Hattori et al., 2024, Cavieres-Lagos et al., 2024). Others develop BIM-based mixed-reality tools that overlay inspection information on 3D models to support on-site or remote bridge inspection and maintenance (Riedlinger et al., 2022, Zakaria et al., 2023).

A smaller set of studies tackles partial automation from vision-based damage detection to 3D localization and BIM linkage. Methods combining deep learning with Structure-from-Motion or reality capture integrate defect detections into 3D bridge models, reducing variability between images and enabling spatial recording of damage (Yamane et al., 2023). However, these workflows typically address either geometry reconstruction and component labelling (Kim et al., 2020) or damage detection and 3D localization (Yamane et al., 2024), rather than delivering a fully integrated, as-damaged BrIM that unifies multimodal capture, automated perception, Scan-to-BrIM, and semantic enrichment in a single, railway-bridge-specific framework.

Methodology

The proposed framework establishes a computational pipeline that connects raw sensor data to semantic BrIM models. As illustrated in *Figure 1*, the architecture is composed of four sequential modules: i) Optimal Reality Modelling; ii) Hybrid Damage Perception; iii) Automated Scan-to-BIM; and iv) Semantic BIM Enrichment via ray-casting and parametric object instantiation.

Optimal reality modelling

The first stage aims to generate high-fidelity 3D reality models suitable for geometric inference. Railway bridge environments are characterized by complex backgrounds, e.g. vegetation, catenary systems, and varying terrain, which introduce significant noise into both photogrammetric and LiDAR datasets.

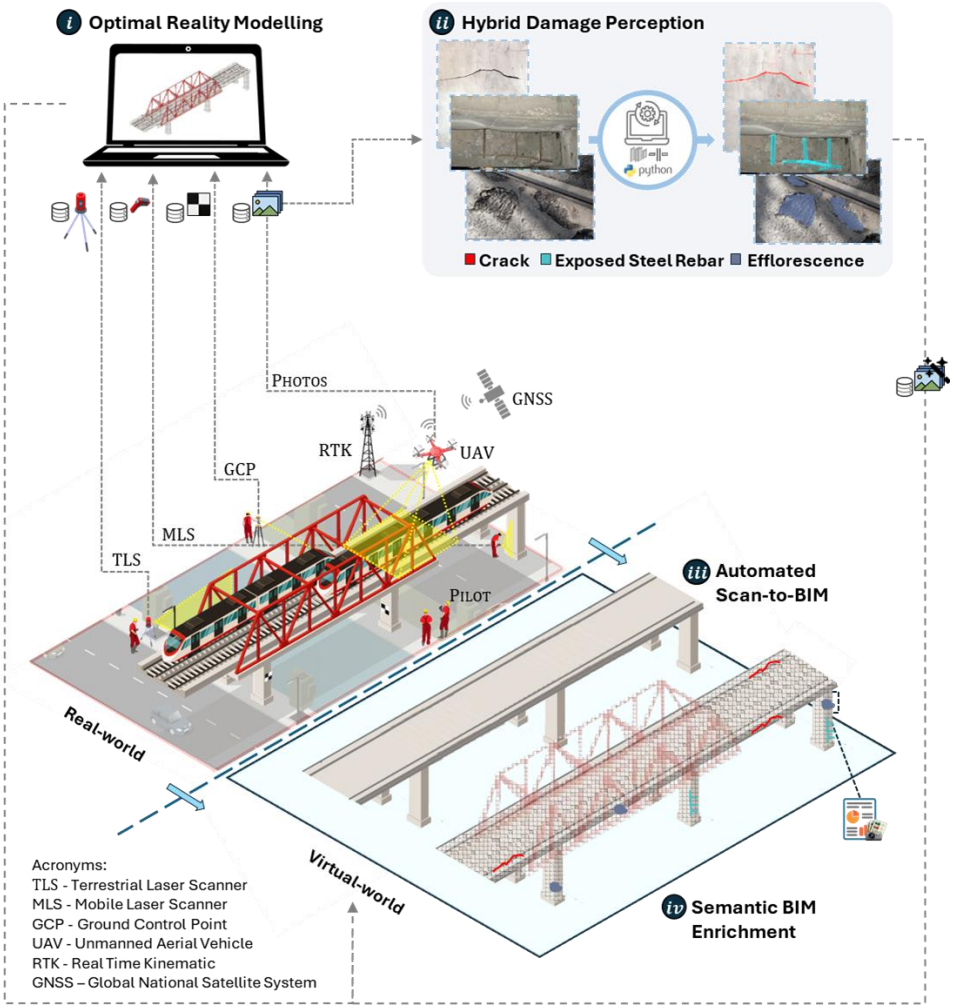

Figure 1: Overview of the proposed end-to-end framework, illustrating the four sequential stages: i) Optimal reality modelling, ii) hybrid damage perception, iii) Automated Scan-to-BrIM, and iv) semantic enrichment.

\

To mitigate these artefacts, a multi-modal fusion strategy was adopted that integrates background-aware filtering prior to reconstruction, illustrated in *Figure 2* (Cabral et al., 2025b). For photogrammetric data, a semantic segmentation network S processes each raw image $I \in R^{H\times W\times 3}$, generating a binary mask M where structural pixels are preserved ($M_{i,j} = 1$) and background pixels are suppressed ($M_{i,j} = 0$). This ensures that the subsequent Structure-from-Motion (SfM) pipeline reconstructs only relevant structural geometry. Simultaneously, LiDAR point clouds acquired via TLS or MLS undergo heuristic filtering based on multi-source geometric proximity (Cloud-to-Cloud distance).

Following data fusion, a Voxel Grid Filtering strategy addresses the non-uniform point densities inherent to multi-sensor capture. The 3D space is discretized into volumetric elements (voxels) V of dimension δ (e.g., 0.01 m). For a set of points $P = \{p_1, p_2, \dots, p_n\}$ within a voxel V_k, the retained point centroid $p_{centroid}$ is computed in Equation (1).

$$p_{centroid} = \frac{1}{N_k}\sum_{i=1}^{N_k} p_i \quad (1)$$

where N_k is the number of points in voxel V_k. This downsampling preserves the underlying geometric topology while normalizing density, ensuring computational tractability for the subsequent deep learning stages without compromising the geometric fidelity required for defect quantification.

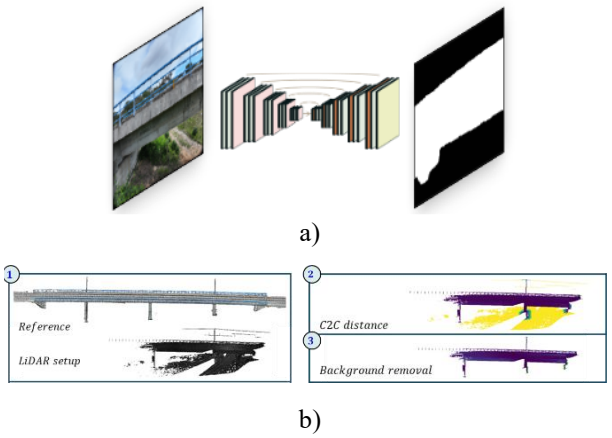

Figure 2: Optimal reality modelling strategy showing background removal for: a) imagery and b) LiDAR (adapted from Cabral et al., 2025b).

Hybrid damage perception

To achieve robust instance segmentation under operational conditions, the challenge of scale variation in high-resolution UAV imagery was addressed. Standard detectors often fail to identify fine cracks when images are downscaled. Thus, it is proposed a hybrid pipeline integrates YOLO11, Slicing Aided Hyper Inference (SAHI), and the Segment Anything Model (SAM) (Cabral et al., 2025a).

The detection phase utilises SAHI to systematically partition high-resolution images I_{HR} into overlapping patches P_k. Each patch is normalised to a 640×640 resolution, the native input size for the YOLO11 detector, ensuring that fine-grained features are preserved without the spatial degradation typically caused by global image downscaling. A YOLO11 detector, trained on railway-specific pathologies, processes each patch independently. The global detection set D_{global} is reconstructed by merging local predictions using Non-Maximum Suppression (NMS) to eliminate redundant bounding boxes.

To transition from coarse bounding boxes to pixel-perfect segmentation, the detected boxes B_{det} serve as geometric prompts for the Segment Anything Model (SAM), as depicted in *Figure 3*. Unlike traditional semantic segmentation networks trained on fixed classes, SAM leverages a Vision Transformer (ViT) backbone to generate zero-shot masks for each prompted instance. The segmentation objective is to minimize the boundary error between the predicted mask and the ground truth.

This hybrid approach ensures that fine-grained defects (e.g., hairline cracks) are detected at their native resolution while their boundaries are segmented with the precision of a foundation model.

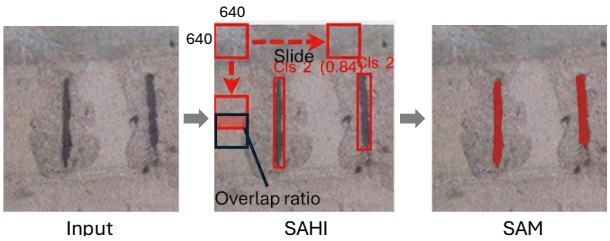

Figure 3: The hybrid perception pipeline: SAHI-assisted detection feeding into SAM-based segmentation.

Automated Scan-to-BrIM

The third stage automates the conversion of unstructured point clouds into parametric Bridge Information Modelling (BrIM) elements. It replaces manual modelling with a deep learning-based keypoint regression network trained on synthetic data.

Given the scarcity of labelled bridge point clouds, it employs a procedural generation engine to create a synthetic dataset. This engine, based on Revit® and Dynamo©, is used to randomise bridge geometrical and structural parameters. Nvidia Omniverse© is then leveraged to simulate laser scanning technology and generate semantically labelled point clouds. *Figure 4* illustrates the overall data generation and perception workflow.

The reconstruction network based on Yolo-Pose accepts point cloud slices S_i along the bridge alignment and regresses a set of structural keypoints $K = \{k_1, k_2, \dots, k_m\}$ defining the cross-sectional profile, as illustrated in *Figure 5*. The network is trained by minimising the Mean Squared Error (MSE) between predicted keypoints $\hat{K}$ and ground truth K_{GT} , as defined in Equation (2).

\

$$L_{keypoint} = \frac{1}{m}\sum_{j=1}^{m}\left|\left|\hat{k}_j - k_{GT,j}\right|\right|^2 \quad (2)$$

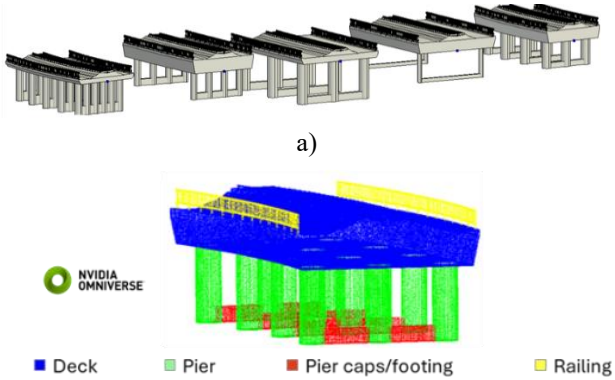

Figure 4. Synthetic bridge point cloud generation pipeline: a) bridge modelling and parameter randomisation using Revit® and Dynamo©; b) laser scanning simulation and semantic point cloud generation using NVIDIA Omniverse©.

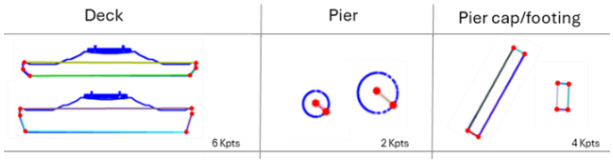

Figure 5: Labelled dataset for YOLO-Pose keypoints defining the cross-sectional profile.

Once inferred, these keypoints drive the instantiation of Industry Foundation Classes (IFC) entities. Structural elements are generated via lofting algorithms, ensuring the resulting model is fully parametric and interoperable, namely, IfcColumn, IfcBeam, IfCSlab and IfcWall (Amroune et al., 2022).

Semantic BIM Enrichment

The final stage transforms the geometric model into an "as-damaged" BrIM model by mapping 2D perception results into the 3D BIM environment.

Damage masks from Stage 2 are projected onto 3D space using a ray-casting algorithm. For a pixel u, v classified as damage, a ray $r(t)$ is cast from the camera center C through the pixel on the image plane. As defined in Equation (3).

$$r(t) = C + t \cdot K^{-1} \cdot [u, v, 1]^T \quad (3)$$

where K is the camera intrinsic matrix. The intersection of $r(t)$ with the 3D mesh geometry determines the spatial location of the defect. To consolidate detections from multiple overlapping images, a spatial clustering algorithm refined by Otsu thresholding is applied to filter low-confidence projections. *Figure 6* illustrate this process

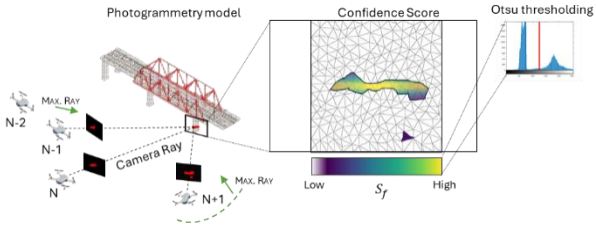

Figure 6: Multi-view ray-casting-based projection of 2D damage detections onto the 3D mesh for semantic enrichment.

The resulting 3D clusters are ortho-rectified to calculate engineering metrics (area, length, width). Finally, defects are instantiated as IfcBuildingElementProxy objects and hierarchically linked to their host structural element (e.g., IfcColumn) using the IfcRelContainedInSpatialStructure relationship.

This process establishes a direct link between visual inspection data and the BrIM model, enabling automated condition assessment and maintenance planning.

Validation and Results

Case Study Description

The proposed framework was experimentally validated on an operational reinforced concrete railway bridge located in Porto, Portugal, which is depicted in *Figure 7*. The structure consists of a single-track deck with a width of 11.33 m and a height of 0.80 m, supported by cylindrical piers (0.80 m in diameter and approximately 6.30 m in height), pier footing with a width of 0.40 m and a height of 0.80 m and integral abutments. The bridge exhibits heterogeneous degradation, including cracking, efflorescence, and exposed steel rebars.

This combination of structural complexity and varied damage mechanisms provides a case study for evaluating the robustness and reliability of the proposed automated inspection pipeline. All data acquisition activities were conducted in full compliance with national aviation regulations and railway safety requirements. The UAV flights were carried out with the necessary authorisations and under the supervision and support of the relevant infrastructure and railway authorities.

\

Reality Modelling Quality Assessment

The accuracy of the reality model serves as the foundational constraint for all downstream perception and reconstruction tasks. For the case study, the effectiveness of the proposed multi-modal fusion strategy, i.e. combining semantic background removal for photogrammetry with heuristic filtering for LiDAR, was evaluated based on geometric completeness.

Qualitative inspection of the fused point cloud confirms that the upstream filtering successfully suppressed high-frequency noise sources typical of railway corridors, as illustrated in *Figure 8*. This pre-processing yielded a structurally focused dataset in which the primary load-bearing elements (piers, deck slab, pier footings, and abutments) maintained surface continuity. Quantitatively, the voxel grid filtering strategy significantly reduced the data volume while homogenising point density.

b)

Figure 8: geometric completeness: a) Raw reality modelling containing noise; b) Optimal reality model after filtering.

Damage Perception Performance

The damage identification performance was quantitatively evaluated using a hybrid deep learning pipeline designed to detect and segment three critical railway bridge pathologies, namely, cracks, efflorescence, and exposed rebar.

The model was trained using a multi-source transfer learning strategy to address the scarcity of labelled infrastructure data. The foundational weights were initialised from a model pre-trained on the MS COCO dataset, followed by fine-tuning on a curated subset of the public DACL10K bridge damage dataset (3,737 images). The final domain adaptation was performed on a custom high-resolution UAV dataset comprising 645 training images and 161 validation images (5280×3956 pixels), annotated with pixel-precise masks.

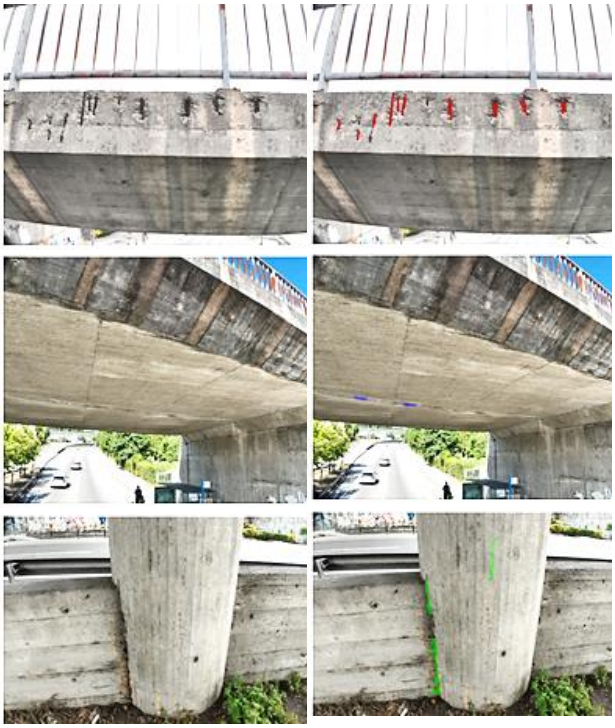
The proposed hybrid pipeline, which synergises a YOLO11 detector with Slicing Aided Hyper Inference (SAHI) and the Segment Anything Model (SAM), achieved a Mean Average Precision (mAP50) of 0.621 for detection across all classes on the validation set.

This step proved critical for the Scan-to-BIM stage by removing non-structural outliers, the effective geometric topology was preserved, allowing the keypoint regression network to operate on clean cross-sectional profiles.

In total, 170 distinct damage instances were identified and segmented, comprising 75 cracks, 13 efflorescence regions, and 82 areas of exposed reinforcement. Figure 9 qualitatively confirmed that the pipeline effectively identified the damage from the UAV image. A class-specific performance analysis highlighted the benefits of the hybrid architectural choices:

Cracks. The native YOLO11 output, enhanced by SAHI's high-resolution inference tiling, proved instrumental for linear defects. It achieved an Intersection over Union (IoU) of 0.495, successfully recalling narrow cracks that typically vanish during standard image downsampling.

Area Defects. For pathologies with complex morphologies but clearer boundaries, the two-stage refinement using SAM (prompted by YOLO bounding boxes) outperformed native segmentation. This approach yielded IoU scores of 0.331 for efflorescence and 0.205 for exposed steel rebars.



By producing well-defined masks, the framework ensures that metric quantification is derived from precise morphological geometry rather than coarse approximations.

Geometric Accuracy of Scan-to-BIM

The geometric validation of the generated Bridge Information Model (BrIM) was assessed by computing the signed Euclidean deviations between the generated IFC elements and the ground-truth reality capture point cloud. *Figure 11* depicts the BrIM model. The global mean geometric deviation for the bridge was approximately 14.46 mm. It is important to note that the upper surface of the deck was not modelled due to occlusion by the ballast and track superstructure; thus, this does not reflect in the deviation calculation. This accuracy aligns with the requirements for Level of Development (LOD) 300 (BIMForum, 2024), which requires elements be graphically represented as specific systems with precise quantities, sizes, shapes, locations, and orientations.

A component-level error analysis reveals distinct performance characteristics across structural elements. The pier caps and footings exhibited the lowest mean deviation (5.32 mm), followed closely by the abutments (9.29 mm). The cylindrical piers showed a mean deviation of 19.6 mm, while the deck slab presented the highest deviation at 22.89 mm. This confirms that synthetic domain randomisation is a viable strategy for overcoming the scarcity of labelled infrastructure datasets.

\

Figure 9: Qualitative results of the hybrid perception engine: a) original image; b) prediction damage, i.e., cracks (green), efflorescence (blue), and exposed rebar (red).

Semantic Enrichment and Damage Quantification

The final phase of validation focused on the semantic enrichment capability, the transformation of the BrIM model from a simple structural component into an "as-damaged" BrIM model. The ray-casting and clustering algorithms successfully mapped the 2D perception results onto the 3D IFC entities, establishing a coherent spatial database of defects.

Figure 11: the automated generated parametric BrIM geometry (LOD 300).

The enriched BIM environment enabled the automatic extraction of aggregate damage metrics. *Figure 10* illustrates the damage mapped to the georeferenced BrIM model, with corresponding dimensional attributes and reference image as well as the corresponding orthophoto. For the case study bridge, the primary contribution is the instance-level granularity; each defect is instantiated as an IfcBuildingElementProxy and hierarchically linked to its host element (e.g., a specific pier). Beyond local statistics, the system quantified a total crack length of 13.82 m, an efflorescence surface area of 0.112 m², and an exposed reinforcement area of 0.241 m². This structured data format allows asset managers to query the model for element-specific condition ratings, bridging the gap between raw visual data and actionable maintenance decision-making.

Discussion

This research resolves the historical discontinuity between automated damage detection and structural digitalization by integrating multimodal reality capture with Bridge Information Modelling (BrIM). While conventional pipelines typically terminate at 2D imagery or unstructured point clouds, the proposed framework embeds quantified defects as *IfcBuildingElementProxy* objects. This approach transforms a static BrIM into an interoperable "as-damaged" model, supplying asset

\

managers with actionable, element-specific condition metrics for automated maintenance decision-making.

Experimental validation on an operational railway bridge demonstrated that high-fidelity reality modelling is a strict prerequisite for automated inspection in complex environments. By employing a multi-modal fusion strategy—combining semantic background removal for photogrammetry with heuristic LiDAR filtering—the framework successfully isolated structural geometry from background noise (e.g., vegetation, catenary systems). Consequently, the automated reconstruction achieved a global mean geometric deviation of 14.46 mm, satisfying Level of Development (LOD) 300 requirements.

The findings also highlight the inadequacy of standard object detectors for capturing fine-grained infrastructure pathologies, as standard image downscaling often eliminates hairline cracks. Integrating Slicing Aided Hyper Inference (SAHI) with YOLO11 preserved these linear defects at their native high resolution. Subsequent processing with the Segment Anything Model (SAM) generated zero-shot, pixel-perfect masks, ensuring damage quantification was driven by precise morphology rather than coarse bounding box approximations.

To address the scarcity of annotated 3D point clouds for Scan-to-BIM, the framework successfully implemented synthetic domain randomization. Generating simulated data via Revit®, Dynamo©, and NVIDIA Omniverse© proved highly effective for training accurate keypoint regression networks, yielding component-level deviations as low as 5.32 mm.

Despite robust performance, current limitations include the inability to model the bridge deck's upper surface due to track superstructure occlusions, alongside the methodology's exclusive focus on surface-level manifestations of damage.

Conclusions

This study presented and validated an end-to-end computational framework that effectively brings together multimodal reality capture and semantic Bridge Information Modelling (BrIM). By integrating AI-driven background removal, a hybrid YOLO11–SAHI–SAM perception engine, and synthetic-data-trained Scan-to-BIM reconstruction, the methodology overcomes the scalability limitations inherent to traditional manual inspection.

The experimental validation on the bridge located at Porto (Portugal) confirms that high-fidelity reality modelling is a prerequisite for automated inspection. The proposed multi-modal background filtering strategy proved essential for reducing geometric noise, enabling automated reconstruction algorithms to converge with millimetre-level accuracy (mean deviations < 23 mm).

Furthermore, the results demonstrate that standard object detectors are insufficient for the complexity of infrastructure pathologies. The integration of Slicing Aided Hyper Inference (SAHI) and the Segment Anything Model (SAM) was critical for decoupling detection from segmentation, enabling precise quantification of fine-grained defects, such as cracks, that are typically lost (due to resolution) in standard down sampling processes. Ultimately, the true engineering value of the framework lies in the semantic enrichment stage, which successfully transforms static a BrIM model into an "as-damaged" BrIM model. By embedding quantified defects as intelligent IfcBuildingElementProxy objects, the system delivers interoperable, structured data directly usable for predictive maintenance and asset management.

Future research will prioritise the comparative validation of this automated framework against traditional manual inspection benchmarks for the same asset. Additionally, the synthetic training strategy will be extended to encompass complex masonry and steel truss typologies, thereby enhancing model generalisation. Finally, efforts will be directed towards integrating subsurface non-destructive testing (NDT) data into the BrIM environment, providing a holistic view of structural health that extends beyond surface-level defects.

AUTOMATED GENERATION OF SEMANTIC IFC MODELS FROM LEGACY SEWER NETWORK DATA

Peter Gölzhäuser, Raquel Valles Gomez, Sabine Hartmann, Hendrik Morgenstern, and Katharina Klemt-Albert
Chair and Institute of Construction Management, Digital Engineering and Robotics in Construction, RWTH Aachen University, Aachen, Germany

Abstract

This paper presents an automated workflow for generating georeferenced IFC 4.3 models from legacy data structured according to the DWA-M 150 schema. The DWA-M 150 schema is an XML-based data exchange format for condition monitoring of drainage systems, which is used as a standard by German municipal utilities. The approach consists of three stages: geometry generation from master inventory data, semantic enrichment, and integration of inspection and condition assessment data. The resulting semantically enriched models provide a solid foundation for future digital twin applications in sewer infrastructure management.

Introduction

Germany's drainage and sewerage infrastructure faces the dual challenge of aging assets and necessary expansion (Berger et al., 2020). Furthermore, climate change exacerbates these pressures, with an increased frequency of heavy rain events heightening the risk of flooding (Blöschl et al., 2019). Against this context, the complexity of modern infrastructure assets, coupled with the high cost of labour, makes manual inspection and condition data interpretation increasingly impractical (Tse, 2016). Adopting a more data-driven and automated approach may offer a solution to this problem. However, the data landscape is characterised by fragmentation, often referred to as ''data silos'', which poses a significant obstacle to the adoption of advanced predictive maintenance strategies (Kretschmer et al., 2023). To address this, researchers propose standardized data models that enable both human comprehension and computational reasoning, facilitating seamless integration of heterogeneous data streams into a coherent system view (Du et al., 2023).

This paper presents an automated approach for generating georeferenced IFC 4.3 models from data based on the DWA-M 150 schema, including the visualization of inspection and condition assessment results. By transforming existing municipal sewer data into semantically enriched 3D models, this approach provides the necessary foundation for future digital twin applications.

Background

This section establishes the theoretical framework for the study. It contextualizes the current state of digital sewer data management, contrasting existing practices with the requirements of digital twins and the IFC 4.3 schema. It distinguishes between model generation methods and explains the principles of semantic enrichment to translate structured legacy data into 3D data models.

Digital transformation in sewer infrastructure management

The growing demand for integrated data management drives the construction sector towards the adoption of the *digital twin (DT)*, defined as a dynamic digital representation of a physical asset (buildingSMART International, 2020). This definition can be refined by distinguishing between a *Digital Shadow* (DS)—where data flows automatically from the physical to the digital object—and a full Digital Twin, which includes a bidirectional flow allowing for autonomous control (Ghorbani Bam et al., 2025). To operationalize these concepts, current research proposes a layered reference architecture consisting of Presentation, Platform, Transmission, and Data Acquisition layers (Smarsly et al., 2025). In line with this framework, our study falls within the platform layer, as it focuses on the elements that make up the digital replica, in particular the modeling and data storage elements required for a foundational digital representation.

Currently, sewage networks are typically structured topologically and described using a node-edge model. In this model, nodes represent structural elements such as manholes, inspection chambers and sewage treatment plants, while edges represent connected pipe sections (DWA, 2021). In Germany, the management and standardization of this data are governed by the DWA-M 150 guideline (*Datenaustausch für die Zustandserfassung von Entwässerungssystemen*) (DWA, 2010). In terms of spatial context, Geographic Information Systems (GIS) have become the standard at a macro level. However, they lack the geometric granularity required for component-level maintenance, a task for which Building Information Modeling (BIM) has been proven to be useful (Wang et al., 2019; Valles Gomez et al., 2025).

The role of Building Information Modeling and open standards

The release of IFC 4.3 as an ISO standard in 2024 (ISO 16739-1:2024) marked a milestone by extending the schema to include comprehensive support for infrastructure assets. While core entities like `IfcPipeSegment`,

`IfcWasteTerminal` and `IfcDistributionSystem` existed in earlier versions for vertical construction, IFC 4.3 introduces the specialized predefined types and linear referencing capabilities necessary to model civil works such as highway drainage or municipal utilities. This standardisation paves the way for a semantically structured 3D data model. Its open data structures allow for high interoperability, enabling the future integration of sensor data for managing municipal assets throughout their lifecycle (Edmondson et al., 2018).

To bridge the gap between existing infrastructure records and new digital standards, two methodological approaches can be differentiated:

1. **Scan-to-BIM (Reality Capture):** Processes involve capturing spatial data via Terrestrial Laser Scanning (TLS), photogrammetry, or SLAM-based mobile mapping to generate high-density point clouds, followed by a reconstruction process. Recent research has focused on automating the subsequent reconstruction process via Deep Learning architectures for semantic segmentation (Jäkel et al., 2025; Kellner et al., 2025). While effective for visible, aboveground structures such as bridges or facades, the lack of line-of-sight and the logistical constraints of physical access render reality capture and large-scale modeling for extensive underground utility networks highly challenging.

2. **Legacy-to-BIM (Information Reconstruction):** Often characterized as semantic enrichment in recent literature (Belsky et al., 2016; Jiang et al., 2023), reconstructs or augments models from existing datasets. The approach proposed in this paper uses the implicit semantics within legacy records (such as structured XML files like DWA-M 150) to algorithmically generate semantics and geometry. The research challenge lies in translating data attributes into the 3D shapes, properties, and topological relationships required by BIM standards.

While legacy data for sewer systems is often highly available and structured in domain-specific formats (e.g., DWA-M 150), there is currently no direct, standardized mapping to transform this data into the explicit geometry and semantic structure required by the IFC 4.3 standard.

Approaches to geometric and semantic enrichment

The concept of *semantic enrichment (SE)* has emerged as a response to the interoperability gaps inherent in digital construction workflow (Sacks et al., 2017). Addressing this challenge, Belsky et al. introduced ''SeeBIM'' (Semantic Enrichment Engine for BIM), a prototypical framework designed to interpret the implicit information contained in building models. Their rule-based inference engine utilizes domain expert knowledge—such as the connection constraints between precast concrete elements—encoded into ''IF-THEN'' logic to deduce new semantic objects and relationships from raw geometry. While highly effective, this approach fundamentally relies on inferring semantics from geometric and topological evidence within standard IFC files (Belsky et al., 2016). The workflow follows a logical path of Geometry → Topology → Semantics, deriving meaning from scanned shapes (Sacks et al., 2017). In the context of this study, however, the challenge is inverted. The source data (DWA-M 150) is semantically rich, but does not include a 3D-model. Consequently, the approach required for legacy sewer data must follow the path of Semantics → Topology → Geometry, utilising the structured attributes in the XML to generate the geometric representation.

This methodological inversion prompts a re-evaluation of the term ''semantic enrichment''. Bloch refines the prior definition by distinguishing between enrichment and enhancement. In her framework, *semantic enrichment* describes a process using inference engines to derive new information from the model itself (creating new knowledge), whereas *semantic enhancement* refers to the integration of external data sources into the model (linking existing knowledge) (Bloch, 2022). The workflow proposed in this paper occupies a hybrid position between these two concepts: it *enhances* the model by mapping external attributes to IFC property sets, yet it *enriches* the model by algorithmically generating 3D geometry and topological connections that did not previously exist in the 2D source data. Thus, while acknowledging the taxonomic distinction between enrichment and enhancement proposed by Bloch (2022), this paper adopts semantic enrichment as a comprehensive umbrella term to describe the hybrid process of both inferring model geometry and integrating external legacy records.

Research gap

Current research focuses on either digital twin dynamics (e.g., simulation, sensors) or geometric reconstruction (Scan-to-BIM), but lacks standardised methods for the automated semantic translation of legacy data sources into open BIM standards.

Since the DWA-M 150 schema provides rich, structured semantic data, converting these records to IFC 4.3 through a ''Legacy-to-BIM'' approach offers a pragmatic solution. This methodology is particularly relevant given the proliferation of Machine Learning techniques in both semantic segmentation and enrichment (Schönfelder et al., 2023). However, by their very nature, these approaches entail probabilistic uncertainties (Kellner et al., 2026). In contrast, the use of a well-structured database source enables deterministic, rule-based algorithms to create georeferenced semantic models with high accuracy, thereby circumventing the uncertainty associated with machine learning.

Methodology

This section presents the technical methodology for the automated generation of the IFC model and semantic en-

richment from DWA-M 150 data. The proposed approach maintains a separation of geometry and semantics, enabling both processes to run independently of each other. This allows for flexibility in scenarios where geometry originates from alternative sources, such as point clouds resulting from 3D scans, and facilitates regularly updating condition data resulting from new inspections. Figure 1 shows a schematic representation of the conversion pipeline.

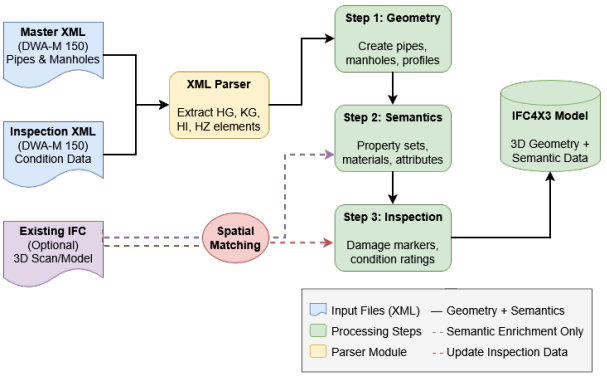

Figure 1: Overview of the conversion pipeline

Data basis and requirements

The process relies on input data structured according to the DWA-M 150 schema, which has been widely adopted by German municipalities and is integrated into most Sewer Information Systems. Although the algorithm presented in this paper was designed specifically for this standard, the underlying approach is transferable and adaptable to other structured data formats.

Within DWA-M 150, each infrastructure element is described by a set of standardized identifiers that are defined as mandatory or optional within the schema. Pipe sections (''Haltungen'' in German) use the identifier prefix `<HG>`, while nodes (''Knoten'' in German) use `<KG>`. The standard defines four element categories:

- **Basic Data** (HG/KG): Designation, material, dimensions, construction year
- **Geometry Data** (GO/GP): Coordinates and spatial information
- **Inspection Data** (HI/KI): Camera survey metadata and observations
- **Condition Data** (HZ/KZ): Damage classifications and assessments

The source file functions as a hierarchical data tree where the root element `<Data>` contains collections of pipes `<HG>` and nodes `<KG>`. Geometry is explicitly defined in `<GO>` (Geometry Objects) subsections, providing Easting, Northing, and Elevation values for each feature point `<GP>`.

Automated geometry generation workflow

The workflow is implemented as an automated converter in Python using IfcOpenShell for IFC 4.3.2.0 generation and NumPy for vector-based geometry calculations. Its geometry module handles coordinate transformations, profile creation, and extrusion operations. The converter also includes a parser module for the DWA-M 150 XML serialisation, which handles all element types (HG, KG, HI, HZ, and HM) and a mappings module for code translations and reference table handling.

Profile definition

The cross-sectional profile of each pipe is determined from the profile type code (`HG305`) and dimensional attributes (`HG306`, `HG307`). The converter supports three profile types:

- **Circular profiles** (code `DN`): Most common, represented as `IfcCircleHollowProfileDef`
- **Egg-shaped profiles** (code `EI`): Typical for combined sewers, created as custom parametric profiles using `IfcArbitraryProfileDefWithVoids` with standard DIN ratios.
- **Rectangular profiles** (code `RE`): Used for larger collectors, represented as `IfcRectangleHollowProfileDef`

Since the wall thickness is not specified in DWA-M 150, a diameter-dependent lookup table based on common precast concrete specifications is used (e.g., 60 mm for DN 150, 75 mm for DN 300–500, up to 220 mm for DN 2200), with linear interpolation for intermediate sizes.

Elevation handling

Missing Z-values are common in legacy datasets. The converter employs linear interpolation when multiple elevation points are known, assumes a flat profile when only one is available, and applies a configurable default value when no elevations exist. To ensure transparency, the converter uses a custom property set, `DWAM150_DataQuality`, to document the assumptions made.

Geometry extrusion

Pipes are modeled as `IfcPipeSegment` entities by extruding the assigned profile along the direction vector between consecutive geometry points. When a pipe section contains more than two geometry points, the converter creates multiple connected linear segments to approximate the polyline path. Manholes and inspection chambers are created as `IfcDistributionChamberElement` elements, with parametric geometry —consisting of a main shaft, an eccentric tapered cone, adjustment rings, and a cover plate— with a forced minimum height of 0.8 meters to prevent geometric degeneration when cover and invert elevations are identical.

Visual quality indicators

To ensure transparency regarding data completeness, color-coding distinguishes elements with complete data from those requiring assumptions:

- **Blue**: Pipes with complete data

- **Red**: Pipes with missing or interpolated values
- **Yellow**: Nodes with complete data
- **Orange**: Nodes with incomplete data

Semantic enrichment framework

The DWA-M 150 schema is optimised for data transport between systems, encoding attributes as 5-character field codes (e.g., `HG304` for pipe material) with values referencing internal code tables. For a functional digital twin, this technical encoding must be transformed into human-readable, queryable IFC property sets. The semantics module handles this transformation through code mapping, property set assignment, and spatial matching for data fusion.

Data mapping strategy

The DWA-M 150 standard encodes attributes using a two-level reference system. At the global level, field codes identify attribute types (e.g., `KG305` for the manhole material). At the local level, attribute values are numeric codes referencing lookup tables within the XML file. A mapping dictionary translates 5-character field codes into human-readable German property names. For example:

- `HG001` → ''Bezeichnung'' (Designation)
- `HG304` → ''Material''
- `HG305` → ''Profilart'' (Profile Type)
- `HZ001` → ''Station'' (Position along pipe)
- `HZ014` → ''Schadensklasse'' (Damage Classification)

Semantic values are resolved using a two-stage lookup: the parser first dynamically builds a dictionary from the XML's internal Reference Tables (`<RT>` elements), then falls back to built-in mappings for codes not defined in the source file. For instance, in the material field `HG304`, a value of ''10'' is resolved to ''Beton'' (Concrete), ''50'' to ''Steinzeug'' (Vitrified Clay), and ''70'' to ''Kunststoff'' (Plastic).

Spatial matching algorithm

The converter supports two strategies for assigning semantic data to geometry: name-based matching and spatial matching. By default, the converter uses the pipe designation (`HG001`) to find the corresponding IFC element by name. This works well when the same data source provides both geometry and attribute data. Spatial matching becomes necessary in several scenarios. First, when inspection data comes from a different source than the master data, such as when importing camera survey results from a third-party contractor. Second, when pipe names have changed between data exports or contain inconsistencies. Third, when working with geometry obtained from 3D laser scans, point clouds, or photogrammetry that does not include attribute information. The spatial matching algorithm builds an index tree of all geometric elements in the existing IFC model and calculates the geometric centroid, typically the midpoint between start and end points for pipe sections. First, the algorithm queries the spatial tree at the exact centroid location. If exactly one element intersects that point, a match is found. If no elements are found, the search radius expands exponentially—doubling from an initial radius of 10 cm (0.1, 0.2, 0.4 m, etc.) up to a configurable maximum (default: 5 m) to ensure that coordinate differences due to rounding or survey accuracy do not prevent valid matches. When multiple elements fall within the search radius, the match is considered ambiguous, and no automatic association is made. The converter reports these ambiguous cases so that operators can resolve them manually. The centroid-based approach was chosen for its simplicity. Alternative strategies such as bounding-box overlap, direction-vector similarity, or topological connectivity matching were not implemented in the current version, as the centroid approach proved sufficient for straight pipe segments in the test dataset. The limitations of this algorithm for curved segments and dense junction areas are discussed further in Section 4.5.

Property set assignment

Once a match is found, the attributes are assigned to the IFC object using custom property sets prefixed with `DWA_`. Custom property sets are needed because the IFC 4.3 standard does not define property sets that fully accommodate the DWA-M 150 domain model—for example, `Pset_Condition` provides only a single overall assessment field, whereas DWA requires a triple classification (tightness, structural stability, and operational reliability) with per-defect station coding. To ensure both usability and data lineage, two distinct property sets are created for each data category: one includes decoded values for end users, while the `*_raw` version preserves the original DWA codes for traceability and automated validation. For the static master data (''Stammdaten'' in German), which includes basic and geometry data elements, the following property sets are created:

- `DWA_Stammdaten`: Contains the decoded attribute values (e.g., Material: ''Concrete''). This is intended for end-users in BIM viewers.
- `DWA_Stammdaten_raw`: Preserves the original DWA code values (e.g., Material: ''10'').

For inspection and condition data, additional property sets are created following the same approach:

- `DWA_Inspektionsdaten` / `..._raw`: Inspection metadata.
- `DWA_Zustandsdaten` / `..._raw`: Condition observation data.
- `DWA_DamageReference`: Links damage markers to parent pipes with station, classification, and a human-readable damage description.

Inspection data integration

Beyond static master data, the converter supports inspection records `<HI>` and condition observations `<HZ>`. In

DWA-M 150, damage observations are recorded as linear stations — distances in meters from the inspection start point (typically the upstream manhole). The `HZ001` field stores this 1D station value, which is converted to a 3D world coordinate by interpolating along the pipe's direction vector. Individual damage observations are visualized as 3D ring-shaped color-coded markers, as shown in Figure 2, according to the German condition classification:

- **Class 0 (Green):** No damage / informational
- **Class 1 (Red):** Immediate action required
- **Class 2 (Orange):** Short-term action needed
- **Class 3 (Yellow):** Medium-term action
- **Class 4 (Grey):** Long-term monitoring

This enables operators to immediately identify critical sections requiring maintenance intervention.

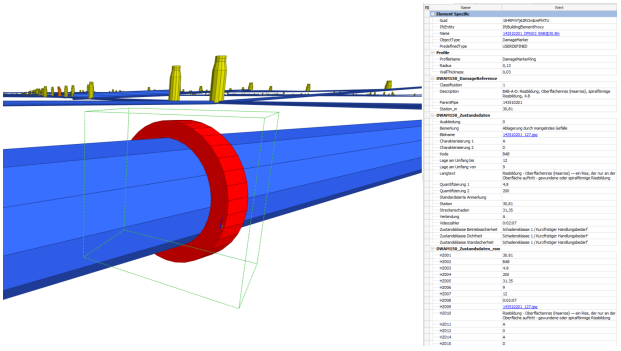

Figure 2: Damage Marker shown in BIMvision

Results and discussion

The workflow was validated using a combination of real-world and synthetic datasets. Real municipal master data from the German municipality of Alsdorf was used to test geometry generation and semantic enrichment with static master data. Although name-based matching is the primary method for data integration from the same source, the spatial matching algorithm was also tested using this dataset. Synthetic inspection data was generated to test the inspection data integration, covering the full range of damage classifications and several station positions across the pipes. The following sections evaluate geometric accuracy, semantic data verification, inspection data integration, and system performance, followed by a discussion of current limitations.

Geometric model accuracy

Georeferencing accuracy was validated by overlaying the generated IFC model on a Digital Terrain Model (DTM) created in Autodesk Civil 3D. The DTM was constructed using GeoTIFF elevation data obtained from the state geodata portal of North Rhine-Westphalia (Geoportal NRW), and orthophotos as visual overlay, referenced to the ETRS89 / UTM zone 32N coordinate system (EPSG:25832). The unmodified IFC file was then superimposed on the DTM using both Desite and Autodesk Infraworks, as illustrated in Figure 3. Coordinates from several pipe elements along the outer boundary of the network were extracted from the IFC file and from the combined model and verified against the original DWA-M 150 source data. This comparison confirmed that UTM coordinates were correctly preserved in the generated model.

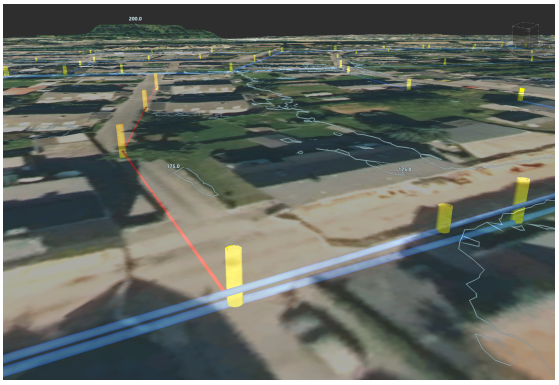

Figure 3: Coordination Model in Autodesk InfraWorks

Semantic data verification

The semantic enrichment was validated using real-world municipal datasets from the German municipality of Alsdorf, containing 701 pipe sections and 702 nodes. Both matching strategies were tested independently. Since both geometry and master data originated from the same DWA-M 150 source and were consistent, name-based matching achieved a 100% success rate, linking all 701 pipes and 702 nodes to their corresponding semantic attributes. Spatial matching achieved a success rate of 97.6% for pipes (684 of 701 matched), with 17 pipes (2.4%) remaining unmatched. 14 of these 17 pipes were curved segments with more than two geometry points, where the centroid-based matching fails due to geometric segmentation. The remaining three pipes were unmatched due to overlapping geometries at complex junction points, where multiple pipes shared near-identical centroids. For nodes, spatial matching achieved 99.6% accuracy (699 of 702). The resulting IFC models were inspected in BIMvision, where the dual property set structure enabled visual verification of key properties (such as material types), while retaining the raw data for quality checks.

Inspection data integration

To validate the inspection data integration, synthetic inspection data was generated following the official DWA-M 150 example file structure. The synthetic dataset was created by selecting 50 pipes from the Alsdorf master data and generating inspection records with DWA-M 150 element hierarchy: pipe sections (`<HG>`) with geometry objects (`<GO>/<GP>`), inspection headers (`<HI>`), and condition observations (`<HZ>`). The dataset contains 251 condition observations distributed across all five damage classifications. The converter successfully parsed all inspection records and generated correctly positioned damage markers with appropriate severity color-coding. Linear station values across the pipes (`HZ001`) were correctly trans-

formed to world coordinates via linear interpolation. The precision is limited only by the input coordinate resolution (typically millimetres in UTM) and the station value precision from the source data. However, the matching algorithms could not be tested using the synthetic data, as it was derived directly from the master data with identical pipe names and coordinates, resulting in a 100% matching rate.

An alternative validation method could include introducing controlled perturbations, like coordinate offsets (e.g., 0.5–2.0 m), renaming pipe identifiers to simulate naming inconsistencies between data sources, or merging inspection records from a genuinely independent data export. As no more heterogeneous datasets were available at the time of testing, this remains a limitation, and future work includes testing with real inspection data from third-party contractors, or alternatively, introducing synthetic perturbations to simulate real-world data inconsistencies.

System performance and quality assessment

The developed workflow successfully achieved its primary objective of automated generation and semantic enrichment of 3D sewer models from DWA-M 150 master data. The resulting model features a complete geometric representation of pipes and nodes, correct georeferencing, and comprehensive semantic information based on the DWA-M 150 standard embedded in property sets. This demonstrates the feasibility of automated, standard-based data transfer from DWA-M 150 to IFC using open-source tools such as `IfcOpenShell`. In terms of quality, the converter captured all objects from the source data, provided that the input data adhered to the standard. Semantic consistency was verified by checking that the attributes matched the DWA identifiers, with the raw values preserved in a separate property set to mitigate data loss from missing reference table entries in the source. The output adheres to IFC 4.3.2.0 and was validated using the buildingSMART Validation Service. The models were additionally loaded in BIMvision and Blender (Bonsai) to confirm practical interoperability. Performance was satisfactory, with geometry generation completing in approximately 15 seconds and semantic enrichment in approximately 18 seconds (name-based) or 14 seconds (spatial) on a workstation equipped with an AMD Ryzen 9 8945HS processor and 32 GB RAM.

Limitations and challenges

Regarding the geometric model accuracy, the system faces challenges primarily related to source data quality, such as missing height values, which necessitated defaults. The manholes are represented as simplified parametric geometries, consisting of cylindrical elements, a tapered cone, and a cover plate. This representation does not account for asymmetric bases, varying wall thicknesses, or non-circular shaft cross-sections. A realistic representation of the nodes would be more demanding. In DWA-M 150, curved pipes are represented by three or more geometry points. During IFC generation, these are approximated as multiple straight segments. While this linear representation facilitates the centroid-based matching algorithm, arc-based swept solids could represent curved pipe alignments more smoothly in future iterations. For the semantic enrichment, the centroid-based spatial matching algorithm shows limitations when handling curved pipe sections. The spatial matching algorithm calculates the centroid from all original geometry points, but this centroid may not fall within any single IFC segment's bounding box. It should be noted that the DWA-M 150 schema only provides discrete coordinate points, making linear approximation the only deterministic geometric representation; fitting arc or spline curves would require additional assumptions about curvature that are not supported by the source data. Matching precision could be improved by calculating separate centroids for each segment of curved pipes or by adopting alternative geometric matching strategies. As more diverse datasets become available in the future—including geometry from laser scans, where curved representations may exist—alternative matching strategies for this specific case could also be evaluated.

Regarding validation, the reliance on synthetic data means that the matching algorithms remain untested for inspection and condition data. The current implementation can therefore only be interpreted as a proof-of-concept for the pipeline architecture, with the matching algorithm requiring further validation as real-world datasets become available. Additionally, specific sewer properties like ''Flood Area'' lack native IFC entities, requiring mapping to IFC spatial entities (eg. `IfcSpatialZone` or `IfcGeographicElement`), potentially reducing interoperability with downstream analysis tools.

Comparison with existing approaches

Compared to proprietary Sewer Information Systems and transformation workflows, this open-source approach offers significant advantages in transparency and flexibility. The separation of geometry generation from semantic enrichment allows for the enrichment of any valid IFC geometry, such as that derived from 3D scans, provided the coordinates match. This makes the workflow particularly suitable for research and development contexts, where adaptability is required. Regarding transferability to other infrastructure domains, the workflow components differ in their degree of generalizability. The geometry generation engine (profile extrusion, coordinate transformation, elevation handling) and the spatial matching algorithm can be reused directly for any node-edge network topology. In contrast, the DWA-M 150 parser, the field code mapping dictionaries, and the reference table resolution logic are domain-specific and would require replacement when adapting the workflow to other standards (such as DVGW for gas and water networks). The IFC entity mapping (e.g., which DWA element types correspond to which IFC classes) is also domain-specific but follows a pattern that can be systematically replicated for other schemas.

Conclusion and outlook

This section consolidates the workflow's main contributions and outlines future development directions.

Key achievements

The study successfully developed a two-stage automated workflow that translates DWA-M 150 sewer infrastructure data into a fully structured, georeferenced, and semantically enriched IFC 4.3 model. This work validates the feasibility of bridging traditional Sewer Information Systems (KIS) and Building Information Modeling (BIM) using open standards (IFC, DWA-M 150).

Key technical achievements include decoupling geometric extrusion from semantic enrichment to enable data integration from heterogeneous sources. To facilitate this process, the study developed and evaluated name- and centroid-based spatial matching algorithms, achieving integration accuracies of over 97% for the spatial matching of pipe segments on real-world municipal datasets. Furthermore, the workflow effectively dismantles existing data silos by translating specific DWA-M 150 attributes into standardised, human-readable IFC property sets, while retaining the original codes for algorithmic validation. Finally, this approach has been extended to operational condition monitoring by translating 1D linear inspection stations into visual, colour-coded 3D damage markers. Having been validated against official buildingSMART configuration rules and coordinated with municipal digital terrain models, this Legacy-to-BIM methodology establishes a tangible, standard-compliant foundation for future predictive digital twin applications in underground infrastructure.

Future improvements

Technical improvements could address geometric and topological limitations. Currently, pipes are linearly simplified; integrating OpenCASCADE/STEP via `IfcOpenShell` would allow for complex profiles and curved segments. Connection geometry between pipes and nodes could also be automated for cleaner transitions. The spatial matching algorithm could be extended with directional similarity scoring and topological connectivity analysis to resolve ambiguous cases. To support hydraulic simulations, semantic flow definitions could be implemented using the IFC concept of ''Port Nesting''. Furthermore, hardcoded defaults for missing data could be replaced with dynamic calculations based on slope or rule-based plausibility checks. For inspection data, integration with the BIM Collaboration Format (BCF) would enable linking damage observations to external documentation such as inspection photographs and video frames. However, BCF currently lacks native fields for precise damage coordinates, requiring either format extensions or hybrid approaches.

Standards and digital twin potential

While the current approach aligns with DWA-M 150, the upcoming DWA-M 145-3 standard (incorporating GML for coordinates) will require adaptations in XML parsing logic, though the general methodology remains valid. The enriched IFC model serves as a foundation for a digital twin, enabling flood prevention simulations and integration with sensors for predictive maintenance. While developed for wastewater infrastructure, the methodology is transferable to other utility networks characterized by similar data structures: water distribution, gas networks, and district heating systems all employ node-edge topologies with standardized attribute schemas.

TOPOLOGY-DRIVEN SEMANTIC INTEGRATION OF INDEPENDENT BIM MODELS FOR RENOVATION ANALYSIS

Jacopo Cassandro and Claudio Mirarchi
Department of Architecture, Built Environment, and Construction Engineering (DABC),
Polytechnic of Milan, Milan, Italy

Abstract

This paper proposes a topology-driven semantic integration approach to align as-is and to-be BIM models in building renovation scenarios. Starting from independent IFC files, a surface-based topological analysis infers physically meaningful contacts between envelope objects using coplanarity, opposite orientation, vertical overlap, and an overlap-coverage metric. The detected adjacencies are then represented as cross-model semantic relations by instantiating `bot:Interface` links between the corresponding `bot:Element` individuals in a dedicated knowledge graph, preserving model independence. The resulting topology enables cross-model SPARQL queries to extract and aggregate energy-related data at the envelope-system level without IFC merging or manual data preparation.

Introduction

Building renovation workflows increasingly rely on Building Information Modeling (BIM) based digital representations to support design, analysis, and decision-making processes (Han et al., 2025; Ismail et al., 2017). In practice, however, renovation projects are typically characterized by multiple BIM models representing different project phases, such as the existing (as-is) condition and the proposed retrofit (to-be) intervention. These models are often developed at different time stages, so they are simultaneously independent of each other, stored in separate IFC files, and lack explicit machine-interpretable semantic relationships that describe how the introduced objects physically relate to the existing building (Pauwels and Terkaj, 2016; Rasmussen et al., 2017).

This fragmentation represents a significant challenge for automatic data analysis by machines, such as the extraction of energy assessment for the envelope system. While the physical reality of a renovated building envelope is composed of coherent construction systems (e.g., walls upgraded with insulation layers), this coherence is not explicitly represented in conventional BIM models. As a result, properties relevant for performance evaluation are distributed across independent models, preventing automated system-level reasoning and requiring manual interpretation, model merging, or ad hoc data preparation.

Existing approaches to BIM-based analysis often assume that relevant relationships are already encoded within a single model or can be derived through explicit semantic links. However, such assumptions rarely hold in renovation scenarios, where as-is and to-be models remain semantically detached. Geometry-based methods can detect spatial proximity or collisions, but they typically do not provide a structured mechanism to transform geometric evidence into persistent, machine-interpretable relations suitable for higher-level analysis (Gan et al., 2022). Conversely, ontology-based approaches offer rich semantic representations, yet they rely on the availability of explicit relationships that are not present in independent BIM models (Karmakar and Delhi, 2023; Moreira, 2024).

This paper addresses this gap by proposing a geometry-driven and ontology-based approach for aligning independent as-is and to-be BIM models through surface-level topological analysis and semantic linking. Rather than merging models or imposing predefined semantic structures, the proposed method infers physically meaningful adjacency relations directly from geometric surface evidence and explicitly encodes them as semantic relations, reusing the Building Topology Ontology (BOT) and Building Element Ontology (BEO). In this way, objects that are fragmented across different models but belong to the same physical construction system can be coherently related in a machine-interpretable manner.

The main contribution of this work lies in enabling cross-model reasoning over building envelope systems without compromising model independence. By transforming geometric contact evidence into explicit semantic constructs, the proposed approach allows distributed BIM data to be aggregated, queried, and exploited for performance-oriented analyses, such as energy evaluation(Utkucu et al., 2025; Massafra et al., 2024). The approach is demonstrated through a case study focusing on envelope retrofit, showing how independent BIM models can be semantically linked to support automated data extraction and downstream simulation workflows.

The paper is structured as follows. Section *Methodology* presents the proposed methodology, including geometry-driven topological analysis and semantic enrichment. Section *Topological analysis and overlap metrics* formalizes the algorithm for the analysis of objects surface-based matching and the associated overlap metric. Section *Case study and results* reports the case study and discusses the

results, while the final sections address semantic linking, energy-oriented data exploitation, and future work.

Background

Topology in BIM

Several studies have investigated the representation of topological relationships within BIM models to support advanced querying, navigation, and analysis tasks. Graph-based approaches encode building components and their relations as nodes and edges, allowing the computation of shortest paths, connectivity patterns, and higher-level structural properties (Han et al., 2025). Graph databases have been used to transform IFC models into object graphs, supporting advanced querying, algorithms, and topological analysis in IFC versions (Ismail et al., 2017). In parallel, IFC-based graph data models use weighted graph principles and automatic algorithms to extract and query topological relationships among 3D elements more efficiently than traditional 2D/3D representations (Khalili and Chua, 2015). More recent work has introduced the notion of Topological BIM (TBIM), a space-oriented BIM representation tailored for building performance management; TBIM relies on topological and conditional modeling principles to derive semantically enriched information models to build performance simulation (Massafra et al., 2024). Graph-based topological models have also been used to support semi-automated dataset generation for residential buildings, showing that explicit spatial graphs can serve as a robust backbone for downstream analytical tasks (Massafra, 2025).

Beyond purely topological representations, several approaches leverage geometry-based techniques—such as surface adjacency, coplanarity, and contact area analysis—to infer spatial relationships between building elements. These methods extend graph-based BIM representations by incorporating geometric evidence to identify physically compatible interfaces between components, for instance, in modular or surface-driven modeling strategies (Gan et al., 2022). However, geometry-based inferences are typically applied within a single BIM model and produce transient results that are not persisted as explicit semantic relations, limiting their applicability to cross-model renovation scenarios.

BIM-to-RDF

The translation of BIM data into semantic representations has been extensively explored as a means to improve interoperability, data integration, and querying capabilities. Ontologies such as IfcOWL enable a comprehensive mapping of the IFC schema into RDF triples, supporting formal reasoning and semantic querying. Pauwels and Terkaj (2016) formalized a standardized EXPRESS-to-OWL conversion procedure specifically targeting IFC, producing a recommendable ifcOWL ontology in OWL2 DL that balances fidelity to the original schema with practical usability. Due to the size and complexity of full IFC-to-RDF mappings, several lightweight ontologies have been proposed to represent core aspects of building topology and element classification in a more tractable way; notable examples include BOT and BEO ontologies, which focus respectively on spatial/elementary topology and on reusable element taxonomies (Rasmussen et al., 2017). More recently, domain-specific performance ontologies like the Holistic Building Performance Ontology (HBPO) provide unified schemas to connect BIM data with multi-domain building performance simulation tools (acoustics, lighting, energy) (Utkucu et al., 2025). In the Linked Building Data (LBD) context, these ontologies are combined with IFC and other domain schemas to support data-driven modeling of building topology, while frameworks such as Onto4Reuse address ontology reuse and alignment across BIM-related domains (Moreira, 2024). In parallel, semantic enrichment has been proposed as a strategy to reconstruct implicit or missing information in IFC-based models, particularly where exported data lack the relational structure needed for higher-level reasoning. Rule-based enrichment techniques infer missing topological relations, reorganise building hierarchies, and support automated code compliance checking by encoding domain knowledge as declarative rules (Karmakar and Delhi, 2023). Nevertheless, most of these semantic approaches assume that relevant relationships are explicitly present in the source models, or can be directly mapped from the IFC schema, and do not tackle the derivation of new topological relations from geometric evidence, nor the reconstruction of topology between independent as-is and to-be models. These approaches confirm that BIM models often lack explicit relational topology and that enrichment is necessary to make such information machine-interpretable. However, existing semantic enrichment methods are typically domain-specific, rely on rule sets tailored to particular use cases (e.g. regulatory checking or asset management), and operate on single BIM models. As a result, they offer limited support for renovation workflows in which as-is and to-be models are authored independently, stored in separate IFC files, and need to be semantically linked through derived topological relations.

Research gaps and research questions

The literature review highlights significant advances in graph-based BIM representations, geometry-driven spatial analysis, and semantic enrichment techniques. However, these approaches are typically developed in isolation and do not fully address renovation workflows characterized by the coexistence of independent as-is and to-be BIM models. In particular, there is a lack of methods capable of deriving persistent, machine- interpretable adjacency relations from geometric evidence and exploiting them for system-level performance analysis.

This research addresses the following questions:

- RQ1: How can adjacency relations between independent BIM models be inferred from surface-level geometric evidence?
- RQ2: How can such relations be semantically created

without model merging?
- RQ3: How can the resulting semantic model support performance-oriented data extraction?

Methodology

The proposed methodology enables the identification and semantic formalization of cross-model adjacency relations between building envelope objects belonging to independent as-is and to-be BIM models, which are typically disconnected in renovation workflows. The approach combines geometry-driven topological analysis with semantic knowledge graph representation, enabling aggregation of relevant properties (e.g., thermal transmittance) at the envelope-system level, despite their distribution across separate IFC files. This enables the use of domain-specific analysis tools (e.g., energy simulation software) to evaluate renovation scenarios without requiring the IFC model to be merged.

The proposed method transforms geometric surface-contact evidence into semantic envelope systems, thereby enabling the integration of distributed BIM data for energy performance evaluation. By decoupling geometric analysis from semantic representation, the approach preserves model independence while supporting cross-model reasoning and system-level assessment.

As illustrated in Figure 1, the workflow is structured into four main steps: independent IFC model, geometry-driven topological analysis and semantic translation, semantic enrichment through topological relation, and data extraction for domain-specific analysis.

Step 1 – Independent IFC model.

The IFC^{as-is} model is analysed and a corresponding IFC^{to-be} model is generated. Both models are treated as independent data sources, each containing specific objects and performance-related properties associated with different project phases. The objects of both models lack explicit relationships that a machine can interpret.

Step 2 – Geometry-driven topological analysis and semantic translation.

- *Step 2.a – Surface-based topological analysis.*
  A geometry-driven topological analysis is performed on the geometric representations of the as-is and to-be models to identify surface-level contact evidence between envelope objects. Topological adjacency is inferred from geometric conditions, including the detection of coplanar and oppositely oriented surfaces exhibiting a significant overlap area. This process produces a set of candidate adjacency relations expressed as pairs of element identifiers (GUID) and associated overlap metrics.
- *Step 2.b – Semantic representation of BIM data.*
  In parallel, the IFC^{as-is} and IFC^{to-be} models are independently translated into RDF reusing BOT and BEO ontology, generating two separate knowledge graphs (KG) that preserve the original model structure, geometry references, and performance-related properties.

Step 3 – Semantic enrichment based on geometry-driven topological analysis.

The geometric adjacency evidence obtained in Step 2.a is subsequently materialized as new semantic relations between the KG^{as-is} and KG^{to-be} generated in Step 2.b. Specifically, adjacency relations are instantiated as topological relations using the BOT ontology (e.g., `bot:Interface`), enabling the formal representation of cross-model envelope systems. This step represents the transition from geometry-driven evidence to explicit, machine-interpretable topological knowledge that can be queried, reasoned upon, and exploited in downstream analyses.

Step 4 – Data extraction for domain-specific analysis.

The enriched knowledge graph is queried using SPARQL to retrieve envelope-system-level data, including thermal properties originating from both the as-is and to-be models. These data are then provided as input to external energy analysis software to support detailed performance assessment of renovation strategies.

Topological analysis and overlap metric

This section builds upon the geometric processing and semantic preparation steps introduced in the previous methodology, focusing on the formal definition of topological analysis and its associated overlap metric. In the proposed approach, topological analysis is not assumed as an input condition but is derived from geometric surface evidence through a geometry-driven inference process. The objective is to identify physically meaningful adjacencies between building objects belonging to independent IFC_{as-is} and IFC_{to-be} models.

Geometry-driven topological analysis

Geometry-driven topological analysis is defined as the process of identifying adjacency relations between objects belonging to independent BIM models based on geometric surface evidence. Rather than relying on predefined semantic links or model merging, adjacency is inferred by analysing the spatial configuration and mutual compatibility of envelope surfaces.

This geometry-driven topological analysis enables the creation of cross-model relations that are not explicitly represented in the original IFC data, but are essential for system-level reasoning in renovation workflows.

Geometric preprocessing and surface abstraction

Each target building object (e.g., wall) is first converted from its native IFC geometric representation into a triangulated surface mesh. This tessellation step is required to homogenize heterogeneous IFC geometry definitions (e.g., swept solids, boundary representations) into a common computational format suitable for surface-based analysis.

Formally, each object Obj is represented as a set of trian-

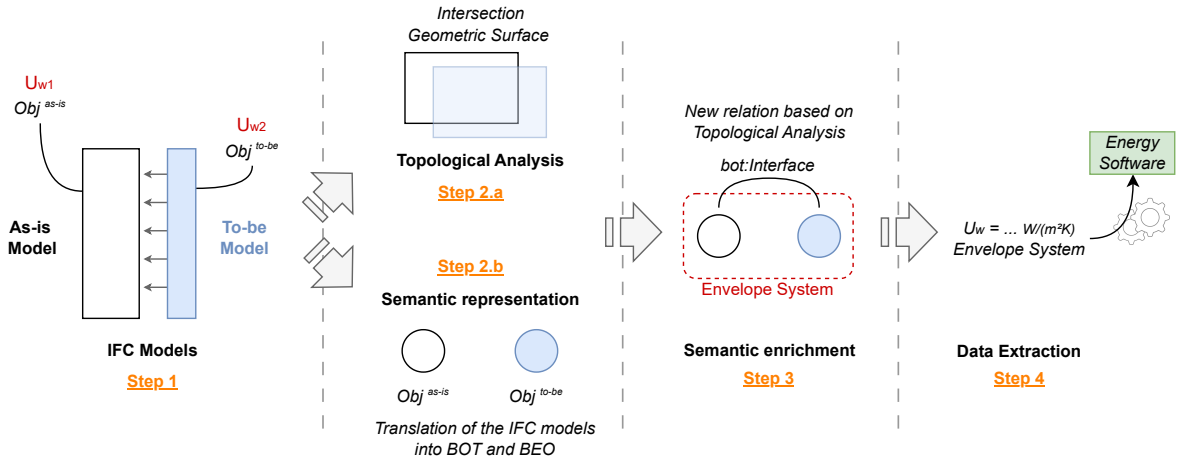

Figure 1: Methodology

gular faces:

$$\mathcal{T}(Obj) = \{t_k \mid t_k = (\mathbf{v}_{k1}, \mathbf{v}_{k2}, \mathbf{v}_{k3})\} \tag{1}$$

where $\mathbf{v}_{ki} \in \mathbb{R}^3$ are the triangle vertices expressed in a shared world coordinate system.
To reduce the computational complexity of subsequent operations, an axis-aligned bounding box (AABB) $B(Obj)$ is computed for each object and used for broad-phase spatial filtering. Only object pairs whose bounding boxes intersect are considered for further analysis.
For each triangle t_k, fundamental geometric descriptors are computed, including surface normal, area, and supporting plane. Individual triangles are then aggregated into *macro-faces* representing extended planar surface regions by grouping coplanar triangles with similar orientation. Each macro-face f is characterized by a unit normal $\mathbf{n}_f$, a supporting plane π_f, a total area $A(f)$, and a vertical extent $[z_{\min}, z_{\max}]$.
This surface abstraction step provides a compact and semantically meaningful representation of envelope geometry, enabling robust surface-level comparison across independent models.

Surface compatibility conditions

Let f_a and f_b be two macro-faces belonging respectively to an as-is object Obj_i^{as-is} and a to-be object Obj_j^{to-be}. The two surfaces are considered topologically compatible only if the following geometric conditions are simultaneously satisfied.

Opposite orientation

The two surfaces must face each other, ensuring the physical plausibility of a contact interface:

$$\angle(\mathbf{n}_{f_a}, -\mathbf{n}_{f_b}) < \varepsilon_\theta \tag{2}$$

where $\mathbf{n}_{f_a}$ and $\mathbf{n}_{f_b}$ denote the unit normal vectors of the two macro-faces.

Coplanarity

The supporting planes of the two surfaces must coincide within a geometric tolerance:

$$\text{dist}(\pi_{f_a}, f_b) < \varepsilon_d \tag{3}$$

where π_{f_a} denotes the plane associated with f_a and the distance is evaluated using a point of f_b.

Vertical overlap

To exclude geometrically coplanar but vertically misaligned surfaces, a vertical overlap constraint is introduced:

$$\min(z^a_{\max}, z^b_{\max}) - \max(z^a_{\min}, z^b_{\min}) > \tau_z \tag{4}$$

where $[z^a_{\min}, z^a_{\max}]$ and $[z^b_{\min}, z^b_{\max}]$ represent the vertical extents of the two macro-faces.
Together, these conditions ensure that only surface pairs capable of defining a physically meaningful interface are retained for further evaluation.

Overlap metric definition

For each pair of geometrically compatible macro-faces, a quantitative overlap metric is computed to assess the extent of the contact. Each surface is projected onto a local two-dimensional coordinate system defined on its supporting plane. The union of projected triangles forms a planar polygon representation P_f for each macro-face.
The effective contact surface area is computed as:

$$A_\cap(f_a, f_b) = \text{area}(P_{f_a} \cap P_{f_b}) \tag{5}$$

To provide a normalized and scale-independent measure, an overlap ratio is defined as:

$$\rho(f_a, f_b) = \frac{A_\cap(f_a, f_b)}{A(f_a)} \tag{6}$$

The overlap ratio expresses the proportion of the as-is surface that is covered by the to-be surface, enabling a quantitative comparison between different contact configurations.

Decision rule for adjacency inference

A topological adjacency relation between two objects Obj_i^{as-is} and Obj_j^{to-be} is inferred if at least one pair of their macro-faces satisfies the overlap condition:

$$\exists (f_a, f_b) \quad \text{s.t.} \quad \rho(f_a, f_b) \geq \tau \tag{7}$$

where τ is a user-defined threshold controlling the minimum required contact significance.
This rule allows multiple Obj_j^{to-be} to be associated with a single Obj_i^{as-is}, resulting in a one-to-many topological matching configuration. The inferred adjacency relations constitute the basis for subsequent semantic enrichment. Topological matching is thus formulated as a geometry-driven inference process, in which surface overlap metrics provide both qualitative adjacency relations and quantitative evidence supporting system-level aggregation.

Semantic linking and data exploitation

The set of inferred adjacency relations produced by the geometry-driven topological analysis is subsequently materialized in a semantic knowledge graph. To manage the complexity of IFC representations, the models are translated reusing the BEO ontology, which provides a lightweight taxonomy for objects such as `beo:Wall` and `beo:Insulation`, facilitating more efficient SPARQL querying compared to the direct translation of the EXPRESS schema into IfcOWL which could generate millions of RDF triples. Each objects pair $(Obj_i^{as-is}, Obj_j^{to-be})$ is mapped to its corresponding RDF individuals using the *IfcGlobalUniqueId* as a linking key. To maintain ontological correctness—given that `bot:adjacentElement` is formally restricted to Zone-to-Element relations—the physical contact between the Obj_i^{as-is} and Obj_j^{to-be} is represented through the `bot:Interface` class. This approach allows for the creation of a topological "bridge" between the two models, where a single interface instance is declared as `bot:interfaceOf` both the existing objects and the new retrofit objects. The inferred relations are asserted in a dedicated KG that operates as a federated layer over the original KG^{as-is} and KG^{to-be}. This architecture preserves the integrity of the original BIM data while enabling the explicit representation of cross-model adjacencies derived from geometric evidence. This semantic enrichment enables advanced cross-model querying of envelope systems through SPARQL. By relating objects coming from independent IFC models into a KG, specific data (e.g., *U*-values) can be structured, extracted, and used as input data for domain-specific simulation tools.

Case study and results

As a case study, a typical building envelope retrofit scenario was considered, featuring an existing wall with an opening (a window), as illustrated in Figure 2. Despite its simplicity, the case study already includes relevant complexities, such as multiple elements, the presence of an opening, and partial geometric misalignments (e.g., vertically offset objects). These aspects allow demonstrating the method's ability to correctly identify meaningful adjacencies while effectively excluding false positives. The IFC^{as-is} model represents the existing state, characterized by a multi-layered composition (internal plaster, masonry, and external plaster). The IFC^{to-be} model includes only the retrofit objects, namely an external insulation system applied to the existing wall and a final plaster finish.

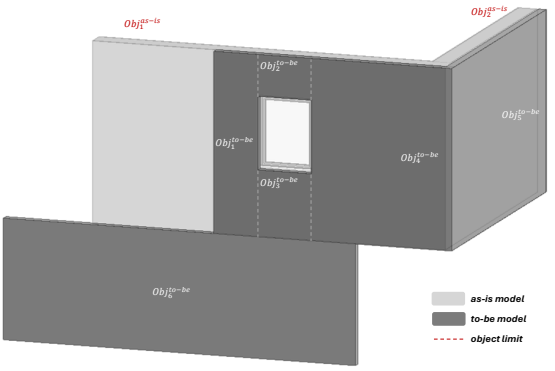

Figure 2: CaseStudy

To evaluate the proposed geometry-driven topological analysis, the retrofit objects were intentionally modeled as separate objects (Obj_1^{to-be}, Obj_2^{to-be}, Obj_3^{to-be}, Obj_4^{to-be}, and Obj_5^{to-be}) and some with a vertical offset relative to the existing objects (Obj_6^{to-be}). This modeling choice was adopted to test the algorithm's ability to distinguish between geometrically coplanar surfaces but with vertically misaligned surfaces and those with physically significant adjacencies, ensuring that only overlapping object surfaces are identified as valid contacts.
The case study was designed as a simplified yet representative scenario that reflects common building envelope renovation scenarios. Although limited in scale, it provides a controlled setting to evaluate the proposed method before its application to larger and more complex case studies within the ongoing research project.
Both models were exported using a shared coordinate system in IFC 4.3 ADD2 format and subsequently processed using a custom Python code (Python 3.10) to perform the geometry-driven topological analysis. In parallel, the IFC models were translated into lightweight semantic representations based on the BOT and BEO ontologies with the IFCtoLBD converter (Oraskari et al., 2024). The reuse of these ontologies provides a more compact and tractable structure compared to full ifcOWL representations, enabling efficient graph-based data management for the renovation process. The resulting RDF graphs were stored and queried using an Ontotext GraphDB.

Geometric matching results

The geometry-driven topological analysis was executed automatically on the two IFC models described in the pre-

vious section, following the methodology steps presented in the section *Topological Analysis and Overlap Metric*. The algorithm successfully identified the contact surfaces between existing objects (Obj_1^{as-is} and Obj_2^{as-is}) and new retrofit insulation objects (Obj_1^{to-be}, Obj_2^{to-be}, Obj_3^{to-be}, Obj_4^{to-be}, and Obj_5^{to-be}), while correctly excluding non-relevant surfaces (Obj_6^{to-be}).
No false-positive adjacencies were detected between geometrically coplanar but vertically misaligned surfaces (Figure 3).

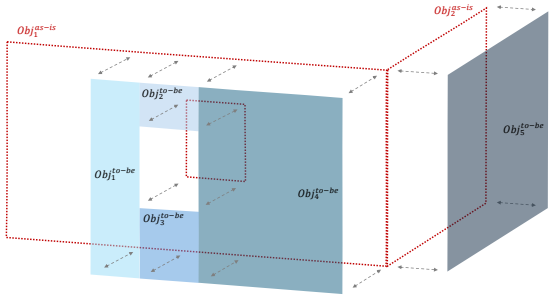

Figure 3: Geometry-driven topological analysis results.

The two existing walls of the IFC^{as-is} model were found to be adjacent to objects in the IFC^{to-be} model. In the scenario visible in Figure 2, a single existing object (Obj_1^{as-is}) was correctly associated with four different objects (Obj_1^{to-be}, Obj_2^{to-be}, Obj_3^{to-be}, and Obj_4^{to-be}), corresponding to the segmented area around the window opening. For all four objects, the coverage ratio computed with respect to the Obj_j^{to-be} surfaces exceeded 94%, indicating that each retrofit object is almost entirely supported by the existing wall, despite covering only a limited portion of its surface.
On the other side, a one-to-one correspondence between an existing object (Obj_2^{as-is}) and a retrofit object (Obj_5^{to-be}), with surface coverage ratios close to 100% on both sides, reflecting a full surface alignment.
The geometry-driven topological analysis results are summarized in Table 1, which respectively illustrate the contact surfaces identified between the existing objects (Obj_i^{as-is}) and the retrofit objects (Obj_j^{to-be}), including the corresponding surface coverage ratios for each detected adjacency. The results confirm that only geometrically and vertically aligned surfaces are selected, while areas associated with openings or without existing objects behind are correctly excluded. Furthermore, the results confirm the ability of the proposed algorithm to identify meaningful adjacency relations across independent IFC models and to quantify their geometric consistency through surface-based overlap metrics.

Semantic linking results

The adjacency relations inferred at the geometric level were automatically generated in a dedicated RDF case-study graph (KG^{link}). Starting from the set of matched object pairs produced by the geometry-driven topological analysis, the linking process was executed automatically.
Each pair of matched objects was identified across the independent KG_{as-is} and KG_{to-be} using the *IfcGlobalId* as a unique linking key. For each identified contact, a `bot:Interface` individual was automatically instantiated in KG^{link} and asserted as `bot:interfaceOf` both the existing `bot:Element` and the corresponding retrofit `bot:Element`. This approach enables the explicit and ontologically consistent representation of object-to-object adjacencies across independent BIM models.
All interface instances and their properties were generated directly from the output of the geometry-driven algorithm, ensuring full traceability between geometric evidence and semantic assertions (Figure 4). The resulting structure transforms a set of geometrically fragmented objects into a coherent, machine-interpretable system in which individual components are explicitly related through formal semantic constructs, thereby enabling consistent reasoning, querying, and exploitation via SPARQL.

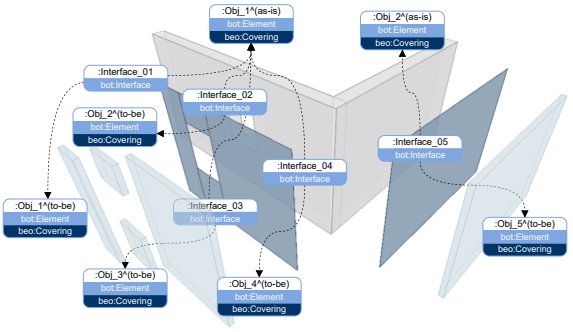

Figure 4: Ontology-based adjacencies as `bot:Interface` instances linking as-is and to-be objects.

Energy-oriented data extraction

The semantic linking introduced in the previous step enables the formulation of cross-model SPARQL queries that directly operate on physically meaningful object-to-object relations. By exploiting the `bot:Interface` individuals created in KG^{link}, existing and retrofit objects that are physically adjacent in the renovated envelope can be queried jointly, despite originating from independent KG^{as-is} and KG^{to-be} representations.
In this context, energy-related properties are retrieved by traversing the `bot:interfaceOf` relations and accessing the property states associated with the linked objects. Specifically, the thermal transmittance values of both the as-is and the to-be objects are extracted through their respective IFC property representations, using the *IfcGlobalId* as a stable linking key. This allows the selective retrieval of thermal properties only for object pairs that have been previously identified as physically adjacent through geometry-driven analysis.
As a result, thermal transmittance values that are distributed across separate BIM models can be aggregated at

Table 1: Geometry-driven topological analysis results with objects GUID and surface coverage ratios.

3320QKjsPDs8e51pe4k$Fe	2ew7MBEPb01OZYaDjw2rmp	Coverage Obj_2^{as-is}: 100% Coverage Obj_5^{to-be}: 99.56%

the level of the renovated envelope assembly. The query returns, for each interface, the identifiers of the connected objects and their corresponding thermal transmittance values, providing a structured and machine-interpretable dataset that can be directly consumed for system-level energy performance evaluation. This demonstrates how geometry-derived semantic relations act as an enabling layer for performance-oriented data extraction without requiring IFC model merging or manual data preparation.
Importantly, the query operates at interface level rather than at individual object level, implicitly shifting the data extraction perspective from single BIM objetcs to physically reconstructed envelope systems. The query is independent of specific IFC schemas or modeling conventions and can be reused across different renovation scenarios, provided that geometry-derived interfaces have been materialized in the linking graph. In this context, a SPARQL query was defined to retrieve, for each detected interface, the identifiers of the connected as-is and to-be objects with their associated thermal transmittance values (Listing 1). The query selectively extracts thermal properties only for object pairs that have been previously identified as physically adjacent through geometry-driven analysis, ensuring that energy-related data are aggregated at the envelope-system level rather than at individual object level.

Discussion

The case study demonstrates the effectiveness of the proposed approach in identifying physically meaningful adjacency relations between objects belonging to independent BIM models and in enabling their subsequent semantic integration for performance-oriented analyses. Despite the limited scale of the test scenario, the results confirm the robustness of the geometry-driven topological analysis in accurately detecting real physical contacts while systematically excluding irrelevant adjacencies, such as geometrically coplanar but non-touching surfaces and regions associated with openings.
A key contribution of the proposed method lies in its ability to operate across independent as-is and to-be models without requiring prior alignment, model merging, or manual re-modelling. Through geometry-driven topological analysis and semantic linking, the method explicitly encodes which objects from different models are physically related in the built environment. This capability is particularly relevant in renovation scenarios, where the physical reality of the building envelope is distributed across multiple BIM representations that remain semantically disconnected in conventional workflows.
By creating object-to-object adjacencies as explicit semantic relations, the method enables the reconstruction of coherent envelope systems that exist in reality but are not directly represented in the virtual models. In practice, multiple retrofit components, such as insulation panels, can be correctly interpreted as belonging to the same functional

wall assembly, despite being modeled as separate objects in the to-be model. This transformation allows the machine to reason about which objects jointly contribute to the same physical construction package, overcoming a well-known limitation of geometry-only or model-centric BIM analyses.

From a data exploitation perspective, this semantic reconstruction directly supports the automated extraction and aggregation of performance-related properties. System-level data, such as thermal transmittance (U-values), can be computed by combining properties originating from distinct models but semantically linked through the identified interfaces. As a result, the output of the proposed workflow constitutes a ready-to-use, structured dataset that can be consumed by external energy simulation engines and emerging Digital Twin platforms, without additional manual interpretation or data preparation.

More broadly, the approach contributes to bridging the gap between raw geometric evidence and higher-level semantic representations that are required for advanced analysis and decision-making. This enables comparison of renovation strategies, supporting building-level decision-making. By making physical relationships between independently modeled objects explicit and machine-interpretable, the proposed method enhances interoperability, traceability, and automation in renovation-oriented BIM workflows.

Conclusion

This paper presented a geometry-driven and ontology-based approach to identify and semantically represent adjacency relations between independent BIM models in renovation scenarios, enabling cross-model reasoning and reconstruction of envelope systems without model merging. By combining surface-based topological matching with semantic linking through the BOT ontology, the proposed method enables the explicit representation of physical relations not encoded in BIM data, allowing fragmented objects to be integrated into coherent building systems.

The case study demonstrates the robustness of the approach in detecting adjacencies while excluding irrelevant configurations. It further shows that fragmented retrofit objects can be correctly interpreted as part of coherent envelope systems, reflecting real construction logic rather than the modeling constraints of individual BIM models.

Through the creation of object-to-object adjacencies as machine-interpretable semantic relations, the proposed workflow bridges the gap between raw geometric evidence and structured semantic data. This enables the automated aggregation and extraction of performance properties, supporting system- and building-level performance analysis and enabling comparison of alternative renovation scenarios, while providing a ready-to-use input for energy simulation, and emerging Digital Twin platforms, without requiring manual model alignment or re-authoring. In conclusion, the proposed approach enables a shift from object- to system-level reasoning, which is essential for supporting renovation decision-making processes.

Despite the promising results, some limitations can be identified. The accuracy of the geometry-driven topological analysis depends on the quality of the IFC geometric representations, which may vary across authoring tools and levels of detail. Furthermore, the present validation is limited to a small-scale case study and does not provide a comprehensive evaluation of computational performance on large and highly detailed models. Future research will focus on validating the approach on larger and more complex case studies, such as multi-wall assemblies, multiple openings, and non-orthogonal geometries, as well as on systematically evaluating its computational performance and scalability in real-world renovation scenarios.

LATENCY-AWARE CONSTRUCTION ACTIVITY RECOGNITION USING KINEMATIC AND PHYSIOLOGICAL SENSORS

Umutcan Kılıç and Semra Çomu
Boğaziçi University, Türkiye

Abstract

Wearable sensors are increasingly being used to monitor worker activity and safety. While Human Activity Recognition (HAR) studies predominantly rely on kinematic data, physiological signals remain mostly underexplored due to the delayed nature of physiological responses. This study investigates the fusion of physiological and kinematic modalities by systematically evaluating temporal offsets to compensate for physiological latency. Results show that classification performance is sensitive to delay magnitude, with optimal performance achieved using an 8-second window and a 4-second time lag. Based on these findings, a latency-aware fusion protocol is proposed to enable robust multimodal HAR in wearable-based worker monitoring systems.

Introduction

The construction industry is characterized by dynamic and hazardous working environments, making occupational safety and health (OSH) a significant concern. To mitigate OSH-related risks, various methods have been proposed to monitor the physical and physiological status of the workforce (Antonaci et al., 2024). Enabling continuous and non-intrusive worker monitoring, Human Activity Recognition (HAR), which refers to automatic identification of human activities and movements using machine learning and deep learning algorithms, has emerged as a prominent approach for data-driven safety assessments and productivity tracking (Sedaghati et al., 2025).

HAR systems can be categorized into two types based on data modalities: visual and non-visual (Sun et al., 2022). Compared to vision-based systems, non-visual HAR solutions are cost-effective, capable of fine-grained recognition, less vulnerable to environmental conditions, and better at protecting worker privacy, making them attractive options for construction settings (Sun et al., 2022).

Non-visual HAR systems are predominantly based on kinematic data derived from Inertial Measurement Units (IMUs), such as accelerometers and gyroscopes (Shin et al., 2025). While effective for classifying physical movements such as walking, bending, or standing, kinematic sensors are inherently limited to describing motion-related patterns. They provide minimal insight into the physiological effects of construction tasks on workers' bodies, such as physical exertion, fatigue, or physiological stress, which are critical metrics for comprehensive safety monitoring (Kazar & Comu, 2021). On the other hand, physiological data, including Heart Rate (HR), Blood Volume Pulse (BVP), Electrodermal Activity (EDA), and Skin Temperature (ST), offer a promising complementary data stream to fill this gap. However, despite its potential to provide a holistic view of worker well-being, physiological data remains mostly unexplored in the context of activity recognition models (Demrozi et al., 2020).

One of the primary barriers to effectively integrating physiological data into HAR models is temporal misalignment. Unlike kinematic signals, which change instantaneously with body movement, physiological responses exhibit biological latency. For instance, while individual variability exists, a cardiovascular response to physical exertion typically occurs a few seconds after the onset of the stressor (Javorka et al., 2003). Similarly, EDA responses typically exhibit a latency of 2 to 6 seconds following a sudden physiological stressor (Yu et al., 2024). Consequently, standard sensor fusion approaches that align data streams strictly based on timestamps result in a mismatch between the physical action and the biological reaction, introducing noise into the dataset rather than enhancing it.

This study aims to address the synchronization challenge by investigating different temporal alignment strategies for multimodal HAR. We utilize machine learning (ML) to test the performance of proposed data fusion strategies and compare different data modalities. In particular, we systematically analyze the impact of different window sizes and the introduction of artificial time-lags to the physiological data stream, aiming to bridge the gap between physical action and physiological reaction. Based on this analysis, the study proposes a latency-aware fusion protocol designed to enable robust multimodal worker monitoring.

Methodology

The experimental study was conducted in a controlled environment at the Structure Laboratory of Boğaziçi University, spanning approximately 660 m² with a ceiling height of 12 meters. The experimental dataset was collected from five healthy male subjects, with no record of an injury or condition that might affect their postures or physiological responses, during independent sessions.

Before each session, the participants were briefed regarding the experiment and provided their informed consents. Table 1 summarizes the demographic details of participants, including age, height, and weight.

Table 1: Participant details

ID	Age (years)	Weight (kg)	Height (cm)
1	26	91	193
2	25	105	187
3	57	98	180
4	58	59	170
5	26	63.5	174

To capture a comprehensive set of kinematic and physiological data, the participants were instrumented with two wearable devices. An Apple iPhone 16 Pro Max smartphone (Apple Inc., Cupertino, CA, USA) was positioned at the lumbar region using an adjustable cloth belt to record gross body movements via its Inertial Measurement Unit (IMU). Because of its proximity to the human body's center of mass, this placement enables effective analysis of overall movement patterns (Wlodzimierz, 2018). The "Physics Toolbox Sensor Suite" application was utilized to log tri-axial gyroscope and accelerometer data (both at 100 Hz), storing the files locally in Comma Separated Values (CSV) format. Simultaneously, an Empatica EmbracePlus smartwatch (Empatica Inc., Boston, MA, USA) was worn on the non-dominant wrist to acquire kinematic data associated with hand movements and physiological signals. Although the smartwatch hardware includes a gyroscope, only tri-axial accelerometer data was recorded (at 64 Hz) due to access restrictions imposed by the "Academic & Basic Research" plan of Empatica. Physiological data included Blood Volume Pulse (BVP) recorded at 64 Hz, Systolic Peaks, EDA recorded at 4 Hz, and ST recorded at 1 Hz. The data collected by the smartwatch was retrieved via the manufacturer's dedicated data access platform as Avro files and subsequently converted to CSV format for further processing. Based on raw Systolic Peaks data, instantaneous HR values were derived by computing inter-beat intervals (IBI) and converting them to beats per minute. HR values outside the physiologically plausible range of 40–200 bpm were discarded as artifacts. The resulting irregularly sampled HR measurements were transformed into a continuous signal using linear interpolation and resampled at 10 Hz to obtain a uniformly spaced time series suitable for temporal analysis and multimodal synchronization. In addition, ST signals, originally recorded at 1 Hz, were upsampled via linear interpolation to a uniform sampling frequency of 4 Hz to prevent data loss at sliding window boundaries.

To capture physiological responses under varying levels of physical exertion, participants followed a physically demanding experimental protocol lasting approximately 30 minutes, designed to simulate continuous construction work. Each session began with a 5-minute seated rest baseline measurement phase (no movement or talking) to capture resting levels of EDA, ST, and cardiovascular signals derived from BVP, including systolic peaks and IBI (Posada-Quintero et al., 2018; Damoun et al., 2024). For analysis purposes, the first and last 30 seconds of the baseline measurement phase were omitted to account for participant settling time. Following the initial omitted period, the subsequent 240 seconds were labeled as the sitting baseline. Any remaining data from the seated baseline measurement was excluded from the analysis to prevent data leakage.

The experiment sessions were structured into four identical activity blocks and were performed across four custom-built stations designed to replicate common construction-related tasks. The first station involved six repetitions of walking on a narrow wooden plank (measuring 2.95 m in length and 0.15 m in width, elevated 25 cm above ground level) to challenge balance and stability. For safety purposes, buffer planks with a width of 20 cm were installed on both sides; however, participants were instructed to walk strictly on the central narrow plank. The second station consisted of two repetitions of accessing a mezzanine platform (measuring 6.3 m by 2.0 m at a height of 2.8 m) via a spiral staircase. Upon reaching the platform, participants walked to its end before descending back to ground level. The third station required participants to climb a standard scaffold (measuring 2.7 m by 0.8 m), featuring two working levels at heights of 0.60 m and 2.55 m. Participants ascended the scaffold using a ladder, reached the upper working level, and descended. The fourth station focused on material handling and involved transferring four separate loads (one 10 kg metal plate, one 5 kg metal plate, and two 1 kg wooden plates) from a platform at 30 cm height onto a pallet truck bed positioned at 10 cm height. Participants then pulled the loaded pallet truck over a distance of approximately 25 meters before returning to the starting position to unload the weights.

Each activity block began with a 60-meter regular walking segment, followed by the execution of all four stations in sequence, and concluded with an additional visit to the first station. After completing the first two blocks, participants took a one-minute standing rest period to emulate a brief work break. After this short recovery phase, the remaining two blocks were performed. The experiments were concluded with a one-minute seated rest period to capture post-activity physiological recovery dynamics. Figure 1 illustrates the content of an experimental session.

To establish precise ground truth for activity labeling, the experimental sessions were recorded on video at 60 fps using an Apple iPhone 16e (Apple Inc., Cupertino, CA, USA) and a GoPro Hero 4 (GoPro Inc., San Mateo, CA, USA). The smartphone captured the third-person view, while the GoPro recorded the first-person view of a given participant. Third-person videos were embedded with real-time timestamps with millisecond precision using the "Timestamp Camera Basic" application. Subsequently,

first- and third-person recordings were synchronized using visual cues via CapCut software.

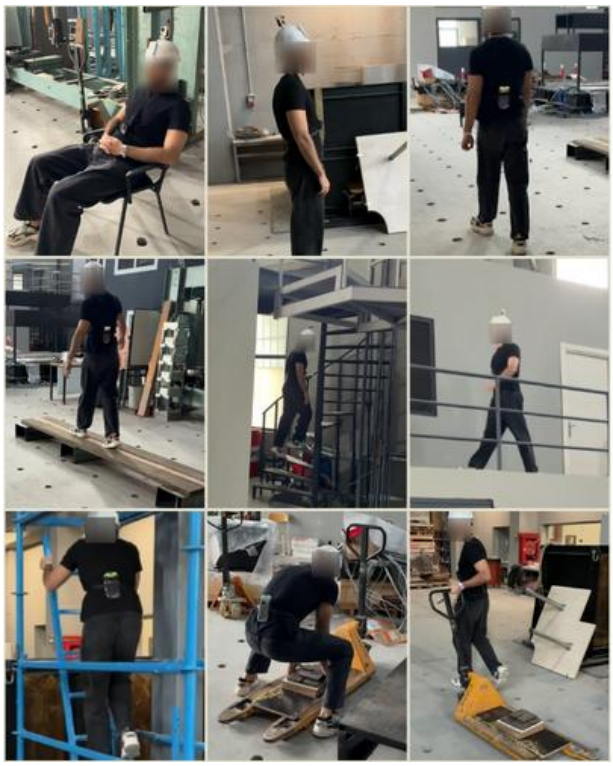

Figure 1: Typical content of an experimental session

Ground truth labeling was performed manually using ELAN software, where activity start and end points were annotated relative to the video timeline (ELAN, 2025). Based on the video footage, various activity types were labeled as shown in Table 2. All annotations were performed by trained annotators following a predefined labeling protocol, which was designed to minimize inter-rater variance by establishing rules that define exact start and end moments of activities. Interruptions during the experiment or other unclassified movements were labeled as junk and excluded from the analysis.

Table 2: Activity Types and Annotation Labels

Activity	Types	Label
Sitting	-	Sitting
Standing	-	Standing
Walking	Normal, Plank, Mezzanine Platform, Scaffolding	Walking
Climbing Stairs	-	N_Stairs
Climbing Ladder	-	V_Stairs
Bending	Hip Hinge, Squat	Bending
Cart	Pulling, Pushing	Cart
Junk	-	Junk

To mitigate temporal discrepancies caused by the Variable Frame Rate (VFR) inherent in smartphone video encoding while converting video-relative timestamps to Unix timestamps for feature extraction purposes, we implemented a piecewise linear interpolation-based conversion algorithm. To serve as anchor points, we extracted the first and the last frames of a given video, as well as a reference frame every 3600 frames (approximately 60 seconds) using FFmpeg (Version 6.0). For each extracted frame, we recorded the exact start time of the frame relative to the video start and the Unix timestamp embedded within the frame, both with millisecond precision. The algorithm was then applied to convert the manually annotated video-relative activity start and end timestamps into sensor-compatible Unix timestamps using (1),

$$T_{unix}(t) = U_i + \frac{(U_{i+1} - U_i)}{(V_{i+1} - V_i)} \cdot (t - V_i) \qquad (1)$$

where t represents the annotated video-relative timestamp, and (V_i, U_i) and (V_{i+1}, U_{i+1}) denote the video-relative and Unix timestamps of the two consecutive anchor frames enclosing t, respectively. This approach effectively compensated for the non-linear time drift associated with VFR, ensuring millisecond-level alignment between the visual ground truth and the multimodal sensor data.

Following the conversion of all ground truth annotations to Unix timestamps, the synchronized multimodal sensor data were segmented using a sliding window approach. Sliding window segmentation is commonly employed in time-series machine learning to compute window-level feature representations, where each window contains a fixed-length segment of data and adjacent windows overlap by a predefined percentage to preserve temporal continuity and increase the number of training samples. Based on the selected window lengths and overlap ratios, sliding windows were generated over the entire duration of each experimental session independently for each participant.

Since experiment sessions followed a continuous flow, a consensus-based labeling strategy was employed to assign activity labels at the window level. Rather than isolating different activities, we generated windows with selected lengths and overlap percentages from the start of a session, marked with the start Unix timestamp of the sitting baseline measurement. For each window, ground truth labels corresponding to the annotated activities were examined, and a window was assigned a class label only if at least 75% of its duration was occupied by a single activity. Windows that did not meet this criterion were considered mixed and excluded from the analysis. This threshold was empirically selected as a trade-off between label purity and data retention, aiming to reduce noise introduced by transitional movements while preserving a sufficient number of valid samples.

For each window, statistical and temporal features were extracted independently from each sensor channel. For BVP, HR, EDA, and ST signals, extracted features included mean, standard deviation, maximum, range,

energy (2), slope (defined as the difference between the last and first sample within each window, normalized by the window duration), and delta (defined as the difference between consecutive windows).

$$E = \frac{1}{N}\sum_{i=1}^{N} x_i^2 \quad (2)$$

Baseline-based z-score normalization was applied to level-dependent physiological features (mean, standard deviation, maximum, and energy) using (3) to reduce inter-subject variability and ensure comparability of the data across participants, whereas change-based features (range, slope, and delta) were computed in the original signal scale to preserve absolute variation within each window.

$$z_i = \frac{(x_i - \mu)}{\sigma} \quad (3)$$

where x_i denotes the physiological feature for the ith window, and μ and σ are the mean and standard deviation of the feature calculated over the baseline measurement period, respectively.

For kinematic data (accelerometer and gyroscope), axis-wise (x, y, z) features (mean, standard deviation, minimum, maximum, and range) and magnitude-based features including signal magnitude area (SMA), vector magnitude–based features (mean and standard deviation), and linear or angular jerk (approximated using first-order differences of acceleration and angular velocity signals, respectively) were extracted.

Table 3 and Table 4 summarize the feature sets generated from the multimodal sensor data.

Table 3: Physiological feature set and applied normalization methods

Sensor	Features	Normalization
BVP	Energy, Mean, Standard Deviation	z-Score
BVP	Range	None
HR	Maximum, Mean	z-Score
HR	Range, Slope	None
EDA	Energy, Maximum, Mean, Standard Deviation	z-Score
EDA	Range, Slope	None
ST	Mean	z-Score
ST	Delta	None

To explicitly investigate the effect of biological response latency on activity classification, we utilized a systematic parameter search strategy. While the sensor data were segmented using multiple window lengths (1, 2, 4, and 8 seconds) combined with overlap ratios of 50% and 75%, we simultaneously introduced temporal offsets ranging from 0 seconds (no delay) to 8 seconds in 1-second increments. This resulted in a total of 72 distinct window configurations. In this protocol, kinematic features were extracted synchronously with the ground truth activity labels to capture immediate physical motion. In contrast, physiological features were extracted from a time window shifted forward by the delay amount, aiming to align the delayed biological response with the causing physical activity. This approach allows for a controlled assessment of how explicit temporal alignment influences classification performance, independent of window size.

To evaluate the contribution of physiological signals to HAR models, we compared the performance of models trained on six different sensor combinations. This approach resulted in 240 distinct model configurations: for kinematic-only models, 3 sensor combinations with 8 window configurations each; and for models involving physiological data, 3 sensor combinations with 72 window configurations each. Based on the extracted feature vectors for each model configuration, activity classification models were trained using a Random Forest (RF) classifier with 100 estimators (trees), which is widely adopted as a strong baseline in machine learning (ML)–based HAR studies (Demrozi et al., 2020). To avoid data leakage and ensure robust, subject-independent evaluation, a Leave-One-Subject-Out (LOSO) cross-validation scheme was employed. In each fold, data from one participant were reserved for testing, while data from all remaining participants were used for training. Model performance was evaluated using standard classification metrics, including accuracy, precision, recall, macro and weighted F1-scores, as well as confusion matrices, enabling both class-wise and overall performance assessment. This procedure was iterated for all 240 model configurations, enabling a comparative assessment to identify the optimal temporal alignment strategy and to see the performance differences between different sensor configurations. Since all five experimental sessions had similar durations, F1-scores were reported as the average performance across all LOSO folds, unless otherwise specified.

Table 4: Kinematic feature set

Sensor Type	Feature Type	Features
Accelerometer	Axis-wise (x, y, z)	Maximum, Mean, Minimum, Range, Standard Deviation
Accelerometer	Magnitude-based	Linear Jerk, Mean Vector Magnitude, Signal Magnitude Area, Standard Deviation of Vector Magnitude
Gyroscope	Axis-wise (x, y, z)	Maximum, Mean, Minimum, Range, Standard Deviation
Gyroscope	Magnitude-based	Angular Jerk, Mean Vector Magnitude, Signal Magnitude Area, Standard Deviation of Vector Magnitude

Results and discussion

First, we analyzed the distribution of ground truth activity labels to characterize the dataset. Based on the video annotations, we calculated the combined total duration of the five experiment sessions to be 9756.833 seconds. As summarized in Table 5, "Walk" constituted the largest portion of the data with 4277.145 seconds (43.84%), followed by "Junk" segments and "N_Stairs".

Following the exclusion of invalid segments (i.e., Junk) and the removal of transitional periods where 75% label consensus was not met, valid windows were retained for model input. Table 6 summarizes the resulting window counts across different activity types for various window lengths at 50% overlap. On the other hand, setting the overlap to 75% resulted in approximately twice the number of analysis windows compared to the values given in Table 6.

The resulting class distribution reveals a natural imbalance often encountered in HAR literature (Lim et al., 2021). For instance, the dataset used by Sikder & Nahid (2021) exhibits an imbalance ratio of 8.41:1 (max:min), which is comparable to the 11.76:1 ratio observed in our dataset. “Walking” emerged as the dominant class, accounting for approximately 51% of the total samples. In contrast, short-duration or less frequent activities such as “Bending” and “V_Stairs” represented approximately 5% and 6% of the samples, respectively. This observed imbalance underscores the necessity of utilizing macro-averaged metrics alongside weighted metrics to ensure a fair assessment of the model's capability to recognize less frequent activities.

To evaluate the contribution of physiological signals to HAR models, we first compared the performance of models trained on different data modalities, fused using a simple fusion strategy (no temporal offsets), with window lengths of 1, 2, 4, and 8 seconds, and 50% and 75% overlap. The average classification performances of the resulting models are summarized in Figure 2.

As anticipated, scenarios relying solely on physiological data yielded the lowest results (Average Macro F1: 16.29%). Notably, a theoretically uniform random classifier would achieve an F1 score of 14.29%, which is only 12.28% worse than the physiological-only model. This marginal difference confirms that physiological signals alone are insufficient for distinguishing complex locomotor activities. In contrast, the model utilizing only the smartphone IMU data from the lumbar region, a standard configuration in HAR literature, achieved an average Macro F1 score of 69.61%, establishing a strong baseline. For instance, the RF-based LOSO model trained by Chen and Shen (2017) using a similar sensor configuration and placement achieved an average Macro F1 score of 67.21% while classifying 5 activities, indicating that our model performed comparably to previously reported results. The highest performance was observed in the configuration that combined kinematic data from both the smartphone and the smartwatch (Average Macro F1: 79.17%). On the other hand, the simple fusion of physiological signals into this optimal kinematic model resulted in a slight performance decline (Average Macro F1: 77.54%). These findings support the claim that the simple fusion of inherently latent physiological data may introduce noise or redundant information, thereby degrading the classifier's predictive capability rather than enhancing it.

Subsequently, we investigated the interaction between model performance and artificial temporal delays. Figure 3 illustrates the fusion model's sensitivity to different temporal delays across various window sizes and overlap ratios. Based on the results, we identified two key trends.

First, larger time windows consistently yielded higher performance. Specifically, the 8-second window achieved the highest Macro F1 scores across nearly all delay settings, with a few exceptions marginally favoring the 4-second window. This superiority is likely attributable to the ability of longer windows to simultaneously capture slow-varying physiological signals and sudden kinematic changes associated with an activity within the same window.

Secondly, the introduction of artificial delays revealed a surprising but expected concave relationship with performance. While simple fusion (0s delay) provided satisfactory results, particularly for longer windows, introducing a temporal shift to the physiological data significantly enhanced Macro F1 scores. For instance, the highest performance observed in this study was obtained at a 4-second delay with an 8-second window and 75% overlap (Macro F1: 81.22% ± 7.64%), highlighting the potential performance gains of integrating physiological sensors under a latency-aware fusion framework. In comparison, the simple fusion counterpart without temporal delay (0-second delay with an 8-second window and 75% overlap) achieved a lower Macro F1 of 80.12% with a higher standard deviation (± 8.14%), indicating that compensating for physiological latency not only improves overall accuracy but also enhances the consistency of the model across different subjects. However, further increasing the delay almost always led to a degradation in classification performance. This finding aligns with established physiological literature, which suggests that physiological responses typically lag behind the onset of a physical stressor by approximately 2–6 seconds (Javorka et al., 2003; Yu et al., 2024).

Lastly, we compared the confusion matrices and class-wise performance metrics for the overall best-performing model (latency-aware sensor fusion model utilizing an 8-second time window, 75% overlap, and a 4-second temporal shift) and its kinematic-only counterpart (Smartphone + Smartwatch). As illustrated in Figure 4 and Figure 5, both models demonstrated strong diagonal dominance. However, the inclusion of temporally aligned physiological data yielded noticeable improvements in specific activities. A closer inspection of the class-wise performance reveals that the most significant gains were observed in the “Cart” and “Walking” activities. These two activities present a critical challenge for kinematic-only models: the body posture similarity between the activities. As a result, kinematic sensors alone fail to

Table 5: Descriptive statistics of annotated activty classes

Activity	Count	Total Duration (s)	Avg. Duration (s)	Min. Duration (s)	Max. Duration (s)	Distribution (%)
Walking	488	4277.145	8.765	0.435	103.649	43.84%
Junk	486	1683.380	3.464	0.068	94.000	17.25%
N_Stairs	33	1078.334	32.677	3.333	117.434	11.05%
Standing	84	751.653	8.948	5.900	11.800	7.70%
Cart	32	666.601	20.831	3.500	31.800	6.83%
Bending	105	585.852	5.580	0.834	23.470	6.00%
V_Stairs	40	390.132	9.753	5.559	14.951	4.00%
Sitting	5	323.736	64.747	54.423	71.011	3.32%

capture the physical effort required to maneuver an approximately 110 kg pallet truck. In contrast, the latency-aware fusion model integrates the physiological markers of this high-exertion task, allowing the classifier to distinguish it from walking, despite the ambiguous kinematic cues. As a result, the number of "Walking" activities falsely classified as "Cart" decreased from 50 to 8, increasing the F1-score for the "Cart" activity from 60.83% to 67.14%. This suggests that while kinematic sensors effectively capture the distinct motion trajectories of the activities, they may struggle to differentiate the subtle intensity variations associated with them. The physiological signals, acting as an indicator of effort, provide the necessary complementary information to resolve these ambiguities.

Table 6: Total number of activity samples for different window lengths at 50% overlap

Window (s)	1	2	4	8
Walking	8065	3790	1629	650
Standing	2121	1046	505	239
N_Stairs	1416	664	294	102
Cart	1301	637	302	135
Bending	1073	480	180	67
V_Stairs	742	351	156	54
Sitting	593	293	142	67
Total Samples	15311	7261	3208	1314

These class-specific improvements highlight the mechanism behind the performance boost. The 4-second temporal offset effectively synchronizes the delayed physiological response with the immediate kinematic changes. Without this alignment (as observed in the simple fusion case discussed earlier), the physiological marker of a demanding activity registers after the activity label has ceased, creating noise. By shifting the windows, we ensure that the classifier receives both the motion pattern of an activity and the corresponding metabolic effect simultaneously. Consequently, the fusion model does not merely rely on how the subject moves, but also how much effort the movement entails, leading to a more robust and context-aware recognition system.

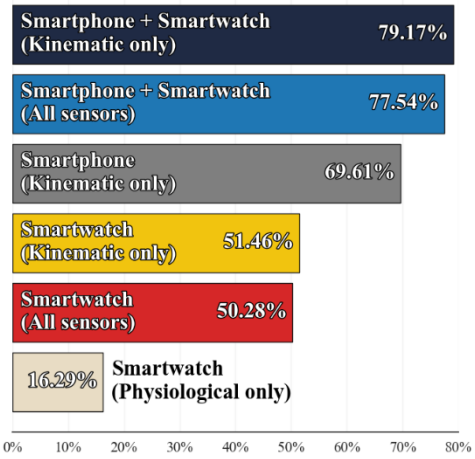

Figure 2: Average Macro F1-scores across various sensor combinations and their simple fusion

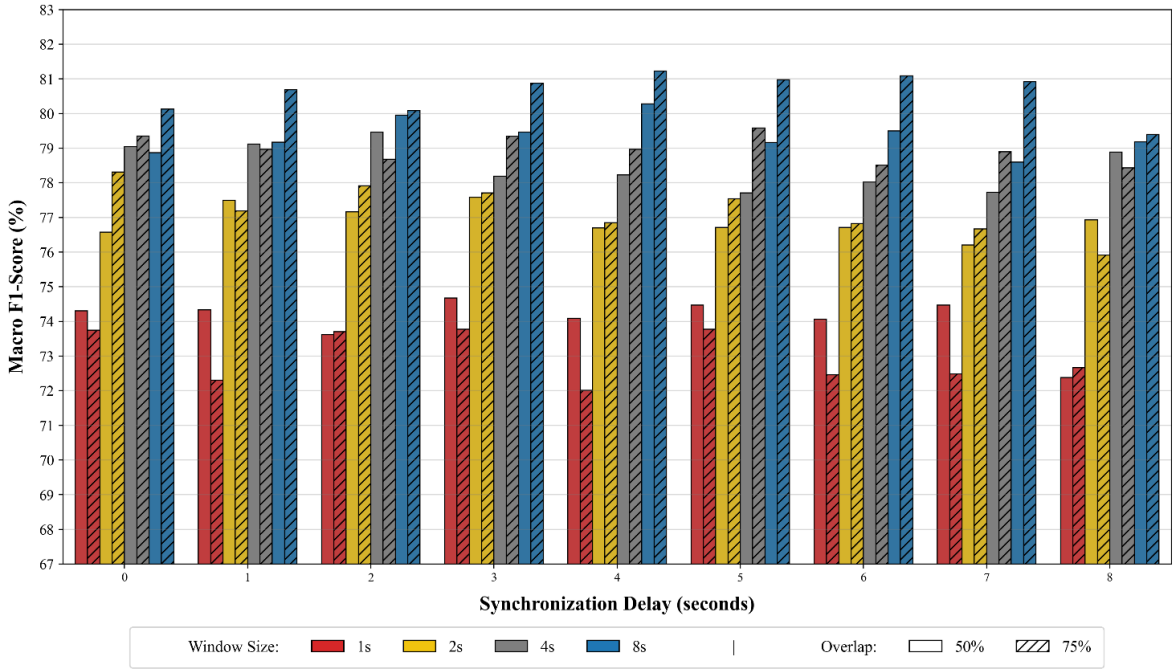
As a final step, we measured the average inference time of the best-performing model to evaluate the feasibility of the proposed approach for real-world applications. Using a standard desktop CPU (2.50 GHz, 16 threads), the model classified a single data window in approximately 0.06 milliseconds on average. This low computational cost indicates that the proposed latency-aware fusion model is lightweight enough to be deployed on edge devices or microprocessors available in modern wearable devices with negligible delay, satisfying the critical requirement for real-time safety monitoring in construction environments.

Ultimately, this study demonstrates that bridging the temporal gap between instantaneous motion and delayed physiological response is essential for developing context-aware HAR systems capable of distinguishing



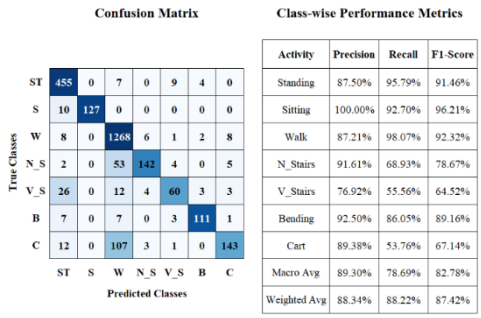


Figure 3: Performance variations of the fusion model as a function of artificial temporal synchronization dealys for different windows sizes and overlap ratios

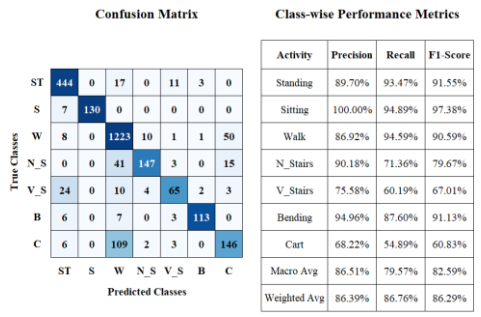

activities defined not just by how we move, but by how much effort is exerted. The proposed latency-aware fusion model achieved a Macro F1 score of 81.22% and a Weighted F1 score of 86.79% (Pooled Macro F1 score of 82.78% and Pooled Weighted F1 score of 87.42%), underscoring its potential to enhance construction site safety through robust worker monitoring.

Class-wise Performance Metrics

Activity	Precision	Recall	F1-Score
Standing	87.50%	95.79%	91.46%
Sitting	100.00%	92.70%	96.21%
Walk	87.21%	98.07%	92.32%

Conclusion

This study investigated the impact of temporal alignment strategies on the performance of multimodal Human Activity Recognition (HAR) systems for construction worker monitoring, focusing on the fusion of kinematic and physiological data. By systematically evaluating different window sizes and artificial temporal delays, the study aimed to address the synchronization challenges caused by the latency of physiological responses.

In total, we trained and evaluated 240 distinct model configurations to systematically investigate the impact of temporal alignment. The results demonstrated that the temporal alignment of data streams significantly affects the classification performance of multimodal models. The latency-aware fusion model, utilizing an 8-second time window with 75% overlap and a 4-second temporal delay, achieved the highest performance with a Pooled Macro F1-score of 82.78% and a Pooled Weighted F1-score of 87.42%, significantly outperforming both the kinematic-only counterpart and the simple fusion approach. These improvements are largely attributed to the effective compensation of physiological latency, which ensures that the delayed metabolic markers of physical exertion are correctly aligned with the corresponding motion data.

Furthermore, the analysis revealed that the inclusion of temporally aligned physiological data is particularly critical for distinguishing activities that share similar kinematic patterns but differ in physical intensity. For instance, the latency-aware model successfully differentiated between "Walking" and high-exertion "Cart" pulling tasks, reducing misclassification rates where kinematic-only models failed due to postural similarities. In contrast, the simple fusion of physiological signals without temporal correction resulted in a slight

performance degradation compared to kinematic-only models, suggesting that misaligned physiological data acts as noise rather than an informative feature.

While these findings highlight the strong potential of latency-aware multimodal sensor fusion for robust worker monitoring, certain limitations should be acknowledged. First, the experiments were conducted in a controlled laboratory environment with a limited sample size of five healthy male participants (N=5). Although sufficient for a proof-of-concept temporal alignment analysis using a Leave-One-Subject-Out validation scheme, this small sample size inherently restricts the statistical power required for formal significance testing (e.g., paired t-tests) between alternative model configurations. For the generalizability of the results and robust validation of the optimal physiological temporal delay, future research should utilize a more diverse population varying significantly in age, baseline fitness levels, body mass index (BMI) and construction experience. Secondly, although the activities were designed to simulate realistic construction tasks, the controlled nature of the study does not fully replicate the complex, unstructured, and dynamic conditions of an active construction site, where factors such as environmental conditions and worker interactions may influence kinematic and physiological sensor readings.

By addressing these challenges, multimodal HAR systems can be further refined to provide a more reliable and comprehensive solution for occupational safety and health management in the construction industry.

INTEGRATING TIME, COST, AND RESOURCES IN BIM: A PROCESS-ORIENTED FRAMEWORK

Davide Avogaro[1] and Carlo Zanchetta[2]
[1]Department of Management and Engineering, University of Padova, 36100 Vicenza, Italy
[2]Department of Civil, Environmental and Architectural Engineering, University of Padova, 35131 Padova, Italy

Abstract

Current practices in scheduling, cost estimation, and resource accounting rely on fragmented workflows, unclear use of Industry Foundation Classes (IFC), and proprietary tools that hinder interoperability. These limitations lead to error-prone, non-standardized processes. This study proposes a framework based on IFC4.3 that defines construction processes and process templates to integrate time, cost, and resource data within IFC. A web-based prototype demonstrates the approach, enabling automatic generation of WBS, CBS, Bills of Quantities, and 4D simulations. Results confirm the feasibility and completeness of IFC for these domains, providing a foundation for interoperable, standardized project-control tools and future real-case implementations.

Introduction

Effective project control is essential for achieving objectives related to time, cost, quality, and safety. This discipline relies on systematic processes for planning, measuring, monitoring, and managing project performance. The present study focuses specifically on time scheduling, cost estimation, and resource accounting. Traditional methods for managing these domains are often labor-intensive, error-prone, and inefficient (Sheik et al., 2023). In particular, time scheduling frequently depends on the subjective experience of planners rather than on objective and verifiable data (Ciribini et al., 2015). Current practices generally do not support an integrated approach to cost, time, and resource management. Consequently, calculations are duplicated, multiple software tools—often incompatible unless part of the same proprietary ecosystem—must be used, and the same information is stored across separate databases, increasing the risk of data inconsistency (Al-Sinan et al., 2024). When such procedures are not aligned with a common standard such as IFC (International Organization for Standardization, 2024), collaboration becomes fragmented, data exchange becomes unreliable, and stakeholders cannot rely on a shared, consistent representation of project information (Lu et al., 2022).

This paper proposes a process-oriented, integrated framework for managing costs, tasks, and resources based on the IFC4.3 standard (International Organization for Standardization, 2024) through the conceptualization of process templates. The primary contribution of this work is a fully IFC-compliant framework that demonstrates how IFC classes can work together to support the use case of integrated management of time scheduling, cost estimation, and resource accounting. The framework provides a standardized, repeatable, and open-source, data-driven approach. In the ongoing discussion and formalization of the IFC5 standard, the development and dissemination of use cases and frameworks are particularly important. The emerging IFC5 version aims to preserve the semantic scope of IFC4.3 (van Berlo et al., 2021); however, certain branches, such as *IfcProcess* and *IfcControl*, may require reconsideration. Contributions such as the present work can help identify strategical or critical aspects, potential gaps, and redundancies within the standard, thereby supporting informed feedback for future revisions.

Additionally, a prototype web application is presented to demonstrate the practical feasibility and potential of this framework in real-world applications.

Background

Traditional practices rely on manually measuring elements from CAD drawings and calculating task costs, resource usage, or task progress using spreadsheets. Even when Building Information Modeling (BIM) workflows are adopted, practitioners frequently depend on proprietary software or closed ecosystems that limit interoperability among stakeholders. In many cases, BIM is used primarily for quantity extraction, while subsequent data processing continues to be performed in spreadsheets. In other cases, organizations introduce user-defined parameters to encode 4D (planning-related BIM data) and 5D (cost-related BIM data) information, enabling integration with external software tools or spreadsheets through export tables or direct file import. However, these approaches lack standardization and consequently hinder interoperability. Nevertheless,

proprietary software continues to dominate the market, likely due to its current robustness and maturity.

Among approaches based on the IFC standard, a systematic literature review (Avogaro & Zanchetta, 2025) demonstrates that existing research provides limited guidance on managing these domains individually, and even less on their integrated handling. The same study also highlights the lack of tools capable of supporting comprehensive, IFC-based management of time, cost, and resources. While adopting IFC is a crucial step toward achieving interoperability in data management, it is not sufficient to enable effective collaboration on its own. Professionals also require practical tools for handling IFC data and supporting collaborative workflows. In this context, web-based platforms represent an effective solution (Park et al., 2017), as they enable remote collaboration, facilitate the reuse of shared information, and provide intuitive interfaces that do not require specialized programming skills.

Relevant contributions in the literature include (Cassandro et al., 2025), who propose a resource-centric approach that integrates building geometry with scheduling and cost data using ontologies as a semantic foundation. In addition, (Sheik et al., 2023) developed an automated progress monitoring framework based on IFC, leveraging classes such as *IfcTask*, *IfcCostItem*, and *IfcConstructionResource*, and implemented a supporting web-based application. Moreover, Blender, when used with the Bonsai extension (IfcOpenShell, 2025), provides dedicated functionalities for time scheduling, cost estimation, and resource accounting based on IFC classes.

Methodology

A previous study (Avogaro et al., 2024) demonstrated that the IFC standard provides a high level of product definition, offering a substantial number of properties that cover most construction domains. This enables the definition of *IfcElementType* entities containing the shared information required to describe their corresponding *IfcElement* instances. In practical terms, this allows the creation of reusable product templates that can be applied across multiple projects, thereby reducing professional effort and enhancing interoperability and collaboration. The same logic can be extended to the construction processes associated with specific element types. In most cases, all instances of a given product type follow a similar sequence of construction processes. This observation led to the conceptualization of *process templates*, defined as the digital representation of all processes required to construct a given product. Two categories of processes are identified: (1) *construction processes*, which consume resources to produce a building element, and (2) *other processes*, such as transport or curing, which do not directly contribute to the physical creation of the product.

Construction processes typically consume four types of resources: human resources, materials, products, and equipment. Each resource is associated with a cost, and the aggregation of these costs determines the total cost of the process. However, only human resources and equipment contribute to time consumption, thereby defining the duration of each process. Within a process template, multiple processes may occur sequentially or in parallel, and the total duration of an element is determined by the time elapsed between the start of the first process and the completion of the last.

Processes are generally associated with different phases of a project. For example, within a process template for a concrete wall, concrete casting belongs to the structural phase, whereas painting belongs to the finishing phase. To ensure effective project scheduling, each task must be correctly assigned to its corresponding phase. This hierarchical organization defines a Work Breakdown Structure (WBS) for the project. Similarly, a Cost Breakdown Structure (CBS) aligned with the WBS is required to enable consistent cost management across different phases and processes.

Following the conceptualization of the framework based on project management principles, a detailed analysis of the IFC4.3 standard (buildingSMART Technical, 2024) was conducted to assess its capability to represent these data structures and relationships. The results of this analysis are presented in the following section.

Subsequently, a prototype web application was developed to test the proposed framework and to provide an open-source environment for managing and inputting the associated data. The implementation details are described in the Implementation section.

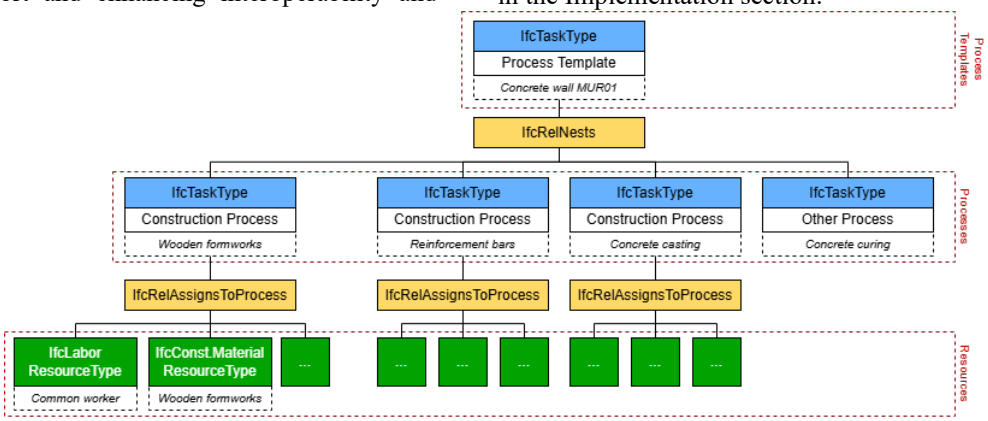

Figure 1: Process Template structure

Analysis

Within the IFC data model, a process template can be represented by an *IfcTaskType* entity that aggregates other *IfcTaskType* entities corresponding to individual processes, as illustrated in Figure 1. Each construction process consumes different types of resources, which in IFC are modeled as subclasses of *IfcConstructionResourceType*. These include *IfcLaborResourceType*, *IfcConstructionMaterialResourceType*, *IfcConstructionProductResourceType*, and *IfcConstructionEquipmentResourceType*, representing human resources, materials, products, and equipment, respectively. In this structure, a construction process represented by an *IfcTaskType* is associated with one or more *IfcConstructionResourceType* entities, as shown in Figure 1.

To support the standardized definition of construction processes, price lists can be used as databases that provide detailed descriptions of construction activities. These lists typically include the unit cost of each activity, the required quantities of resources, and the associated costs for each resource, as illustrated in Figure 2. Additionally, information on the time consumption of labor and equipment resources provides a robust basis for calculating man-hours or machine-hours, enabling accurate estimation of the time required to complete a unit of work.

Construction Process					
Code	**Description**			**Meas. unit**	**Price**
VEN25-01.08.02b	PRE-MIXED DURABLE CONCRETE XC1 workability class S3 (semi-fluid), exposure class XC1, C 25/30			m^3	129,21
Resources					
Code	**Description**	**Qta**	**Meas. unit**	**Unit Price**	**Price**
VEN25-RU.01.04.a	GENERAL CONSTRUCTION WORKER	0,150	h	27,33 €	4,10 €
VEN25-PR-B.02.03.b	PRE-MIXED DURABLE CONCRETE XC1 workability class S3 (semi-fluid), exposure class XC1, C 25/30	1,050	m^3	114,02 €	119,72 €
VEN25-AT.14.05.00	HOT RENTAL OF ELECTRIC CONCRETE VIBRATOR	0,150	h	35,96 €	5,39 €

Figure 2: Example of price voice data

By leveraging *IfcConstructionResourceType* entities, all relevant price list data can be encoded within the IFC model. In subsequent stages, these data are combined with the quantities associated with each *IfcElement* to derive overall costs and durations. Specifically, the *BaseCosts* attribute of an *IfcConstructionResourceType* is used to represent the unit cost of a resource, while the *BaseQuantity* attribute defines an *IfcPhysicalQuantity* that expresses the resource consumption per unit of product. The *Name* attribute of this quantity specifies the relevant measured parameter (e.g., *GrossVolume*) or a calculation formula, as illustrated in Figure 3.

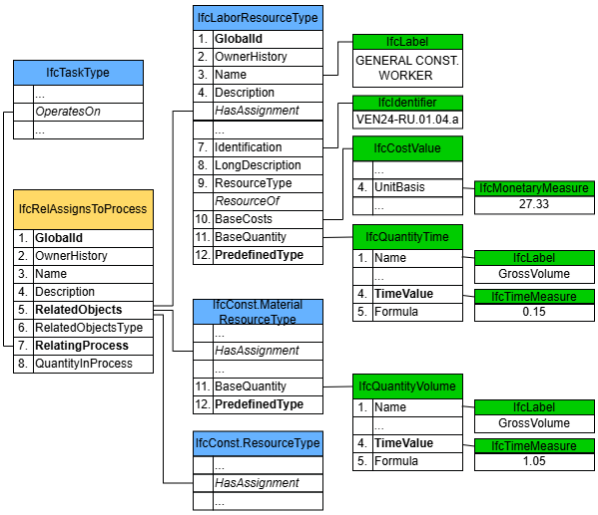

Figure 3: Use of the IfcConstructionResourceType subclasses

The total unit cost of a product corresponds to the sum of all associated resource costs. In this regard, a process template is considered as a structured arrangement of *IfcTaskType* and *IfcConstructionResourceType* entities that enables the standardized representation of price-list information within the IFC schema.

In the preceding paragraph, the procedure for encoding price list data into the IFC data model using process templates was described. The following section explains how to relate and instantiate the classes of a process template with specific *IfcElement* instances. The objective is to associate one or more *IfcBuildingElement* instances with an instantiated process template. As illustrated in Figure 4, the hierarchical structure of the process template represented through *IfcTaskType* entities is replicated using *IfcTask* entities, which now contain the actual duration of each process. The sum of these durations yields the total duration of the process template. A parallel structure is created for *IfcCostItem* entities, where the *IfcCostItem* corresponding to the process template aggregates the values of the individual process-level *IfcCostItem* instances.

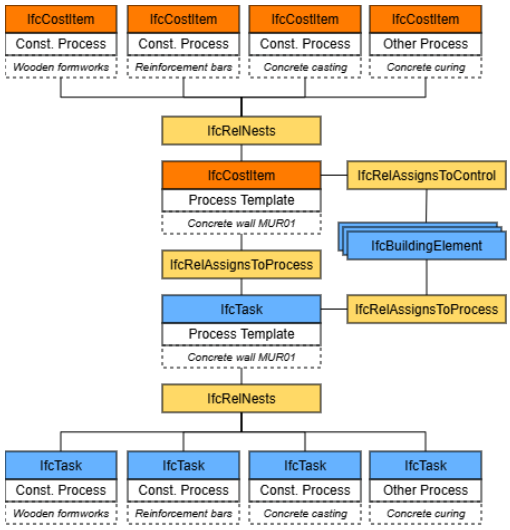

Figure 4: Symmetry in the hierarchical structure of IfcTask and IfcCostItem entities

Once the quantities of the various *IfcBuildingElement* instances associated with a process template are known, they are aggregated—through a scripted procedure—to enable the calculation of the corresponding resource quantities. For each *IfcConstructionResourceType* defined within the process template, the *BaseQuantity* attribute is retrieved, allowing identification of both the target parameter specified in the *Name* attribute of the *IfcPhysicalQuantity* (e.g., *GrossVolume*) and the quantity of resource consumed per unit of product. The target parameter is then extracted from the quantities of the building elements and used in the calculation by multiplying it by the consumption rate per unit of product. The resulting value is assigned as the *BaseQuantity* of the instantiated *IfcConstructionResource*. Based on this quantity, an *IfcCostItem* is created for the resource, and its *IfcCostValue* is computed by multiplying the resource quantity by the unit cost defined in the corresponding *IfcConstructionResourceType* (*BaseCosts* attribute). This procedure is repeated for each *IfcConstructionResourceType* associated with the process template. All resource-level *IfcCostItem* entities are then aggregated under a parent *IfcCostItem*, which sums their values and is associated with the corresponding *IfcTask* representing the construction process. This logic is consistent with the ISO 9000 definition of processes and with the ICOM process diagram. The resulting structure is presented in Fig. 5.

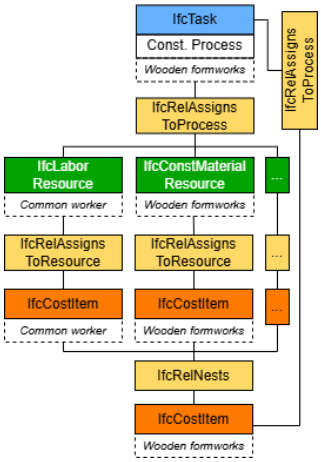

Figure 5: Relationships between IfcConstructionResource, IfcTask, and IfcCostItem entities

The duration of each *IfcTask* corresponding to a construction process is determined by the duration of the resources that consume time. As shown in Figure 2, resources such as labor and equipment require measurable time inputs. Using this information, it is possible to calculate the number of man-hours or machine-hours required to perform each construction process. However, these values represent workloads, not durations. For example, eight man-hours performed by two workers correspond to a four-hour task duration. The *Usage* attribute of *IfcConstructionResource* enables the use of the *IfcResourceTime* class, which includes the *ScheduleUsage* attribute that specifies the number of resources working concurrently. The ratio between *ScheduleUsage* and the required work quantity yields the resource-based duration. For each construction process, a script identifies the longest resource duration, which becomes the duration of the corresponding *IfcTask*.

Other processes—such as maturation or transportation—that do not rely on resource consumption may also have predefined durations and costs, which contribute to the overall duration and total cost of the process template.

Each process within a process template may include a defined starting date, from which its finishing date can be derived by adding the corresponding duration. Tasks may also incorporate sequencing relationships, constraints, and other scheduling logic. All temporal information is stored in the *IfcTask* entities and their associated *IfcTaskTime* objects. These data can be used to generate Gantt charts and construct a WBS. Furthermore, the hierarchical organization of *IfcCostItem* entities enables the creation of a CBS that mirrors the WBS, supporting procedures for monitoring actual costs over time and improving the overall quality of project control. Finally, for each task in the WBS, it is possible to extract a detailed list of resources and thereby generate task-specific Bills of Quantities.

Implementation

To evaluate the proposed framework, the authors developed a prototype application. The system is implemented as a Single-Page Application (SPA) using the React framework. The web application relies on libraries from That Open Company (*That Open Company*,

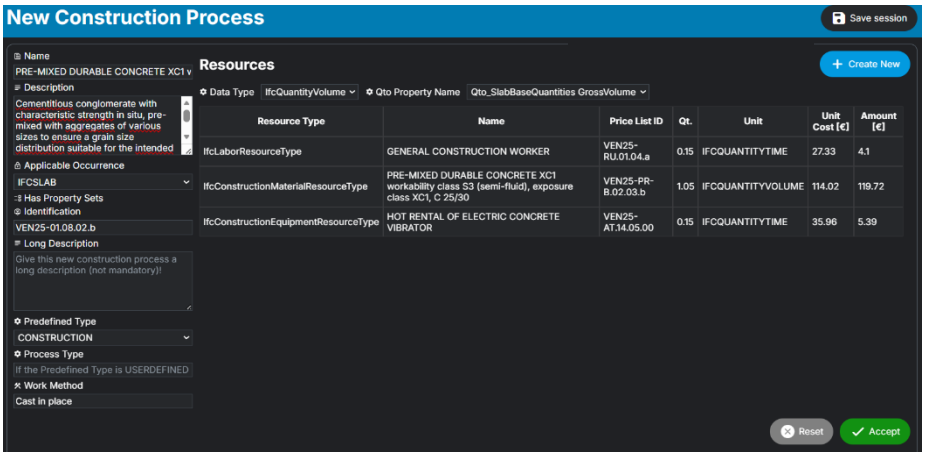

Figure 6: New Construction Process page

2025) to visualize IFC models and to read, write, and manage IFC objects.

The first interface page enables users to create new processes, as shown in Figure 6. The user interface allows the input of all attributes of an *IfcTaskType* entity. Among the most relevant attributes, *ApplicableOccurrence* specifies the IFC class to which the process applies (e.g., *IfcWall*), while *PredefinedType* allows the application to distinguish between construction processes (e.g., CONSTRUCTION, INSTALLATION, etc…) and other types of processes (e.g., MOVE, ATTENDANCE, etc…). For construction processes, the user can define the physical quantity to be considered (e.g., *IfcQuantityVolume*) and the corresponding property (e.g., *GrossVolume*), including formulas where necessary (e.g., "Qto_WallBaseQuantities GrossVolume − Qto_WallBaseQuantities GrossSideArea × 0.1"). The application provides selectable options for physical quantities and properties based on the IFC class specified in *ApplicableOccurrence*. These data are stored in the *BaseQuantity* attribute of the associated *IfcConstructionResourceType* entities. Within the same interface, the user can also define the list of *IfcConstructionResourceType* entities and their attributes. Upon saving, all information is written to an IFC-SPF file stored on a server, which functions as a shared database to support data reuse across users and to minimize redundant input.

The second interface page mirrors the structure of the first but is dedicated to creating new Process Templates, as shown in Figure 7. As before, the user completes a set of attributes for an *IfcTaskType* entity; however, *PredefinedType* is pre-filled as USERDEFINED, and the *ProcessType* attribute is set to PROCESSTEMPLATE. The user can assemble the set of processes that compose the template by selecting from those previously stored in the IFC-SPF database. Once completed, the template is saved to the shared database. An additional interface page presents multiple synchronized panels. The first panel, shown in Figure 8, provides a 3D model viewer alongside a list of available process templates. After selecting one or more model elements, the user can associate a process template with them.

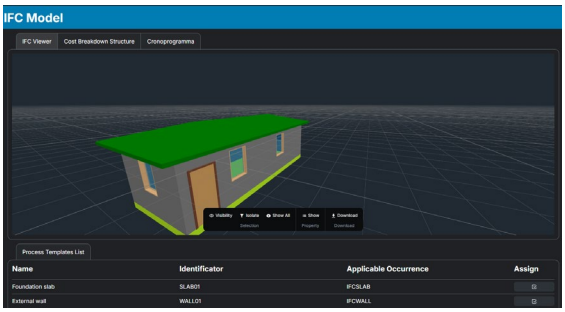

Figure 8: IFC viewer integrated with the process template assignment interface

For each construction process, the application opens a dialog prompting the user to specify the number of resources that contribute to time consumption, enabling accurate calculation of process duration, as shown in Figure 9. The dialog also requires the assignment of the process to a Work Breakdown Structure (WBS) work package, ensuring alignment with the Cost Breakdown Structure (CBS). For non-construction processes, the application instead requires manual input of duration and cost.

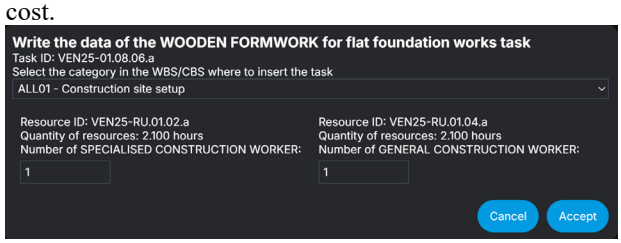

Figure 9: Resources consumption dialog

Results

The prototype enables automated cost estimation, time scheduling, and resource accounting based entirely on data. A second panel presents the Cost Breakdown Structure (CBS), mirroring the hierarchy of the Work Breakdown Structure (WBS) and reporting the cost associated with each process, as shown in Figure 10. A further panel provides an overview of the resources assigned to each process.

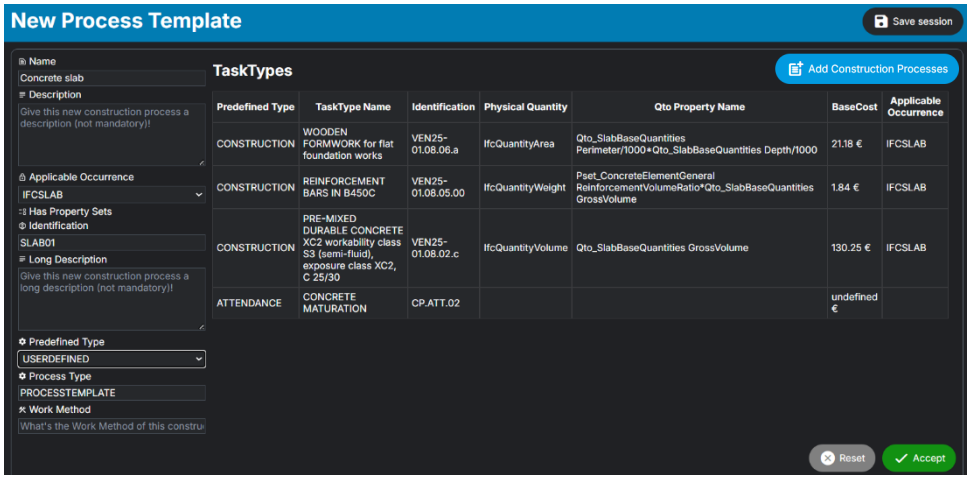

Figure 7: New Process Template page

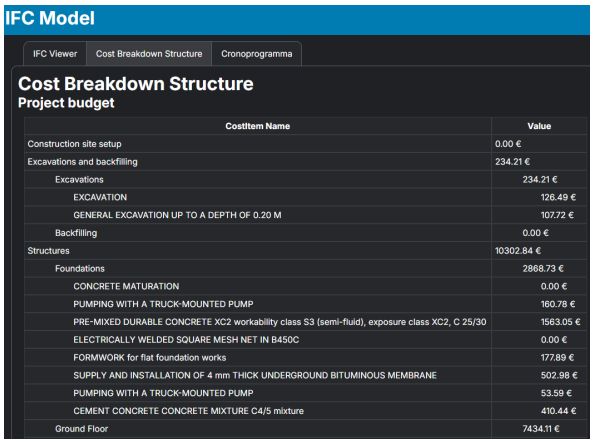

Figure 10: Cost Breakdown Structure page

The third panel displays the WBS, aligned with the CBS, and visualized through a Gantt chart representation, as illustrated in Figure 11. Within this panel, users can refine task durations, assign constraints, reorder tasks, and adjust dependencies through intuitive drag-and-drop interactions. Although the automatically calculated durations provide a reliable baseline, professional judgment is often required to adapt them to project-specific conditions; therefore, manual editing is supported. All modifications are not only reflected in the user interface but are also written back into the IFC model.

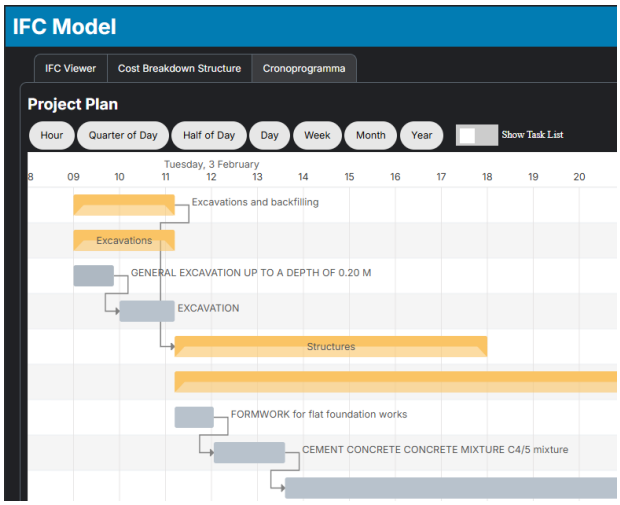

Figure 11: Work Breakdown Structure page trough a Gantt representation of the IfcTask

An additional interface page is dedicated to 4D simulation, allowing users to visualize the temporal progression of the project through animated model playback, as shown in Figure 12.

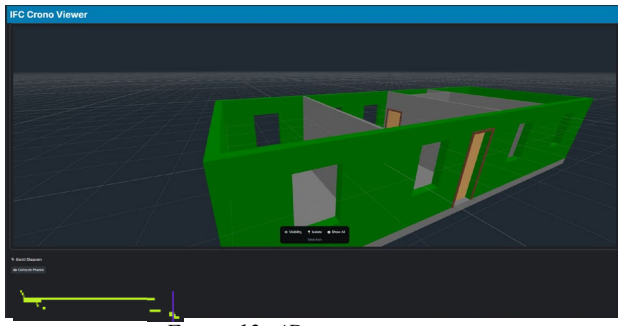

Figure 12: 4D animation page

All IFC files generated by the prototype—both those used as a shared database and those produced as project models—were successfully interpreted using external tools such as KITModelViewer (Institute for Automation and Applied Informatics (IAI), 2025).

Discussion

The testing phase conducted so far has focused on relatively simple building elements, including cast-in-place walls, slabs, windows, and doors. For cost data, the 2025 Veneto Region Price List (Veneto Region, 2025) was adopted, as it was considered appropriate for the scope of the initial experiments. Given that price lists vary significantly across regions and countries, future research will investigate the application of the methodology to real-world case studies, additional IFC classes, and alternative price lists. Although the workflow has been designed to be flexible and adaptable, further validation is required.

The developed prototype also highlights the relevance of web-based applications, which eliminate the need for specialized software installation and provide readily accessible tools for practitioners. The use of open-source libraries, such as those provided by That Open Company, enables professionals with programming expertise to develop customized solutions, helping to address the current lack of IFC-based software tools in these domains. Moreover, as these tools rely on open standards rather than proprietary ecosystems, they support the adoption of IFC and enhance interoperability and standardization across the sector.

The study emphasizes the importance of data reuse and sharing to reduce redundant work and improve interoperability, both through the conceptualization of process templates and the architecture of the prototype. However, the current implementation presents limitations in this regard. The IFC-SPF file used as a database does not provide the robustness of a dedicated database system: concurrent access by multiple users may result in overwriting conflicts, and essential functionalities—such as data consistency checks, input validation, and error handling—are not inherently supported. Future work will focus on developing a dedicated price list database based on Semantic Web technologies using the IfcOWL ontology (buildingSMART Technical, 2025). This approach would ensure consistency with the IFC data model while leveraging Semantic Web capabilities to

enable real-time collaboration among stakeholders (Yang et al., 2021).

To further reduce manual effort, future developments will also explore automated procedures for converting price lists into IFC-based databases, thereby minimizing the workload required from professionals. At the same time, the prototype requires further refinement to improve the user experience and to better address the complexity and variability of real-world projects. For example, it is necessary to support exceptions and variations by allowing users to define additional processes for specific elements that deviate from the standard process template. Once the prototype reaches a more stable stage, it will be possible to evaluate its effectiveness through quantitative metrics such as time savings, productivity gains, and error rates.

Furthermore, the study demonstrates the central role of an effective user interface. The prototype shows that even a complex structure of IFC classes can be navigated and managed by users without prior knowledge of the standard. This is particularly relevant for professionals without programming skills and for public administrations that require BIM data to be delivered in open formats.

Despite the identified technical and functional limitations, the prototype successfully validates the proposed methodology and demonstrates the feasibility of developing applications entirely based on IFC. More importantly, it highlights the potential of the IFC standard to support integrated cost, scheduling, and resource management, and underscores the need for consistent and shared research on standardized methods for its application.

Conclusions

The literature indicates that BIM methodologies can overcome traditional practices for time scheduling, cost estimation, and resource accounting, which are often time-consuming, error-prone, and based on subjective experience rather than data. However, current BIM practices in these domains still rely heavily on proprietary ecosystems, manual procedures, or user-defined approaches that hinder interoperability, lack standardization, and fragment data across multiple environments. The adoption of a common standard such as IFC, which encompasses these domains, offers a promising solution. Nevertheless, previous research (Avogaro & Zanchetta, 2025) highlights key barriers to the widespread use of IFC, including uncertainty regarding the correct use of IFC classes and the appropriate structuring of project-control data within the schema, as well as the lack of software tools capable of effectively managing such data through the IFC standard.

This study presents a process-oriented framework for the integrated management of time scheduling, cost estimation, and resource accounting based on the IFC4.3 standard. By introducing the concept of process templates and systematically mapping them to IFC entities, the research demonstrates that IFC can support a coherent, data-driven representation of construction processes, including their associated resources, costs, and temporal attributes. The proposed methodology enables the standardization and reuse of construction knowledge through template-based structures, reducing redundancy and improving consistency across projects. The implementation of a web-based prototype further validates the practical feasibility of the approach, showing that key project-control outputs—such as WBS, CBS, Bills of Quantities, and 4D simulations—can be generated automatically from IFC-compliant data. These results confirm that IFC can function not only as a data exchange format but also as a central data model for integrated project management workflows.

At the same time, the study identifies several challenges that must be addressed to enable real-world adoption. These include the need for more robust data management infrastructures, improved handling of concurrent data access, and enhanced support for variability and exceptions in construction processes. Furthermore, additional validation through more complex case studies and diverse price lists is required to assess scalability and generalizability.

Overall, this work lays the foundation for interoperable, standardized, and fully data-driven project-control tools, supporting a transition from fragmented and proprietary workflows toward more collaborative and transparent practices in the construction industry. It provides both a methodological foundation and a proof of concept demonstrating that integrated, standardized, and interoperable project-control workflows based entirely on IFC are achievable and beneficial, and it outlines a pathway for future research and tool development aimed at reducing inefficiencies, enhancing collaboration, and promoting the adoption of open standards in the sector.

A SEMANTIC DATA MODEL FOR INTEROPERABLE EXCHANGE OF TEST TRENCH VERIFICATION DATA

Faith Tangara[1], Léon olde Scholtenhuis[1], and Ramon ter Huurne[1]
[1]University of Twente, Enschede, The Netherlands

Abstract

In the Netherlands, nearly 50,000 utility strikes occurred in 2024, costing over €57 million in direct repairs. Test trenches provide centimeter-accurate verification of underground utility positions, yet this valuable data remains trapped in organizational silos, leading to repeated excavations. This paper introduces UTT (Universal Test Trench), a semantic data model extending the Dutch IMKL standard for interoperable exchange of 3D verification data. Developed using OWL/RDF with SHACL validation constraints, UTT provides a unified vocabulary for test trench observations, positions, deviations, and measurement quality. Future work includes prototype implementation and field evaluation.

Introduction

The underground infrastructure of cities contains a complex network of cables and pipes that deliver essential services, including electricity, gas, water, telecommunications, and sewerage. In the Netherlands alone, this network extends over 1.7 million kilometers. As cities pursue energy transitions and climate resilience programs, subsurface construction activity intensifies significantly. Current projections suggest that within the coming decade, one-third to half of urban roads will require reconstruction to accommodate new infrastructure systems including expanded electrical capacity, hydrogen pipelines, and enhanced drainage (COB, 2024).

This intensifying activity correlates with rising damage incidents. In 2024, the Netherlands recorded nearly 50,000 utility strikes at a rate of 137 daily occurrences, with direct repair costs exceeding €57 million (Digitale Infrastructuur, 2024). Including indirect costs such as service disruptions, project delays, and third-party damages, the true economic impact is estimated at 29 times higher (Makana et al., 2018). The root cause lies fundamentally in insufficient localization insights: the Cables and Pipelines Information Centre (KLIC) provides 2D maps based on administrative records that often deviate by over one meter horizontally and typically lack depth information entirely (Yan et al., 2019).

To mitigate this geometric uncertainty, contractors routinely excavate test trenches that expose underground utilities for direct measurement. A typical test trench is one to two meters deep and two to three meters long, allowing surveyors to record positions with centimeter-level accuracy using total stations, GNSS/RTK receivers, or increasingly, LiDAR scanning and photogrammetry. Yet excavating these trenches is itself costly, time-consuming, and carries risk of damaging the very utilities being located, making repeated excavation at the same location inherently undesirable. Despite this, the verified data remains trapped in silos within individual organizations. Once the trench is backfilled, measurements are rarely preserved in structured formats or shared with other stakeholders who may later excavate the same location.

The Dutch Centre for Underground Construction (COB) conducted feasibility studies in 2023 and 2024 that confirmed the value proposition of a ‘test trench database’(COB, 2023, 2024). This database should enable unified exchange of trial trench data among stakeholders in the Dutch utility sector. The feasibility studies found broad stakeholder support and identified standardization of test trench data as the critical prerequisite for implementation. It was recognized that without a common data model, interoperability of data would be compromised, hampering the exchange of test trench data.

This paper addresses this standardization gap by introducing UTT (Universal Test Trench), a semantic data model that extends the Dutch IMKL standard to capture 3D test trench verification data. While 3D utility data is not yet common practice, it is rapidly becoming essential as technologies such as LiDAR and advanced surveying tools gain widespread adoption. The ambition of UTT is therefore not only to standardize current field observations but also to provide future-proof infrastructure for the next generation of high-resolution utility mapping.

The remainder of this paper is organized as follows: the literature review examines related work in infrastructure ontologies and utility data standards; the methodology section describes the ontology development approach; subsequent sections present the UTT design, validation approach, and evaluation results; finally, discussion and conclusions address practical implications and future directions.

Literature Review

Standardization and Ontologies

Standardization is critical to facilitate communication between stakeholders in fragmented industries like construction (Howard & Björk, 2008). Without shared standards, organizations develop their own digital models using different taxonomies and vocabularies for the same assets (A Ter Huurne & Olde Scholtenhuis, 2018) . An ontology addresses this by providing an explicit specification of a shared conceptualization (Studer et al., 1998), encoding agreed concepts based on shared worldviews (El-Diraby & Osman, 2011). Semantic web technologies, particularly OWL and RDF, offer significant advantages over conventional relational or XML-based approaches for this purpose. Linked data principles enable distributed data integration without requiring a single centralized database, making them well-suited to multi-stakeholder environments where organizations maintain their own data stores (Berners-Lee, 2006).

Ontology in Infrastructure Engineering

Semantic web technologies have found application in infrastructure data management. In building information modeling, ifcOWL demonstrates ontology-based data integration (Pauwels & Terkaj, 2016).

For bridge infrastructure, linked data approaches support condition assessment (Hamdan & Scherer, 2020). The CityGML UtilityNetworkADE provides 3D utility representation within city models, with stronger geospatial integration than building-centric approaches (Biljecki et al., 2018 ; Kutzner et al., 2020).

Subsurface utilities remain underrepresented in semantic approaches. While above-ground infrastructure benefits from visual inspection and established BIM workflows, underground assets present unique challenges: they are invisible after installation, subject to undocumented modifications, and often predate digital documentation practices. These characteristics make semantic interoperability valuable yet technically challenging.

Utility Data Standards

Several utility data standards have emerged, each serving a particular purpose yet failing to accommodate the concepts required to comprehensively describe 3D test trench verification information.

At the European level, INSPIRE Utility Networks provides cross-border data exchange concepts for utility network topology (European Commission, 2013). CityGML's UtilityNetworkADE extends this to 3D city model integration, enabling rich geometric representation of underground networks (Kutzner et al., 2020). In the Netherlands, IMKL 3.0 provides the national standard for utility data exchange and maps to INSPIRE for European interoperability (Geonovum, 2022). However, IMKL primarily supports 2D registration and lacks concepts for verification observations or measurement uncertainty. Ter Huurne (2019) developed an OWL-based extension addressing semantic integration in utility asset management, demonstrating the feasibility of linked data approaches in this sector.

PAS 128 defines quality levels for utility detection but functions as an operational directive for survey procedures rather than a data exchange standard (BSI, 2014). International efforts like MUDDI address registry-level data but not verification observations. The gap between registered positions and actual field conditions remains outside existing standards.

While ontologies exist for building and bridge infrastructure, and data standards exist for utility network registration, no semantic model addresses the specific requirements of test trench verification data, including observed positions, deviations from registry data, measurement uncertainty, and verification provenance. UTT addresses this gap.

Methodology

The central goal of ontology development is achieving a shared conceptualization that enables meaningful data exchange between stakeholders who currently use incompatible representations. The methodology follows the Linked Open Terms (LOT) approach (Poveda-Villalón et al., 2022), a systematic framework comprising four iterative phases: requirements specification, implementation, publication, and maintenance. This paper covers the first three phases. LOT was selected

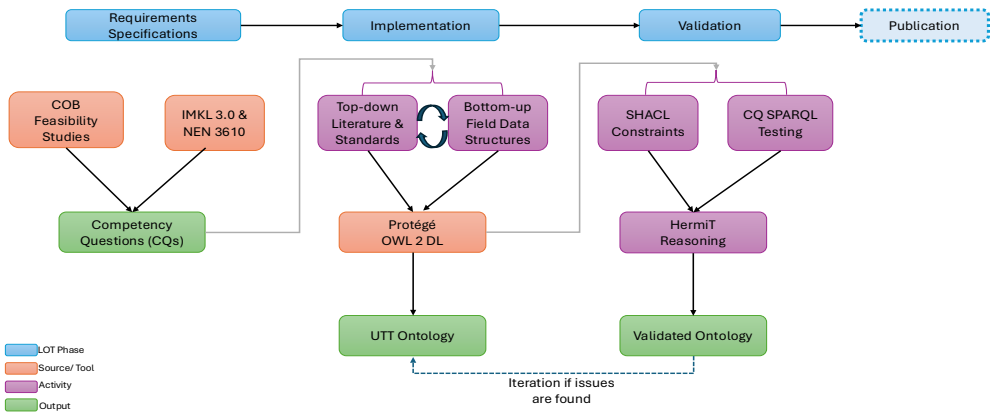

Figure 1:UTT ontology development process following the LOT methodology

because it integrates competency question formulation with standard ontology engineering practices, providing a reproducible process where requirements are formalized as testable queries against the resulting model.

Ontology Requirements Specification

Requirements were gathered through three complementary approaches. First, analysis of two COB feasibility study reports from 2023 and 2024, which collectively involved workshops with 15 organizations including utility network owners, contractors, surveying firms, and Kadaster, identified functional requirements from industry stakeholders. Second, systematic review of IMKL 3.0 documentation and NEN 3610 (the Dutch base model for geo-information) established alignment requirements with existing national standards. Third, iterative discussions with two industry partners from a utility contractor organization provided input on practical data capture workflows and current data formats in use.

The requirements specification yielded the following scope: the ontology must represent (1) the physical test trench excavation with its geometry and dimensions; (2) individual utility observations within the trench; (3) verified 3D positions with quantified accuracy; (4) deviations between observed and registered positions; (5) measurement methods and equipment; and (6) verification provenance including performer, date, and commissioning organization.

Requirements were formalized as competency questions (CQs) that the ontology must answer. CQs function as testable specifications: each translates to a SPARQL query that verifies whether the ontology captures required concepts. Table 1 lists the ten competency questions that guided development.

Table 1:Competency questions defining ontology requirements

ID	Competency Question
CQ1	What classes represent the test trench and its observations?
CQ2	What properties capture depth information for utilities?
CQ3	What measurement methods are defined in the ontology?
CQ4	What accuracy and quality properties are available?
CQ5	What properties link observations to IMKL concepts?
CQ6	What properties capture deviation between registered and observed?
CQ7	What provenance properties track verification performers?
CQ8	What supporting data file formats are defined?
CQ9	What IMKL utility types (thema) can be referenced?
CQ10	Is the trench class properly linked to spatial features?

Ontology Implementation

Implementation combined top-down and bottom-up development strategies (Noy & Mcguinness, 2001). The top-down approach defined concepts derived from IMKL documentation, NEN 3610 spatial object patterns, and PROV-O provenance structures. The bottom-up approach incorporated terminology extracted from existing test trench reports, surveyor workflows, and data formats currently used in Dutch practice.

The ontology was developed using Protégé 5.5 and encoded in OWL 2 DL following ISO 19150-2 transformation rules for geographic information. This standard provides patterns for converting UML-based geographic information models to OWL, ensuring compatibility with Dutch geo-information infrastructure. SHACL (Shapes Constraint Language) shapes define validation constraints for data quality enforcement (W3C, 2012).

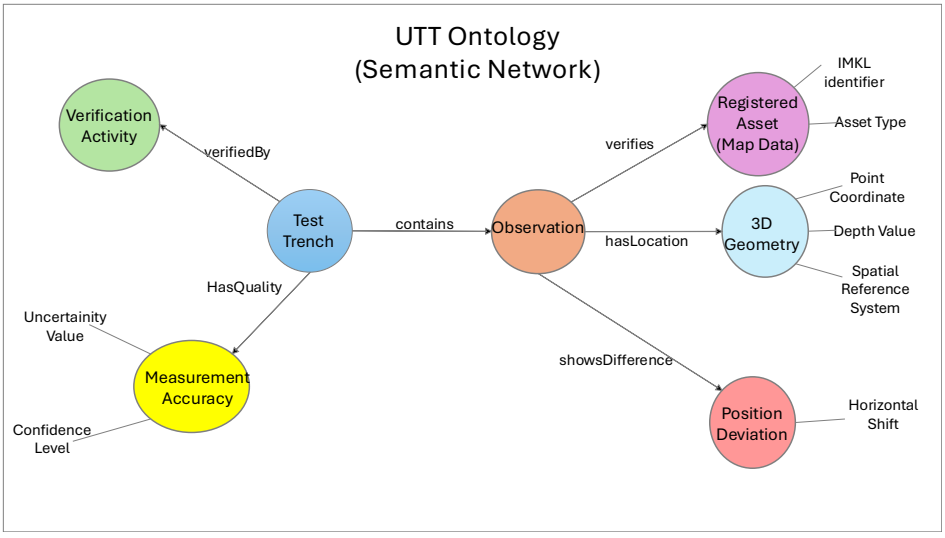

Figure 2:UTT ontology conceptual overview with core classes and relationships

The implementation reuses established ontologies following linked data best practices. GeoSPARQL provides spatial representation capabilities including geometry types and spatial relations. PROV-O (Provenance Ontology) supplies patterns for tracking data

lineage and attribution. SKOS (Simple Knowledge Organization System) structures controlled vocabularies for measurement methods and file formats.

UTT Ontology Design

The UTT ontology comprises 13 classes, 21 object properties, and 17 datatype properties organized into seven functional modules. The complete ontology totals 378 RDF triples with an additional 275 triples in the IMKL subset and 175 triples defining SHACL validation shapes. Figure 2 presents the semantic network showing class relationships and IMKL integration points.

Test Trench and Geometry

The `utt:Proefsleuf` (Test Trench) class serves as the central container for the verification process.

Unlike standard IMKL definitions which focus on the utility network topology, UTT treats the trench as a distinct geospatial feature. A key design decision was to define this class as a subclass of `geo:Feature` (GeoSPARQL). This inheritance allows the trench to possess its own 3D geometry `utt:sleufGeometrie` (Trench Geometry), independent of the utilities contained within it.

UTT represents geometries using GeoSPARQL's `geo:hasGeometry` pattern. Trench geometries are stored as 3D Well-Known Text (WKT) polygon literals representing the excavation footprint, while observed utility positions use 3D WKT point geometries for discrete measurements or 3D linestring geometries for utility segments visible across the trench. Geometries are typed as `geo:wktLiteral` and annotated with their coordinate reference system. For Dutch geo-infrastructure integration, geometries use the Rijksdriehoek coordinate reference system (EPSG:28992) with NAP-referenced heights. This approach enables GeoSPARQL spatial queries such as `geo:sfWithin` and `geo:sfIntersects` while maintaining direct compatibility with GIS tools that consume WKT.

This structural separation is critical for spatial analysis: it allows the ontology to query which assets fall within the excavation volume, regardless of whether they were originally documented in the registry. The class creates a context for areas where utilities were expected but not found by defining the exact boundaries of the verified space.

The use of Dutch-language class identifiers and the Rijksdriehoek coordinate reference system reflects the decision to align UTT with IMKL, the mandatory national standard for utility data exchange in the Netherlands. All classes and properties carry bilingual annotations in both Dutch and English through rdfs:label declarations. The coordinate reference system is specified on individual geometry literals following GeoSPARQL conventions rather than encoded as a structural constraint, permitting adaptation to other national coordinate systems at the instance level.

Observation and Registry Alignment

The `utt:Waarneming` (Observation) class bridges the gap between the physical reality and the administrative registry. While existing standards like MUDDI focus on the asset itself, UTT distinguishes the act of observing from the asset observed. This separation enables the system to handle unknown or "orphan" cables that do not exist in the KLIC registry.

To ensure interoperability, the observation class utilizes the `utt:waargenomenType` (observation) property, which is mapped directly to the `imkl:Thema` (Utility Type) code lists. This design choice ensures that a field surveyor's classification (e.g., "Low Voltage Cable") is semantically identical to the registry's classification, facilitating automatic matching. The `utt:komtOvereenMet` (matches) property explicitly links the observation to a specific `imkl:KabelOfLeiding` (Cable or Pipeline) instance using the NEN 3610 Unique Identifier (GUID). This mechanism effectively connects the physical observation to the official digital record to enable precise validation.

Position Deviation

In many existing utility models, accuracy is treated as a simple attribute. However, to support engineering decisions, UTT models deviation as a distinct class rather than a data property. This reification strategy was chosen to capture the complex vector relationship between the planned and actual location. By treating deviation as a class, the ontology can store multiple dimensions of the discrepancy specifically `utt:horizontaleAfwijking` (horizontal shift) and `utt:verticaleAfwijking` (vertical shift) along with the `utt:afwijkingRichting` (directionality). This allows for querying, such as detecting consistent depth errors in specific asset types.

Verification Provenance

The `utt:VerificatieActiviteit` (Verification Activity) class identifies the specific events and actors responsible for the data collection, ensuring traceability for the verification process (see Figure 3). Modeled as a subclass of `prov:Activity` from the W3C PROV-O standard, this class serves as the connecting node between the physical trench and the administrative data.

This module explicitly links the verification to the `utt:Landmeter` (Surveyor), defined as a subclass of `prov:Agent`, and the `utt:meetmethode` (Measurement Method). By structuring this information as semantic relationships rather than simple text strings, the ontology enables advanced data filtering based on the

acquisition source. For instance, data consumers can distinguish between measurements captured via RTK-GNSS versus those verified by a Total Station, allowing for automated reliability assessments based on the equipment's inherent precision capability.

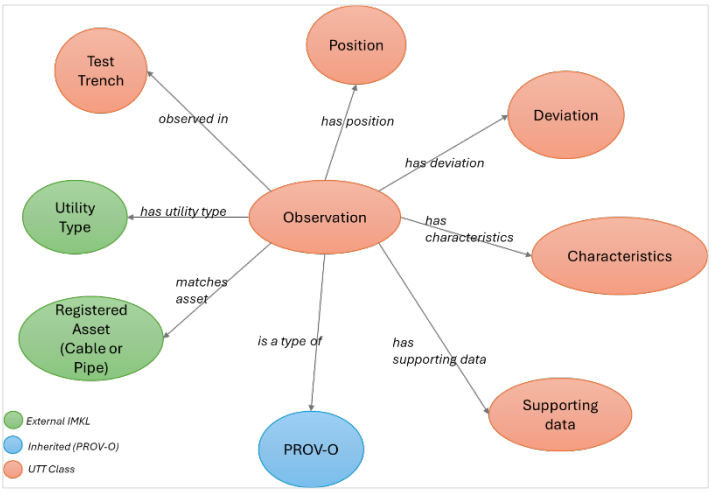

Figure 3:Observation module linking field data to IMKL

Data Validation with SHACL

The ontology includes SHACL (Shapes Constraint Language) shapes that enforce data quality rules. These shapes validate structural completeness, cardinality constraints, and value ranges.

The `utt:ProefSleufShape` (Test Trench Shape) requires each test trench to have exactly one geometry, one verification activity link, and at least one observation. Dimensional properties are constrained to reasonable ranges: trench length up to 50 meters, width up to 10 meters, and depth up to 10 meters.

The `utt:NauwkeurigheidShape` (Accuracy Shape) mandates horizontal uncertainty between 0 and 1.0 meter and vertical uncertainty between 0 and 0.5 meter. These ranges reflect typical achievable accuracies with professional surveying equipment while flagging implausible values.

Severity levels distinguish between violations (structural requirements) and warnings (recommended best practices). For example, linking an observation to a registered IMKL asset is recommended (severity: Info) but not required, acknowledging that unregistered utilities are sometimes discovered.

IMKL Integration Strategy

Integration with IMKL follows a complementary approach rather than modification of the base standard. UTT imports an OWL subset of IMKL classes transformed following ISO 19150-2 patterns. This subset includes core network classes *(Utiliteitsnet (Utility Network), KabelOfLeiding (Cable or Pipeline), Leidingelement (Pipeline Element))*, depth classes, and relevant code lists.

UTT reuses IMKL code lists for utility types *(Thema),* accuracy classifications *(NauwkeurigheidXYvalue (Accuracy XY Value), NauwkeurigheidDiepteValue (Accuracy Depth Value))*, depth reference points *(DiepteAangrijpingspuntValue (Depth Reference Point Value))*, and pipe materials *(PipeMaterialTypeIMKLvalue)*. This reuse ensures observations can be categorized consistently with registry data and supports queries that span both data sources.

The `utt:komtOvereenMet` (Matches) property creates explicit links between UTT observations and IMKL registered assets. This enables deviation calculations and supports use cases where users need to compare verified positions against registered positions for specific utilities.

Query Capabilities & Validation

The ontology enables SPARQL queries answering the competency questions in Table 1. The following query demonstrates retrieval of observations deviating more than 50cm from registered positions:

```
PREFIX utt: <https://w3id.org/utt/def/>
PREFIX xsd: <http://www.w3.org/2001/XMLSchema#>

SELECT ?trench ?observation ?depth ?utilityType
WHERE {
  ?trench a utt:Proefsleuf ;
          utt:heeftWaarneming ?observation .
  ?observation utt:heeftPositie ?position ;
               utt:waargenomenType ?utilityType .
  ?position utt:diepteTovMaaiveld ?depth .
  FILTER (?depth > 1.5)
}
```

Figure 4:SPARQL query for CQ3 - finding utilities deeper than threshold

This query returns all observations where utilities were found deeper than 1.5 meters below ground level, along with their utility type classification. The results enable analysis of depth distribution patterns across utility types and geographic areas. To calculate position deviations;

```
PREFIX utt: <https://w3id.org/utt/def/>

SELECT ?observation ?hDeviation ?vDeviation
WHERE {
  ?observation a utt:Waarneming ;
               utt:heeftAfwijking ?deviation .
  ?deviation utt:horizontaleAfwijking ?hDeviation ;
             utt:verticaleAfwijking ?vDeviation .
  FILTER (?hDeviation > 0.5 || ?vDeviation > 0.3)
}
```

Figure 5:SPARQL query for CQ7 - calculating position deviations

This query identifies observations where registered positions deviated significantly from field-verified positions and supports systematic accuracy analysis of registry data.

The logical consistency was verified using HermiT reasoner in Protégé 5.5 to confirm no contradictory axioms exist and there are no unsatisfiable classes. The competency question was verified by translating each CQ into a SPARQL query. All ten CQs from Table 1 were

successfully answerable using the implemented ontology to confirm functional completeness for the defined scope.

To demonstrate the representational capacity of the ontology, Figure 6 presents an RDF/Turtle serialization of a single test trench containing two utility observations.

Figure 6:RDF/Turtle serialization of a test trench instance with two utility observations

The trench instance is defined with its dimensions and a polygon geometry in three-dimensional coordinate space representing the excavation footprint, with depth captured separately. The first observation records a low-voltage electricity cable at 0.85 meters depth. The associated `PositieAfwijking` (Position Deviation) quantifies that this cable was 0.35 metres horizontally displaced from its registered position. The second observation records a telecommunications cable at 1.10 meters depth without a deviation instance, indicating an unregistered utility with no corresponding registry entry.

Discussion

This paper introduced UTT as a semantic data model addressing the absence of a standardized vocabulary for test trench verification data. Through its development, this study contributes to both the utility data modeling literature and to practice.

To the literature, UTT demonstrates that 3D field verification observations can be represented as linked data by extending existing geo-information standards. Where current standards such as IMKL, INSPIRE, and CityGML UtilityNetworkADE address network registration and topology (Kutzner et al., 2020 ; Geonovum, 2022) UTT introduces complementary concepts for the verification layer: what was actually found in the field, how accurately it was measured, and how it deviates from official records. The reification of position deviation as a distinct class, rather than a simple attribute, enables systematic analysis of registry accuracy patterns, a capability absent in existing utility data models. The integration of PROV-O provenance patterns with domain-specific measurement quality further demonstrates how general-purpose semantic web vocabularies can be combined with domain standards for infrastructure applications.

For Dutch practice, UTT directly supports the national test trench database initiative identified by COB (2024) as critical for reducing repeated excavations. The alignment with IMKL code lists ensures that field observations use identical classifications to the KLIC registry, enabling automatic matching. The explicit uncertainty values in the `Nauwkeurigheid` (Accuracy) class go beyond IMKL's categorical accuracy classes, supporting risk-based excavation planning where engineers can assess whether prior observations meet their precision requirements.

More broadly, test trench excavation is common practice in utility infrastructure management internationally, and the discrepancy between registered and field-verified positions is not confined to the Netherlands. The Dutch-specific elements of the current implementation are limited to the IMKL code lists for utility type classification and the Rijksdriehoek coordinate reference system, both of which are instance-level parameters rather than structural features of the schema. Adaptation to other national contexts would involve substituting these classifications and coordinate declarations while the class hierarchy and property structure remain intact. Because IMKL maps to the European INSPIRE Utility Networks specification, UTT inherits an existing interoperability pathway across jurisdictions. The ontology thus provides a reusable semantic layer for subsurface digital twins, distinguishing as-found observations from as-registered data.

This study has several limitations. The current design focuses on point and line observations; continuous corridor surveys along extended utility routes may require additional geometric patterns. The ontology has been validated for logical consistency and competency question coverage but not yet with large-scale production datasets from multiple organizations. Future work will focus on prototype implementation of the ontology within a triple store, demonstrating data exchange between organizations, and evaluating its merit in operational utility localization practice.

Conclusions

This paper presented UTT, a semantic data model for interoperable exchange of test trench verification data in the utility infrastructure sector. The ontology extends IMKL with concepts for test trenches, field observations, position deviations, quantified accuracy, and verification provenance. SHACL shapes enforce data quality constraints appropriate to the domain.

By providing a standardized vocabulary and validation framework, UTT addresses a critical gap in the utility data

infrastructure that contributes to repeated excavations and damage incidents. The model provides a foundation for developing subsurface digital twins where verified, provenance-tracked observations complement existing registry data.

Future work will deploy the ontology within a GeoSPARQL-enabled triple store to evaluate federated querying across organizational boundaries. The data model will be validated using field datasets from utility contractor organizations to assess representational adequacy across varying trench configurations and utility types. Structured evaluation workshops with industry stakeholders will determine whether the ontology supports decision-making in excavation planning

The ontology is available under Creative Commons Attribution 4.0 license and can be accessed here.

COMPARATIVE ANALYSIS OF UWB AND IMU FOR CONSTRUCTION SAFETY MONITORING

Serdar Bayraktar and Semra Çomu
Boğaziçi University, Istanbul, Türkiye

Abstract

This study compares Ultra-Wideband (UWB) location-based tracking against Inertial Measurement Unit (IMU) gait-based activity recognition for construction safety monitoring. Experiments were conducted in a controlled environment simulating construction hazards (walking on planks, scaffolding, and mezzanines). Results indicate a trade-off: IMU classifiers effectively detect kinematic changes (81.6% accuracy) but fail in spatial awareness, whereas UWB successfully identifies elevation zones (92.3% accuracy) but suffers from vertical signal noise. Rather than viewing these limitations as failures, this study establishes the operational boundaries of standalone UWB and IMU systems in vertical environments, providing empirical baseline parameters for future sensor fusion design.

Introduction

The construction industry is known for its hazardous work environment (Soltanmohammadlou et al., 2019). In 2023, the European Union reported the highest incidence of non-fatal accidents at work within the construction sector, recording 2,899 accidents per 100,000 employed persons (Eurostat, 2025). These statistics highlight the need for targeted interventions to improve the health and safety standards of the construction sites. One important aspect is tracking the site personnel which can help to inhibit occurrence of the accidents by taking the right measures, also enabling the rapid emergency response if an accident occurs. Traditional safety monitoring relies on direct human observations and could not provide real-time coverage of large and complex construction sites (Akhavian & Behzadan, 2016; Zhang et al., 2018). However modern technologies allow real-time tracking of workers, material and equipment. Among these, Ultra-Wideband (UWB) for localization and Inertial Measurement Units (IMU) for activity recognition have emerged as prominent solutions, offering different approaches to safety monitoring.

The UWB positioning system is widely considered as standard for real-time tracking in construction, ensuring centimeter-level error with a clear line of sight (LOS) (Naheem & Kim, 2022). Unlike other wireless technologies such as BLE and Wi-Fi, which rely on Received Signal Strength Indicator (RSSI), UWB operates based on time-of-flight (ToF) measurements. Its short wavelength and high bandwidth contribute to robustness against multipath fading and interference when compared to alternative wireless technologies (Rao et al., 2022). In construction environments, UWB enables reliable real-time positioning of workers, materials, and equipment, particularly in open and unobstructed settings.

Despite its advantages over other wireless technologies, UWB faces limitations under Non-Line-of-Sight (NLOS) conditions, as its positioning accuracy degrades when signals are obstructed by reinforced concrete elements and steel reinforcements commonly found on construction sites (Li & Li, 2025). NLOS leads to disappearances of worker's positions. Another drawback of UWB is the requirement of system setup. The UWB system comes with an upfront cost and needs time and effort to set the anchor sensor throughout the construction site with precise georeferencing before tracking can begin.

An IMU is a micro-electromechanical system (MEMS) sensor package that consists of a 3-axis Accelerometer, 3-axis Gyroscope and generally a magnetometer to measure linear acceleration, angular velocity and magnetic field strength, respectively. By integrating these measurements, position relative to a starting position can be determined (Rao et al., 2022; Leitch et al., 2023). IMU data offers a complementary perspective by capturing both the type of activity and its spatial context (Trigo et al., 2025). Unlike location-based systems, IMUs are not affected by NLOS conditions, enabling uninterrupted tracking (Li & Li, 2025), and their integration into smartphones further improves accessibility. Nevertheless, IMU-based approaches are limited to relative tracking rather than absolute positioning.

In safety-critical construction applications where absolute positioning is required, UWB enables proactive safety measures such as virtual fencing and collision avoidance (Teizer et al., 2008).However, environmental clutter significantly degrades accuracy; metallic obstructions can increase positioning errors from 0.4 m to 1.2 m due to multipath effects (Shahi et al., 2012). Geometric constraints also play a role, as linear anchor layouts cause Dilution of Precision (Maalek & Sadeghpour, 2013). Kılıç et al. (2025) demonstrated that for the MDEK1001 sensors, body placement is decisive: head-mounted tags achieve >99% signal reception by maintaining Line-of-Sight.

In contrast, IMU-based approaches are primarily employed to identify and classify worker activities rather than to provide absolute positioning. Akhavian & Behzadan (2016) and Zhang et al. (2018) demonstrated that sensors embedded in smartphones can reliably recognize construction tasks. However, IMUs do not offer a fixed spatial reference; Li & Li (2025) explain this limitation through accumulated errors, where sensor noise and environmental vibrations progressively distort the estimated trajectory, causing rapid drift and limiting the suitability of standalone IMUs for independent georeferencing.

Consequently, this study presents a comparative analysis of two commonly used approaches: i) infrastructure-dependent UWB systems, which require prior installation, and ii) IMU-based tracking available on standard smartphones. While both sensing modalities have been explored in general tracking applications, this work focuses on experimentally evaluating their performance across different walking modes in complex, multi-level construction environments (e.g., scaffolds, planks, and mezzanine levels). Rather than aiming to identify a single comprehensive solution for continuous safety monitoring, the goal is to examine the practical trade-offs between location-based positioning (UWB) and motion-based recognition (IMU), and to highlight the conditions under which each approach performs more reliably.

Methodology

To evaluate the different methods of classification of walking activity, a multi-sensor data collection was held in a controlled structural engineering laboratory environment. This experiment involved 5 male participants, composed of graduate students and structures lab technicians with ages ranging 25 to 60 years.

IMU of Apple iPhone devices was utilized. 3-axis accelerometer and 3-axis gyroscope of the IMU captured linear acceleration and angular velocity data with App Store achievable smartphone application. The IMU data was captured at a sampling rate of 100 Hz. Two smartphones were placed on the participants' bodies. One of the smartphones was placed on the lumbar region of the participants to capture data close to the body center of mass. The other smartphone was placed in the right front pocket of the participant, representing the practical sensor placement (Figure 1).

Figure 1: Participant instrumented with a UWB tag (hardhat) and smartphones (pocket and lumbar) for data collection.

Location tracking within the controlled experiment setup was performed using 11 Qorvo MDEK1001 Ultra-Wideband (UWB) Transceiver Development Kit modules manufactured by Qorvo. Nine of the UWB sensors were assigned as anchor nodes and were positioned within the experiment area to ensure full coverage possible. The distances between the anchor nodes were measured with a total station and the relative coordinates of the nodes were entered into the Qorvo application available in the App Store. One of the UWB sensor was assigned as a tag and was mounted on the front of the hardhat worn by the participants (Figure 1). Another UWB sensor was assigned as a listener and connected to a Raspberry Pi 5 microcomputer. The listener sensor communicated with the tag sensor and received the relative position among the experiment setup. The location data was collected during each participant's experiment and saved in the CSV format at the end of each trial.

Each participant followed the same predefined circuit four times for their turn. The circuit included four walking scenarios: normal walking, elevated walking, plank walking and scaffolding walking. Normal walking refers to participant’s walking on the ground level. Elevated walking refers to participant’s walking on the mezzanine level. Plank walking refers to participant’s walking on a plank. The plank has 3 m length, 15 cm width and 20 cm height above the ground. Scaffolding walking refers to walking on a scaffold structure.

The ground truth was established by capturing video recordings of all the trials. The video recordings were captured in 720p at 60 fps. Video recordings were later used for labeling the IMU and UWB data.

The raw data collected from the multi-sensor systems were processed and synchronized to enable a direct comparison between the IMU-based system and the UWB-based system. All processing steps were implemented using Python.

The video recordings were labeled using ELAN - Linguistic Annotator software to establish the ground truth (Figure 2). Precise start and end timestamps were generated for five different walking activities on different surfaces: normal walking on ground level(n_walk), walking on a plank(p_walk), walking on mezzanine level(e_walk), walking on upper level of the scaffolding

(s_walk_upper), and walking on lower level of the scaffolding (s_walk_lower). The raw IMU and UWB data were synchronized with these labels using Unix timestamps, and non-relevant segments were removed from the dataset.

A 4th-order Butterworth low-pass filter with a cutoff frequency of 30 Hz was applied to both accelerometer and gyroscope signals to minimize the impact of environmental noises. The IMU data were segmented into sliding windows of 2.0 seconds with 50% overlap. For each window, statistical and frequency-domain features were extracted from the three orthogonal axes of the accelerometer and gyroscope, as well as their calculated magnitudes. A total of 13 features were computed per channel, including mean, standard deviation,

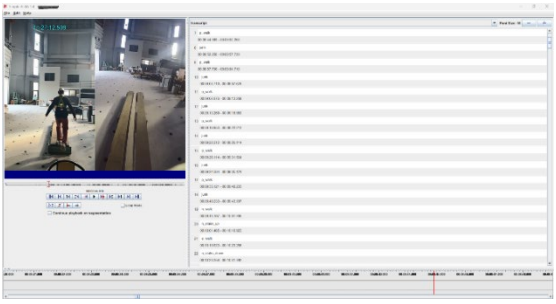

Figure 2: Ground truth labeling interface using ELAN software to segment walking activities

root mean square (RMS), skewness, kurtosis, interquartile range, Shannon entropy, dominant frequency, and spectral entropy.

In terms of determining the optimal configuration for activity recognition, a systematic grid search analysis was conducted. We evaluated sliding window durations ranging from 0.5 to 3.0 seconds, overlap ratios between 25% and 75%, and various feature subsets. Additionally, multiple machine learning algorithms such as linear models (Logistic Regression, LDA), probabilistic models (Naive Bayes), distance-based methods (k-NN), and tree-based ensembles (Random Forest, XGBoost) were compared. The Random Forest classifier (N = 100 trees), paired with a 2.0-second window and 50% overlap, consistently yielded the highest F1-score and generalization performance. Consequently, this configuration was selected for the final analysis. Performance was evaluated using a Leave-One-Subject-Out (LOSO) cross-validation scheme.

The UWB data was processed using a rule-based spatial algorithm that relies on the participant's position relative to the zones defined in the experimental setup. To mitigate signal jitter and non-line-of-sight (NLOS) outliers caused by environmental factors, a context-aware smoothing pipeline was implemented. Rather than applying a blanket filter, the raw coordinate data was first segmented based on hardware disconnections (time gaps > 1.5 seconds) and trial state changes. A rolling median filter (window size = 5) was then applied independently to each segment. This approach prevented the blurring of spatial boundaries between distinct activities while effectively removing anomalous positional spikes.

The UWB tags were mounted on the participants' hardhats. To estimate the vertical position relative to the walking surface Z_{foot}, the participant's standing height ($H_{participant}$) was subtracted from the sensor's Z-coordinate (Z_{tag}), as formulated in Equation (1):

$$Z_{foot} \approx Z_{tag} - H_{participant} \quad (1)$$

The core classification logic involved checking whether the coordinates (X, Y, Z_foot) fell within predefined 3D bounding boxes representing the walking zones. A significant challenge was the inherent noise in the UWB vertical measurements. Statistical analysis indicated a standard deviation of approximately sigma ≈ 0.6 m in the Z-axis for ground-level activities. To address this issue in a systematic manner and avoid arbitrary parameter selection, an empirical sensitivity analysis was conducted to determine appropriate spatial tolerances (buffers). As illustrated in Figure 3, multiple scenarios were evaluated by testing three horizontal (X-Y) to vertical (Z) expansion ratios (1:2, 1:3, and 1:4), systematically increasing the horizontal tolerance in 0.05 m increments. For each configuration, Macro F1-score and overall accuracy were computed to identify the most suitable noise mitigation threshold. The 1:3 expansion ratio demonstrated the most robust performance, establishing a clear "elbow point" at the 0.4 m horizontal mark where the Macro F1-Score plateaued. This suggests a reasonable balance between noise reduction and spatial precision, leading to the selection of final tolerances of 0.4 m horizontally and 1.2 m vertically.

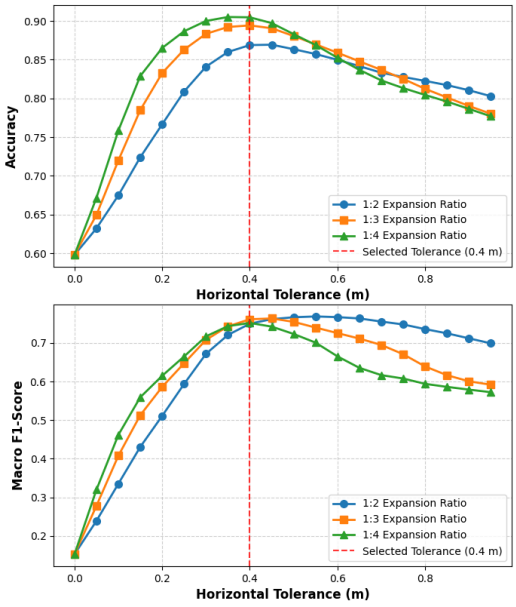

Figure 3: Empirical sensitivity analysis illustrating the effect of horizontal tolerance increments on Accuracy (top) and Macro F1-Score (bottom) across three spatial expansion ratios.

It is noted that these tolerance values are specific to the sensor noise characteristics and the spatial layout of this specific construction site. The point-based spatial predictions were aggregated to match the IMU processing window. The UWB data were segmented into 2.0-second

windows with a 50% overlap, and the final label for each window was determined via majority voting of the rule-based predictions within that window.

Results

In this section, the classification performance of the proposed systems is presented. First, we analyze the impact of sensor placement (Lumbar vs. Pocket) on activity recognition. Second, we compare the best-performing inertial configuration against the UWB rule-based system.

Table 1: Performance comparison of IMU sensor placement (Lumbar vs. Pocket) (N = 4)

Placement	Accuracy	Precision	Recall	F1-Score
Lumbar	**79.57%**	**0.327**	**0.358**	**0.340**
Pocket	75.20%	0.301	0.331	0.314

Table 2: Comparative performance of the Lumbar IMU and UWB systems (N = 5)

System	Accuracy	Precision	Recall	F1-Score
IMU	81.56%	0.443	0.376	0.372
UWB	**92.28%**	**0.713**	**0.808**	**0.732**

In terms of determining the optimal IMU placement, we compared the lumbar region and right front pocket positions. Due to data loss for one participant in the pocket dataset, this specific comparison was restricted to a subset of participants (N =4) to ensure a valid direct comparison. Table 1 summarizes the performance metrics. The Lumbar placement consistently outperformed the Pocket placement across all metrics.

We next compared the better-performing IMU configuration (Lumbar) against the UWB rule-based spatial classifier. Since complete lumbar IMU data were available for all participants, this comparison was conducted using the full dataset (N = 5). The results, presented in Table 2, demonstrate a significant performance divergence between the two approaches.

Although the IMU system has a relatively high overall accuracy (81.56%), its F1-score has a low value (0.372). The confusion matrices (Figure 4) provide insight into this discrepancy. The IMU-based system failed to capture spatial context; samples belonging to Elevated Walk (e_walk) and Scaffolding Walk (s_walk) were predominantly misclassified as Normal Walk (n_walk).

On the other hand, the UWB-based system achieved a dramatically higher F1-score of 0.732. It correctly identified 99% of the (e_walk) samples. The UWB-based system successfully distinguishes the mezzanine level from the ground floor.

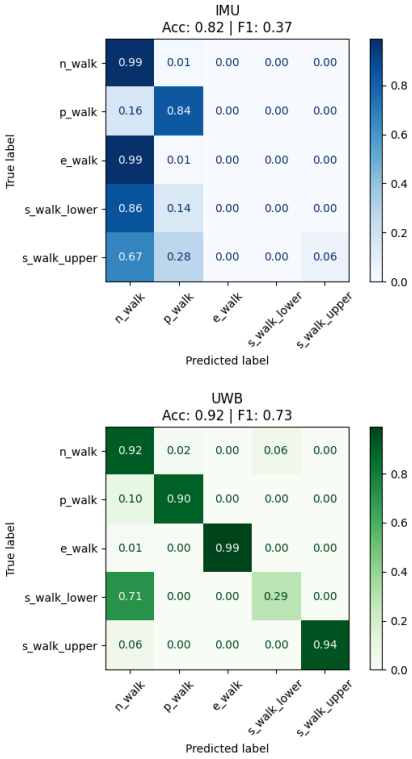

Figure 4: Confusion matrices for IMU(top) and UWB(bottom).

Discussion

The primary objective of this study was to evaluate and compare UWB and IMU technologies for enhancing construction safety, specifically in monitoring worker activities across varying elevation levels. By analyzing sensor performance in controlled experiment conditions, this research sought to identify the operational limitations and complementary strengths of each system. Within this context, the results highlight significant trade-offs between the two systems.

One of the most essential outcomes of this study is the sensor placement's impact on the result. The lumbar placement outperformed the pocket placement which is consistent with the literature. Teng et al. (2024) highlighted the pelvis region as the single optimal sensor location due to its proximity to the body's center of mass. In their analysis of 12 body locations, the pelvis region consistently outperformed the upper thigh.

The observed discrepancy exists in the IMU results between high Accuracy (81.6%) and low F1-Score (0.37) can be attributed to class imbalance. As Figure 5 shows, Normal Walking (n_walk) constitutes the vast majority of the data windows. Consequently, the IMU classifier frequently predicts Normal Walking, inflating accuracy while failing to detect minority classes, as reflected by the low F1-score. This output aligns with the findings by Zimbelman & Keefe (2021) who observed that forestry workers spent 93% of their time in a 'Clear' (idle) state, which similarly degraded the model's ability to detect rare activities.

The UWB system successfully resolved the height awareness opposed to the IMU, achieving a Recall of 0.808. However, it reveals a specific weakness in differentiating between scaffold levels. While the system perfectly separated the Mezzanine (e_walk) from the Ground (n_walk), it struggled to separate the Lower Scaffold (s_walk_lower) from the Upper Scaffold (s_walk_upper). This limitation is directly attached to the spatial rule used to mitigate sensor noise. In this experimental setup, the optimal vertical tolerance exceeded the height difference between scaffold levels, resulting in class overlap.

The most critical finding is the IMU's inability to distinguish between ground level normal walking and elevated walking. Despite achieving 81.56% accuracy, the IMU system exhibited nearly zero recall for elevated walking classes due to the absence of absolute spatial awareness. This is expected, as the kinematic gait patterns of walking on a concrete ground floor and a concrete mezzanine are largely indistinguishable from an inertial sensing perspective. This limitation aligns with findings by Naheem and Kim (2022), who emphasized that while IMUs are effective for relative step detection, they require an external reference like UWB to resolve global positioning and correct for drift.

The analysis demonstrates the distinct operational boundaries of each system. IMU excels at detecting activity dynamics such as distinguishing the balance corrections in (p_walk) vs. (n_walk) but is blind to location. UWB excels at detecting general zones (Ground vs. Mezzanine) but is limited by the trade-off between noise mitigation and spatial resolution.

Practical Implementations and Real-World Limitations

While the controlled laboratory environment provided a necessary baseline for isolating sensor capabilities, deploying these technologies on active construction sites introduces practical complexities.

The current study utilized a localized network of nine UWB anchor nodes to ensure full coverage of a single laboratory space. Scaling this infrastructure to a continuously evolving, multi-story construction site presents significant logistical challenges. Maintaining precise georeferencing for dozens of UWB anchors across an active site requires constant recalibration and high upfront costs. In contrast, the IMU approach is highly scalable, as it leverages standard smartphones already carried by site personnel, requiring zero additional infrastructure.

The UWB system achieved a high spatial accuracy (92.3%) in a controlled setting. However, real-world construction sites are characterized by dynamic clutter such as moving heavy machinery, dense worker interactions, and temporary material stockpiles. The dynamic clutter induces Non-Line-of-Sight (NLOS) conditions. Furthermore, as previously established in literature (Shahi et al., 2012), a critical operational challenge for UWB is multipath interference caused by metallic obstructions. Reinforced concrete and steel scaffolding are common in vertical construction hence these dynamic obstructions and reflections are expected to degrade the baseline accuracy established in this study.

To address these real-world interferences, future deployments should monitor UWB data quality in real-time. When the positioning signal is stable and physically consistent, UWB spatial tracking remains the primary source. However, when the signal exhibits physically implausible movements, the system should dynamically shift reliance to IMU channel.

Conclusion

This study presented a comparative analysis of UWB-based localization and smartphone IMU-based gait analysis in terms of construction safety monitoring. The experimental outputs highlight a distinct trade-off between activity recognition and spatial context. While the IMU-based system effectively detected kinematic changes such as balance differences on narrow planks, its sensitivity to location was worse. The IMU-based analysis failed to distinguish between normal ground-level walking and elevated walking. Conversely, the UWB system provided critical spatial awareness, successfully identifying elevated zones like mezzanines. However, it performed worse in identifying walking on scaffolding due to noise buffering limits.

Rather than framing these limitations as shortcomings of the technologies, this study aims to better understand their practical operating conditions in complex, multi-level construction environments. The findings highlight key limitations, such as the spatial ambiguities associated with IMU-based tracking and the vertical noise observed in UWB measurements. By documenting these behaviors, the study provides a useful empirical reference for future work. Building on these insights, future research can explore more practical sensor fusion approaches that combine the complementary strengths of IMU-based activity recognition and UWB-based positioning, with the goal of improving reliability in real-world construction settings.

Abstract

This paper investigates openBIM-based Green Public Procurement (GPP) and Environmental Product Declaration (EPD) code checking and the suitability of Industry Foundation Classes (IFC) for supporting such checks. The coverage of Italian national requirements is assessed by concepts in the IFC schema and validation procedures such as Information Delivery Specification (IDS). The work was carried out under a research project funded by Northern Italy Venetian Regional Authority (CAM.bio project). For requirements exceeding IDS capabilities: graph-based checks, calculations, and facets outside IDS scope, a Gherkin-style validation combines human-readable scenarios with imperative code. Validation on IFC models is presented, alongside reflection and conclusions.

Introduction

The problem of implementing a digital strategy to monitor EPD and GPP processes is highly discussed both in relation to openBIM approaches (Aragon et al, 2025) standardization of rule checks (Tomczak, 2022) and alignment with Digital Product Passport (DPP) requirements. (Hamidkhaniha et al., 2025)

Several approaches have been developed to trace EPD and GPP requirements in a digital environment highlighting the necessity to adopt rule checking procedures. The majority of the approaches depends on naming standards and/or the definition of proprietary attributes. This causes the impossibility of standardizing those procedures and overpass national or local approaches. Due to the DPP directive this standardization and national codes alignment is necessary to fully support an EU policy for EPD monitoring, neutral and independent digitalization, computational code checking. (Honic et al., 2024). Based on this background, the study focused two research questions:

- RQ1. Is IFC a standard robust enough to support regulatory GPP requirements validation procedures?
- RQ2. Can IFC-based regulatory verification procedures be fully translated into standardized and vendor-neutral procedures such as IDS?

State of the art

The Industry Foundation Classes (IFC) are the predominant open standard to exchange Building Information by means of digital models (BIM). IFC is often regarded as a comprehensive and rich ontology, but in terms of producing data, the standard has limitations when highly specific information is required and proprietary authoring tools adopt specific dialects. At the same time, individual modeler preferences or the intent behind a data exchange has pronounced consequences on the way data is structured and exported. For example, Noardo et. al (2019) documents such tool limitations in the context of geospatial engineering. Gerbino et al. (2021) specifically looks at some of the difficulties in retaining material data across exports.

Limitations on information level available in IFC standard affect the code checking procedures that can be activated. There is a variety of standards and approaches to define information requirements on BIM models. Tomczak et al. (2022) identifies Spreadsheet, Product Data Templates, Data Dictionaries, IDS, mvdXML, idmXML, Level of information need, IFC Property templates and Linked Data + SHACL. These approaches follow a *declarative* approach, the requirements are stated as the intent that needs to be checked. This as opposed to an imperative approach that states the way how to perform the check. A somewhat hybrid form is Gherkin, which combines a natural language textual scenario description coupled with granular implementation steps in an imperative programming language. Gherkin for IFC has been described first in Moult and Krijnen (2020). It has since then been actively employed in the buildingSMART International (bSI) validation service[1].

When removing approaches without software support, approaches in which the semantics are not computer interpretable or that are more focused on the shape of the data, the approaches include IDS, mvdXML, SHACL and Gherkin. Jaud et al. (2025) specifically highlights the

[1] https://validate.buildingsmart.org

limitations of IDS compared to mvdXML, in particular with respect their precision: where mvdXML enables to stipulate the exact graph pattern to require, IDS is more focused on the interpretation of that pattern in end-user facing semantics and does not differentiate for example whether a property is defined on the occurrence or on the type-level. On the other hand, SHACL, described for its relevance to the AEC domain in Oraskari et al. (2021), requires moving the data to the language of the semantic web (RDF; Resource Description Format) which comes with implications in terms of increased dataset size and lacks a rich ecosystem to perform geometrical analysis (Pauwels et al. 2017). mvdXML has considerably less implementation support than IDS, higher complexity and no version-independence due to its focus on and tight coupling with IFC graph patterns.

The necessity for robust data validation is foundational in particular in the sustainability domain because of its transition toward an automated, BIM-based decision-support ecosystem, driven by increasingly stringent Green Public Procurement (GPP) requirements. Current research emphasizes the integration of Artificial Intelligence (AI) and Life Cycle Assessment (LCA) within the BIM environment to streamline the complex trade-offs required for regulatory compliance (Li et al., 2024). This paradigm shift is most critical during the Early Design Stage (EDS), where model-driven material selection dictates the building's ultimate environmental load and its alignment with mandatory sustainability criteria (Kamari et al., 2022). Such aspects state the necessity to rely on standardized datasets.

Methodology

To support the necessity to adopt standardized and openBIM code checking procedures related to EPD and GPP requirements, a study on the alignment with EPD information requirements was developed highlighting the percentage of attributes that are missing in the current IFC data model. To solve the problem of standardizing GPP/EPD information lacks in the IFC schema buildingSMART Data Dictionary (bSDD) technology was used to pivot on neutral attributes on an independent but standardized extension of the data model. The second part of the study was then dedicated to evaluate IDS robustness in supporting IFC based code checking procedures in the sustainability domain. Using standardized information requirements, an IDS-based code checking procedure was tested. Similarly to what was experimented in the first phase also in this phase the methodology was developed to assess the maturity of the standard by determining the actual percentage of code checking procedures that are supported by IDS .

An operational answer to these limits was developed and tested to demonstrate the applicability of the approach in a Common Data Environment (CDE) developed in alignment to those standards.

The analysis of the percentage of requirements and of procedures covered by bSI standards is then presented and commented on as a result of the experimentation and of the level of robustness of the schema.

The rationale behind the chosen methods is to rely on a procedure that includes at least 67% of EPD domain definitions that can be translated into IFC protocols. Furthermore, it must be demonstrated that the missing information can be integrated using only standardized protocols. Similarly, an information technology that allows for the integration of model compliance verification procedures using only open and neutral protocols is considered as promising. To demonstrate this assumption, in the third phase of the study integration scenarios, to properly support the openBIM code checking procedure, were tested.

Experimentation

First phase: specification

This phase defined the interoperability framework for linking CAM environmental requirements to IFC in a structured and verifiable way. The study focused only on mandatory requirements relevant to the design and construction phases, excluding non-binding provisions related to candidate qualification and procurement. Each criterion was systematically indexed within a spreadsheet, and its requirements were summarized highlighting qualitative and quantitative contents.

Subsequently, each item was evaluated and categorized into one of four levels of 'IFC Compatibility: fully IFC compliant, partially IFC compliant, potentially IFC compliant (partially or fully but characterized by high implementation complexity or requirements related to subjectivity of modeling), and non-IFC compliant (qualitative requirements or elements unrelated to information modeling). This assessment was based on three key factors: the formalization of CAM specifications into information requirements covered by IFC; the effective optimization of data entry and validation processes within current BIM applications; the operational feasibility for the stakeholders involved.

To ensure the practical feasibility and reliability of the proposed framework, the study focused exclusively on '*Fully*' and '*Partially*' compliant criteria. Consequently, both 'Non-IFC Compliant' items and those labeled as '*Potentially Compliant*'—due to their excessive technical barriers and operational complexity—were excluded from the research scope.

Development of a specific IFC Mapping and bSDD

The next step was to determine how the selected criteria could be mapped within the IFC schema. IFC4 ADD2 TC1 (version 4.0.2.1) was adopted as the reference schema, balancing standard maturity with compatibility with current industry tools. The mapping analysis process also aimed to:

- identify specific criteria requiring the development of new Classes or Property Sets (Psets) to address information which were not currently included in the IFC schema;
- identify possible difficulties in data writing procedures for operators with BIM Authoring applications (data assignments to abstract classes such

as groups or systems, document associations to elements, data assignments to material layers).

The analysis revealed that, of the total IFC-compliant criteria developed, 8% of the criteria can be fully mapped according to the schema, while the remaining 92% can be mapped according to other openBIM standards, by defining custom Psets and by developing a bSDD classification dictionary.
It also emerged that more than 50% of the criteria were affected by potential operational issues such as assignment to IfcProject, -Site or -Building which may not exist as such in the native environment, usage of document associations and classifications on objects and materials for which tools have limited support, or decompositions such as material layers.

A significant challenge arises from the diverse nature of CAM criteria, which often stipulate specific requirements for construction materials, such as defined recycled content. These requirements encompass a wide array of numerical, textual, and boolean parameters. Furthermore, certain criteria demand properties not natively supported by the IFC schema, specialized quantity take-offs from filtered object selections, or the inclusion of technical documentation linked directly to model entities.

A technical mapping sheet was developed to define, for each criterion, the relevant IFC entities, materials, properties, and document associations. To support consistent data population and semantic interoperability, CAM information was also structured within a dedicated "CAM Classification" bSDD dictionary covering elements, materials, and properties for the purpose of consistency and adoption in tools that support bSDD.

Analysis of validation procedures of each criterion

Finally, the specification phase defined validation rules and tolls needed for each criterion. Validation was initially formalized using the Information Delivery Specification (IDS) format, but the analysis showed that several criteria exceeded current IDS capabilities:

Validation of document association: most of the criteria required a document association validation related to objects or material layers. However, IDS does not support the verification of external files linked via *IfcDocumentReference*;

- Disjunctive logic (OR conjunction);
- Conditional logic (IF-THEN) validation: where the validation of an object's property depends on conditions defined in a (separated or related) entity;
- Element-to-Material recursion: while IDS can verify that an element associated with "Material X" possesses specific properties, it is impossible to shift focus to the material and apply constraints to the material entity itself;
- Data aggregation and computational criteria: performing project-wide calculations, such as verifying that the cumulative weight of all recyclable materials exceeds 70% of the total project mass.

To overcome these limitations, the research implemented an IDS multi-applicability approach and custom scripts to parse the IFC model, extracting data from both entity and material levels to perform the required validation. The analysis concluded by assigning each criterion to one of three automated validation scenarios tailored to the specific complexity of the data to be verified: IDS-exclusive, script-exclusive, blended validation.

Second phase: validation

To develop the GPP-CAM validation phase, multiple IFC model prototypes were created within an authoring tool according to defined rules and mapping in technical sheet to serve as a baseline for subsequent operations as: test data writing and checking limitations, identify formal control strategies according to the effectiveness of IDS rules, define an overall validation workflow.

An operational guide was then developed to support practitioners and streamline the workflow by sharing a general know-how of IDS rules structure and convey multi-step procedure of validation, including best practices for correct model setup and data population to ensure the accurate generation of the CAM information database according to the CAM Classification bsDD.

Operational and software limitations

A preliminary audit of the informational content of the test models revealed significant deficiencies in data quality and completeness.

Recognizing that many errors stem from the inherent limitations of commercial BIM authoring tools rather than user oversight, the methodology incorporated a 'post-procedural editing' phase (authoring&integration). This ensures that models failing validation due to software constraints can be automatically refined and corrected before the final assessment. Consequently, it became necessary to develop dedicated implementation tools within both desktop applications and CDE.

Recurring limitations in commercial BIM authoring softwares that hinder the direct implementation of CAM requirements included:

- *material classification*: difficulty in assigning standardized classification codes directly to material layers;
- *parameter duplication*: issues with redundant project parameters during the IFC merging phase;
- *entity and group classification*: constraints in mapping classifications to complex element groups;
- *document association*: lack of streamlined workflows for linking external documentation to model objects;
- *generic connectivity*: limitations in creating generic connection relationships between elements;
- *schema conversion*: difficulties in converting IfcGroup entities into specific IFC schema subclasses.

Formal control strategies: Editing for validation

To address these software limitations, the project initially tested advanced IFC model manipulation within the open-source Blender environment. By leveraging the integration of the IfcOpenShell library and the graphical

interface provided by Bonsai add-on, the following operations were successfully implemented:

- *document association*: deployment of IfcDocumentReference entities and their corresponding IfcRelAssociatesDocument relationships to ensure formal linkages between external sources (e.g., certifications, technical data sheets) and individual model entities.
- *database structuring*: refinement of the model's internal data structure to ensure full compliance with the IFC schema, thereby correcting inconsistencies generated during export from proprietary software;
- *classification mapping*: assignment of one or more classification codes to model elements using IfcClassificationReference entities and IfcRelAssociatesClassification relationships, facilitating interoperability with external classification systems such as the bSDD.

However, the operational complexity of manual editing highlighted a need for more efficient, less error-prone methods to support large-scale implementation. Consequently, the project shifted toward automated IFC-editing solutions through the development of dedicated 'IfcPatch' recipes in Python. These scripts allow for the automated post-processing and refinement, ensuring a standardized data structure regardless of the constraints imposed by the original authoring tool.

IDS Rule Architecture and Hierarchical Validation

Given the limitations of the IDS format, IDS rules were organized according to a predefined schema where each CAM criterion is decomposed into one or more conditions applicable to the IFC data. For every criterion verifiable via IDS, a multi-specification rule applicability approach was developed to determine compliance. These specifications are structured into three hierarchical levels to enable a step-by-step verification process:

- Level 0 - Applicability: These specifications define the relevance of a CAM rule to the analyzed model. If these conditions are not met, the criterion is either inapplicable to the project or essential preliminary information is absent.
- Level 1 - Entity Classification: These rules ensure that the targeted IFC entities are correctly classified according to the bSDD dictionary. Failure at this level indicates that entities are misidentified, thereby precluding further requirement validation.
- Level 2 - CAM Criterion Validation: These specifications verify whether the IFC model fulfills the actual environmental requirements of the CAM criterion. Non-compliance at this stage necessitates data integration or design adjustments.

This tiered structure facilitates a granular diagnostic process, identifying whether a failure stems from a lack of relevance (Level 0), a classification error (Level 1), or a direct violation of criteria requirements (Level 2).

Orchestrating IDS for conditional logic

The Multiple Applicability Approach was also implemented to overcome the structural constraints of the IDS standard, specifically the lack of support for dependencies or conditional IF-THEN logic. Instead of a single monolithic check, CAM requirements are decomposed into sequential, interdependent IDS files as:

- Triggering Specification: The first IDS file verifies the presence and attributes of the "source" element (e.g., IF an IfcWall is classified as 'LoadBearing').
- Targeted Specification: If the first check is satisfied, a second specification validates the required conditions on the related element (e.g., THEN the associated IfcMaterial must have a specific recycled content property).

Under this approach, CAM Compliance of IF-THEN logic is formally achieved through two valid states:

- Full Compliance: Both specifications are successfully validated, confirming the condition was triggered and the requirement met.
- Non-Applicability: The first specification is not satisfied, indicating the triggering condition is absent (e.g., no LoadBearing walls exist), and thus the requirement is not invoked.

Table 1: Synthesis of validation outcomes

Result level	Status	Meaning
Level 0 Fail	Not applicable	The rule does not apply to the model
Level 1 Fail	Classification Error	Entities are found but not correctly mapped to bsDD
Level 2 Fail	Non-Compliant	Data is present but does not meet CAM thresholds
All Level Pass	Compliant	The model satisfies the CAM criterion

Definition of an Automated Validation Framework

Finally, each criterion was assigned to one of three operational validation scenarios based on its technical complexity:

- Scenario 1: Hybrid Validation (IfcPatch + IDS + Script): The most robust approach. It combines model normalization, standard attribute checking, and complex computational logic for maximum accuracy and traceability.
- Scenario 2: Standard-Centric (IfcPatch + IDS): Suitable for criteria fully expressible through the IDS schema. It ensures high compatibility with international tools but is limited to non-computational requirements.
- Scenario 3: Script-Driven (IfcPatch + Script): Utilized for performance-based criteria that fall outside the IDS scope. It relies on direct analysis of the IFC

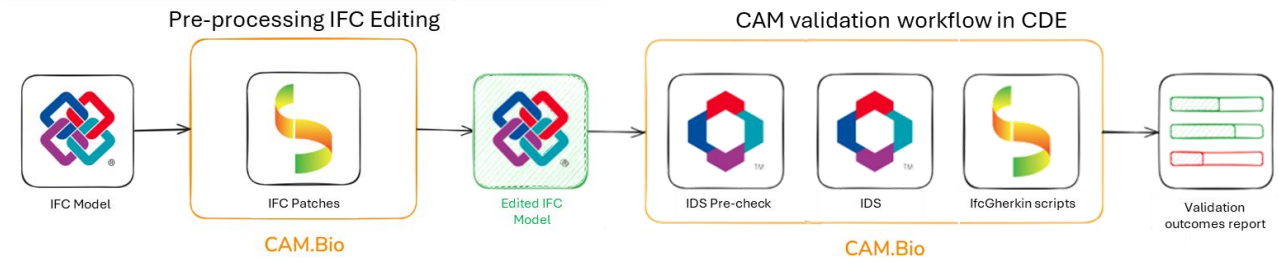

Figure 1: Schematic overview of the contributions of the CAM.bio project wrt. the validation workflow

structure to validate complex environmental constraints and relationships.

This analysis enabled the definition of a comprehensive validation framework that encompasses all potential scenarios, allowing it to adapt seamlessly to each specific criteria by integrating standard protocols with custom computational logic.

- **Phase 1: Pre-processing (IfcPatch):** Uses the IfcOpenShell library to normalize data, correct structural errors, and inject missing relationships or attributes into the IFC model.
- **Phase 2: IDS Pre-check:** A custom module verifies the presence of mandatory information required for formal validation, preventing execution errors.
- **Phase 3: Standard IDS Validation:** Executes .ids files to verify criteria that can be formally expressed via the standard buildingSMART XML schema.
- **Phase 4: Advanced Scripting (IfcGherkin/IfcOpenShell):** Python scripts perform complex verifications unreachable by IDS, such as Boolean logic on materials, cross-entity spatial checks, and geometric quantity aggregations**.**

The defined four-phase validation process can be made scalable and seamlessly integrated into the CDE platform by encapsulating the entire validation workflow (IfcPatch, IDS pre-check, IDS, and custom scripts) within a Docker microservice exposed via RESTful APIs.

openCDE Platform: Implementation and Visualization

To ensure CAM requirements are manageable by non-technical stakeholders and to demonstrate the feasibility of the proposed framework, the research evolved a CDE prototype. The Xeokit viewer was customized to expose CAM entities often hidden in traditional BIM viewers (e.g. TypeEnums). This included a reorganized tree hierarchy for IfcSpatialZone and IfcBuildingSystem, and direct visibility of material-level properties and external documentation (IfcDocumentReference) reflecting CAM Classification bSDD. The platform includes an IDS Authoring Environment for rule creation and a Validator UI for real-time compliance feedback. Third phase: integration and authoring

Given the limitations and dialects of IFC authoring tools, a process is in place to unify and harmonize the data ingested into the system. In the platform (named CAM.bio – the italian word for “change”) this is built around the idea of IfcPatch[2], which is an existing module in the IfcOpenShell family of tools that consists of ‘recipes’ to fix or alter IFC content and write out a revised version. These recipes are implemented in python using imperative code. In our particular case we built a minimal graph rewriting DSL to declaratively encode the intended transformations. In particular it was found that certain tools were unable to provide classification references to material definitions. As a work-around the modeller was instructed to write these as a material property using particular conventions that would be picked up by the IfcPatch recipe. See Figure 2 for part of the implementation, Figure 3 and Figure 4 for the before and after as a minimal graph rendering.

Model validation

As introduced earlier in the text there has been extensive research on validating information requirements. Many of these can also be used to validate design requirements such as CAM, because they use a similar vocabulary. For this project, several have been considered.

IDS is used in the project, it is limited in scope and expressiveness, but well-tested and widely implemented. An additional approach needs to be selected that is richer

[2] https://docs.ifcopenshell.org/ifcpatch.html

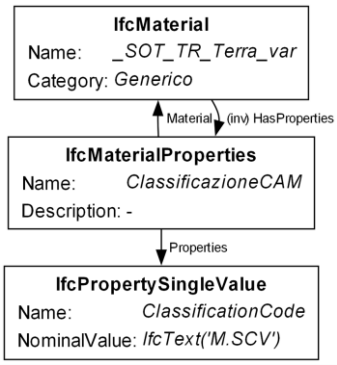

Figure 3: 'Before' situation with classification as property

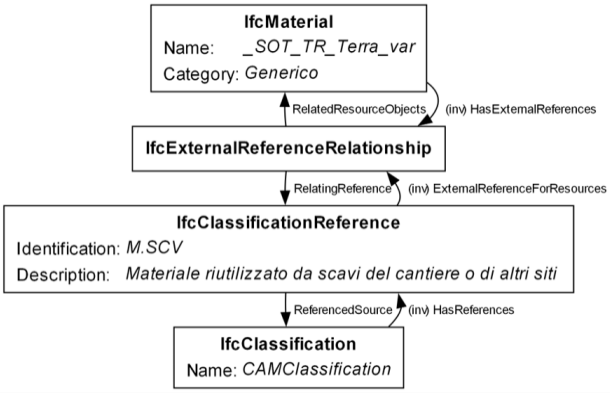

Figure 4: 'After' situation when rewritten

in expressiveness to support implementing the required constraints.

That is also not surprising given that IDS is intended to control the availability of information on top of the modelling mechanisms that IFC and standard model view definitions already propose. mvdXML has the possibility to precisely stipulate graph patterns, but is still lacking many of the constructs needed for the ambitions set out in this paper such as aggregate functions to sum areas together and the ability to assess and compare multiple focus nodes in one scenario.

Naturally, the option exists to implement rules in proprietary software, but this lacks the portability for moving such checks to a web-based platform and is not vendor neutral. Another option is to not use a pre-existing approach at all, and to simply use an imperative programming language to implement the required functionality, which is flexible but comes at a prohibitive cost in terms of shared understanding between domain stakeholders.

The approach selected in the end is Gherkin, which consists of a high level human readable set of scenarios (an example for this project is given in Figure 5) that describe test logic for shared understanding between stakeholders, which are paired with an implementation in (in this case) the Python programming language for the actual execution. As such it can be seen as a middle ground between expressiveness, portability and ease of understanding.

In Gherkin scenarios are broken up into steps, these steps are matched to parameterized implementation functions, as such there obvious advantages: people do not need to understand program code, but can follow the high-level specification; as such there is a shared understanding of the requirements between software engineers as well as other stakeholders; the textual breakdown into statements offers modular reuse of functionality. In order to best understand the technology it's best to look at the code repository that contains the body of rules developed for the validation service[3]. In Figure 6 one sees a table of the functional steps employed in the validation service. This table highlights the relative strength of the Gherkin approach for IFC model verification: Gherkin allows a similar structure of graph pattern building using entity and attribute selection (not too dissimilar from EntityRule and

AttributeRule in MvdXML) and at the same time using highly specialistic predicates that also involve the wide availability of python modules to build rich behavior for the breadth of disciplines represented in the IFC schema and complexity of downstream verification use-cases.

An example of such a scenario that has been built for the CAM.bio project is depicted in Figure 5. The first lines (line 0-5) are descriptive. In line 8 an initial selection of entity instances is made from the model. Their classification is looked up and filtered. For the elements with matching classifications we sum their areas. This is then compared to the 'SuperficiePermeabile' which is another rule implemented in similar fashion.

Discussion and results

Regarding BIM-compliance analysis, the structural limitations identified within the schema are as follows:

- 44% of the criteria cannot be fully implemented due to the absence of specific entities for environmental and infrastructural contexts (e.g., river ecosystems, groundwater). These entities were introduced in the IFC 4.3 version, rendering the current version insufficient for direct ontological mapping. Future research is to be directed at this.
- The current breakdown of IfcMaterial does not allow for an analytical definition of the internal composition of mixtures or composite materials, complicating the verification of chemical-physical performance criteria.

Regarding requirements that are potentially or partially IFC-compliant but were excluded due to implementation difficulties, the following are highlighted:

Regulatory requirements involving subjective or qualitative evaluations (e.g., prevention, mitigation, analysis of existing greenery) that cannot be translated into standardized parametric properties.

- Compliance with external regulations outside the scope of this study; simplifications were adopted, transitioning to manual verification.
- Comparisons between different temporal phases, which are complex to develop and risk imposing workflows that are disproportionately burdensome for the operator relative to the benefits of the verification. This type of analysis could be further explored in future research.
- Criteria requiring the identification of "technical strategies" that conceptually lack a unique digital identity. In these cases, simplification was preferred to avoid the definition of overly extensive custom IfcPropertySet that would be difficult to standardize.

The analysis revealed that, of the total criteria defined by the CAM regulation, more than 76% are IFC compliant. Considering the research screening for determining the project's scope, based on the exclusion of non-mandatory and difficult-to-implement criteria, it emerges that IFC-compliant CAM criteria represent a total of 56% of the total CAM regulation criteria (46% fully IFC Compliant, 10% Partially IFC Compliant, 21% Potentially IFC Compliant, and 23% Non-IFC Compliant.

This study excluded several criteria from its scope, specifically those pertaining to urban and territorial planning. Such criteria necessitate the calculation of spatial proximities between the project site and local public services, a requirement that can be effectively addressed through enhanced interoperability between IFC and GIS models.

Concerning the IFC-mapping analysis, the study identified that out of the 816 entities comprising the IFC4x2 schema, a subset of 39 entities and their respective TypeEnum is sufficient to fulfill the CAM regulatory requirements. These requirements primarily map to the following categories: IfcMaterial, IfcDocumentReference, IfcSpatialElement, IfcSystem, and IfcBuildingElement sub-classes, including their relative predefined types.

The primary challenge encountered during this mapping phase was the necessity for granular discretization of entities based on their ontological and functional characteristics (e.g., IfcMaterial naming conventions, IfcSystem, and IfcBuildingElement) or according to specific document contents (e.g., IfcDocumentReference). This granularity is essential for executing automated filtering operations and rigorous data validation. Additionally, the definition of custom Property Sets proved critical, especially for capturing data related to recycled, recovered, and by-product content within products and materials.

In this context, the development of a dedicated bSDD was fundamental. To define the requirements dictated by the CAM criteria, the dictionary incorporates 144 class codes, categorized as follows (25 codes for the discretization of document types within the IfcDocumentReference entity; 43 for the characterization of building element features; 8 mapping to various IfcSpatialElement sub-classes; 54 for the classification of diverse IfcMaterial types; 14 defining IfcSystem sub-classes)

The project ultimately identified 104 distinct properties. While 13 of these attributes are natively available within the IFC schema, the remaining 91 were specifically introduced via the cam-bSDD.

Concerning Validation, the analysis of the 38 CAM criteria revealed a high dependency on model normalization and multi-layered validation framework. Specifically, 36 criteria (95%) required corrective support via IfcPatch to ensure data consistency. More than 87% of CAM criteria needed Gherkin as a fallback due to technical requirements and entity comparisons not supported by IDS format only.

Table 2: CAM validation procedure breakdown

Validation Component	Criteria Count (out of 38)	% of Total
IfcPatch Support (Pre-processing)	36	95%
IDS Pre-check	21	55%
IDS-only Validation	5	13%
Script-only Validation	14	37%
Hybrid Validation (IDS + Script)	19	50%

Conclusions

CAM.bio contents were fully aligned with the Italian regulatory framework in force at the time of completion (D.M. 23/06/2022 n° 256). As is often the case in building construction field, new legislation updating CAM criteria has taken effect from February 2026.

In this context, the project serves as a baseline reference to support Italian current implementation and the transition to the updated regulatory framework, and provides an example of structured bSDD dictionary development and as a reference for international researchers.

The study establishes limits of the current version of IFC and IDS in supporting computational and openBIM based code checking procedures based on the information requirements needed by the national implementation of EPD directive.

NOT ALL LINKS ARE EQUAL: LINK EXPRESSIVENESS AND DISCOURSE SCOPE IN BIM-GIS INTEGRATION

Judith Krischler[1], Sebastian Schilling[2], Maximilian Sternal[3], Jakob Taraben[1] and Christian Clemen[2]

Abstract

Linking is increasingly adopted in BIM-GIS integration to connect heterogeneous datasets without forcing full schema conversion. Application scenarios are the linked transfer e.g. of BIM and environmental data for permitting or the linking segmented 3D point clouds. However, links are often treated as purely technical connectors, while their interpretability remains implicit. We distinguish closed, shared, and open discourse space and analyze how common link paradigms support the ability to reconstruct sender intention. We also discuss practical trade-offs regarding implementation effort, tooling, and adoption. This paper is intended to help readers select appropriate linking mechanisms depending on BIM-GIS integration goals.

Introduction

Linking has become a central strategy in BIM-GIS integration, particularly where heterogeneous data structures, scales, and modeling assumptions make full schema unification impractical. A linked approach relies on establishing relationships between heterogeneous datasets instead of fully unifying their underlying data models or use naturally imperfect format conversions (Eriksson et al., 2020; Korkmaz and Basaraner, 2024). Instead of converting data between formats such as IFC and CityGML, many integration approaches rely on explicit or implicit links to establish relationships between models, elements, or representations (Liu et al., 2017; Guyo et al., 2021; Beck et al., 2020). If we assume a simple communication model involving a sender and a receiver, the sender creates both the application models and BIM/GIS links. After the data transfer, the receiver must identify the relevant parts of the application models and the intended meaning of the links. The receiving software might e.g. be a Common Data Environment, BIM-coordination software or a web-GIS.

Where the semantic intent behind a link cannot be recovered, e.g., which coordinate transformation was applied or what part-whole relationship was assumed, the receiving system either propagates a silent misinterpretation or must recompute the original analysis (if known) from scratch. The receiver cannot determine whether their interpretation corresponds to the one under which the link was created.

Semantic mismatches between established standards reflect not only technical modeling differences but fundamentally divergent domain perspectives: GIS adopts a global, landscape-oriented view prioritizing spatial relationships and regional context, while BIM employs a detailed, object-centric perspective focused on individual building components (Kolbe and Donaubauer, 2021; Tan et al., 2023; Sani et al., 2022).

An integration by linking both domains must therefore consider different semantic depths and requires flexible integration approaches. In this regard, Mohammed et al. (2026) propose multiple levels of BIM-GIS integration quality and suggest that higher integration levels rely on more expressive linking mechanisms, while also highlighting the need for clearer methodological guidance and standardization.

Despite their importance, links are often treated as technical implementation details or a matter of computational efficiency (Napps et al., 2026). As a result, assumptions about relationship semantics, scope of validity, and interpretability remain implicit, limiting transparency, reproducibility, and reuse of integration results. This is particularly problematic in BIM-GIS scenarios, where relationships may encode non-trivial analytical decisions - such as georeferencing strategies, spatial abstractions, or part-whole interpretations - that cannot be reconstructed from geometry or attributes alone.

Background and Research Questions

Previous work by Krischler et al. (2025) introduced and operationalized four link types - geospatial, geometrical, topological, and mereological - to support context-sensitive BIM-GIS integration within container-based exchange models, compliant to DIN 18290 (Multimodel-Container). The link types do not prescribe a specific technology or schema, but describe what kind of relationship is being expressed and which assumptions are made explicit. The Multimodel-schema was chosen here, as it is successfully implemented and used in (German) construction software for tendering, awarding contracts, and billing.

Geospatial links explicitly relate datasets through their geographic positioning by defining a common spatial reference or transformation parameters, enabling consistent co-registration across BIM and GIS models.
Geometrical links associate datasets via auxiliary (proxy) geometric representations, such as footprints or bounding volumes, to reference spatial subspaces where no shared

identifiers or semantic alignment exist. **Topological links** describe spatial relationships such as containment, intersection, or adjacency independently of exact geometry, allowing robust connections between entities of different dimensionality. **Mereological links** capture part-whole relationships between heterogeneous representations, enabling the association of datasets that describe overlapping or corresponding parts of the same real-world entity at different levels of detail. While this work demonstrated how expressive links can be formalized, it also revealed that identical link structures can have very different meanings depending on where and how they are interpreted.

This paper takes a step back and asks: why do link modeling approaches differ so fundamentally in their expressive power and interpretability? We argue that the key, yet underexplored factor, is the discourse space in which links operate. By making discourse scope explicit, we aim to clarify the relationship between link modeling paradigms, semantic expressiveness, and practical applicability.

The paper addresses the following research questions:

RQ1: How do commonly used link modeling approaches in BIM-GIS integration differ in their level of link expressiveness for geospatial, geometrical, topological, and mereological links?

RQ2: How does link expressiveness influence the ability to reconstruct sender intention and semantic context?

RQ3: What practical requirements and trade-offs are associated with realizing different levels of link expressiveness in BIM-GIS workflows?

Analytical Framework

This paper follows an analytical and comparative research approach. It first introduces discourse space as an analytical framework to distinguish between closed (local), shared, and open (global) semantic contexts in which links between BIM and GIS data are created and interpreted.

Building on this framework, commonly used link modeling approaches from research, standardization, and practice are analyzed comparatively with respect to their level of link expressiveness. Existing approaches are examined and positioned within the discourse space framework, allowing their underlying assumptions, expressive capabilities, and limitations to be discussed systematically.

The analysis further examines how different levels of link expressiveness affect the reconstruction of sender intention and semantic context, and concludes with a discussion on practical requirements and trade-offs for realizing expressive links in BIM-GIS workflows.

Discourse Spaces in BIM-GIS Integration

We define discourse space as the semantic scope within which the meaning of a link is interpretable without additional external knowledge. Prior work implicitly reflects different semantic depth of link interpretation (Bormann et al., 2021), ranging from schema-internal relationships (e.g. through Application Domain Extensions) to ontology-grounded semantic links (Beck, 2023; Hagedorn et al., 2023; Davar Panah, 2025; Schilling and Clemen, 2023). However, these scopes are rarely made explicit as design decision. Three discourse spaces are distinguished within this paper (Figure 1). The primary formal criterion for our "discourse spaces" is where (!) the link schema is located: in the application model (*closed*), in a standalone, use-case-specific link schema (*shared*), or in a formal, publicly accessible ontology in the sense of the Semantic Web (*open*), and whether the link is self-descriptive rather than just serving as a pointer. The W3 community describes "self-descriptive" data as a defined label, definition and comment within the representation itself without relying external documents for description (World Wide Web Consortium, 2014).

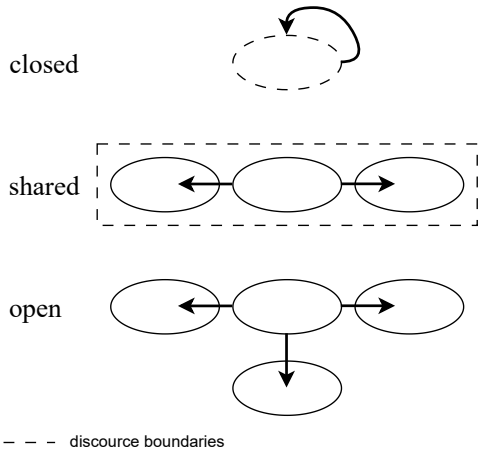

Figure 1: Link paradigms covering local, shared, and open contextual discourse.

Closed (Local) Discourse refers to links whose meaning is interpretable only within a single file, dataset, or schema. Semantics are implicit and depend on internal conventions, such as schema structure, attribute naming, or software-specific behavior. Interpretation requires knowledge of the originating data model, as no externalized semantic contract or self-descriptive semantic content exists within the link itself (e.g. a relational database schema).

Shared Discourse denotes a bounded semantic context established across multiple datasets within a project or integration setting (e.g. within information containers, where there is a semantic agreement on the linkage between datasets). Here, link meaning is self-descriptive and explicitly agreed upon through project conventions, container schemas, or link models, but remains valid only within that context.

Open (Global) Discourse describes links whose semantics are interpretable independently of a specific project and whose links are fully self-descriptive. Meaning is grounded in shared, publicly defined vocabularies or ontologies, typically using globally resolvable identifiers and interpretation does not rely on bilateral agreements (e.g. public ontologies following the FAIR-principles).

These discourse spaces are not mutually exclusive but rep-

Table 1: Categories of Link Expressiveness and Their Impact on Intention Reconstruction

Category	Low Expressiveness	High Expressiveness	Impact on RQ2
Direction	Non-directional	Explicitly directional	Clarifies information flow
Cardinality	Binary (1:1, 1:N)	N-ary, attributed	Preserves complex patterns
Architecture	Embedded	Reified with metadata	Enables rich context
Semantic Strength	Implicit/local	Standardized/global	Ensures consistent interpretation
Link Depth	Document-level	Attribute-level	Supports precise integration
ID Scope	Local	Global/persistent	Enables long-term validity

resent increasing degrees of semantic explicitness and external interpretability.

Link Expressiveness

In this paper, link expressiveness denotes the ability of a link representation to make relationship semantics explicit and machine-interpretable. This includes, but is not limited to:

- explicit relationship type and link directionality
- support for qualified and n-ary relations
- attachment of parameters and constraints
- explicit scope and validity context
- provenance and derivation metadata

Expressiveness is not inherently desirable in all cases as it usually introduces trade-offs in complexity, tooling and governance. The following sections analyze how expressiveness manifests across discourse spaces and link modeling paradigms.

Comparative Analysis of Link Expressiveness (RQ1)

This section presents a comparative analysis of commonly used link modeling approaches in BIM-GIS integration, examining how they differ in their ability to explicitly express geospatial, geometrical, topological, and mereological relationships. The analysis is structured along the previously introduced discourse spaces and positions existing approaches accordingly, thereby making their expressive capabilities and limitations directly comparable.

Closed Discourse: Schema-Inherent and Implicit Links

In closed (local) discourse, links are embedded within data models as references, foreign keys, or structural relationships. Common examples include relational database joins or GML XLinks. These mechanisms typically allow only minimal expressiveness: a link indicates that a relationship exists, but not what kind of relationship it is or why it was established.

Directionality, cardinality, and constraints are either implicit or fixed by the schema. For BIM-GIS integration, this limits expressiveness, particularly for geometrical and mereological (part-whole relationship) links, which often require additional parameters or contextual assumptions.

Local discourse links are easy to implement and widely supported, but they externalize semantic interpretation to documentation or human expertise. Figure 2 shows an exemplary relational database schema for buildings and parcels. The keys do not carry a self-explanatory semantic meaning. The link merely establishes a technical association whose interpretation depends entirely on understanding the specific schema design and naming conventions used by the database creators. Local discourse approaches exist primarily in everyday engineering practice. They are rarely represented in research, as published work focuses on more sophisticated approaches.

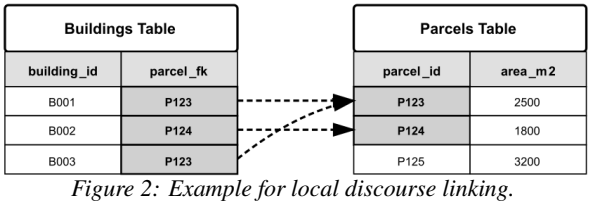

Figure 2: Example for local discourse linking.

Shared Discourse: Objectified Links in Integration Contexts

Shared discourse denotes a bounded semantic context established across multiple models within a project or integration setting. Within this scope, link meaning is fixed through explicit agreements, schemas, or link models that enable consistent interpretation among participating datasets, but remains valid only within that specific integration context.

Examples from research and standardization include information containers that intend to support the integration of heterogeneous information artifacts by organizing them in a common container while preserving their original representations. The ISO 21597 standard (Information Container for Linked Document Delivery, ICDD) introduces an explicit mechanism for representing relationships between documents by modeling links as independent, objectified entities. A similar approach, implemented in the DIN-standard 18290 (Multi-Model Container, MMC), enables links to carry types, metadata, and provenance information, supporting traceability and reproducibility in multi-model environments (Fuchs, 2015). Figure 3 shows an example link between a building model and a parcel in an MMC.

By separating information objects from their relationships, both standards establish a clear conceptual distinction between domain data and integration semantics. Links are

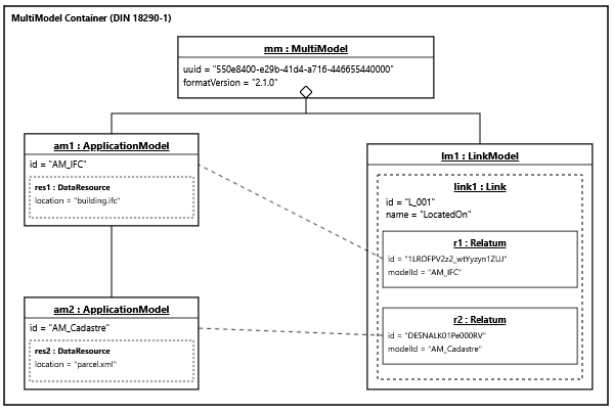

Figure 3: Example for shared discourse linking.

modeled as explicit objects with identifiers, types, and metadata, allowing richer expressiveness than schema-inherent references. In this discourse space, geospatial links can explicitly encode transformation parameters, geometrical links can reference spatial subsets, and topological or mereological relationships can be typed and directed. However, the semantics of these link types are typically defined by project agreements or domain-specific conventions rather than globally standardized vocabularies. Former research has focused on exploiting and extending both schemas to allow more semantic expressiveness, as by Hagedorn et al. (2023) or Krischler et al. (2025) and to include queries as external links.

Shared discourse enables consistent interpretation across participating tools and stakeholders, but links remain context-bound and require governance within the integration setting.

Open Discourse: Ontology- and Graph-Based Linking

Open discourse is realized through semantic web and graph-based approaches, where links are expressed using globally defined predicates and identifiers. Relationships are first-class entities that can be independently queried, extended, and reasoned over. However, the choice for a graph-based approach does not necessarily imply semantic expressiveness, but rather the quality of the used ontology (Akbarieh et al., 2025).

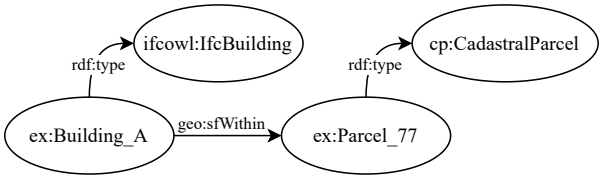

Figure 4: Example for open discourse linking.

For example, semantic web approaches that use URI-identified concepts from established ontologies, such as linking a building element to a concept from the Building Topology Ontology (BOT) (Rasmussen et al., 2020) using *bot:hasSpace*, or links expressed using standardized relationship types from domain-independent vocabularies like Dublin Core (*dcterms:isPartOf*) or schema.org (*schema:containedInPlace*) carry semantics that are globally documented and machine-interpretable without requiring knowledge of the specific BIM-GIS integration context. Works from Hbeich and Roxin (2020); Ji et al. (2024); Wang and Issa (2020) use ontological approaches to overcome integration challenges. Senthilvel (2024) presents a comprehensive approach for managing and validating semantically rich, objectified links using information containers and the BuildLinks Ontology, with a strong focus on provenance, link semantics, and standard compliance. This work allows for an open discourse as it relies on shared metadata understanding as well as semantic web technologies, even if using information containers as carrier.

This paradigm enables the highest degree of expressiveness for all four BIM-GIS link types, including qualified relations, temporal validity, and formal constraints. Mereological and topological semantics can be grounded in axiomatized vocabularies, enabling inference beyond explicitly stated links. The cost of this expressiveness lies in higher conceptual complexity, infrastructure requirements, and limited industry adoption.

Impact on Intention Reconstruction (RQ2)

Intention reconstruction refers to the ability of a receiving system to infer the semantic intent behind a link without reliance on external documentation or institutional memory. It operates on three levels: machine-readability of the link predicate, semantic reconstructability based on a shared vocabulary, and recovery of the originating analytical decision (why the link was created and under which assumptions it remains valid). The categories in Table 1 primarily address the first two levels, though all three matter in practice. Machine-readability suffices for visualization, semantic reconstructability is required for cross-organizational coordination, and intention recovery becomes critical where a link recomputed by a downstream actor may encode different assumptions than the sender intended. The link expressiveness as characterized in Table 1 influences directly whether reconstruction is possible.

Each category contributes differently to reconstruction, e.g. direction clarifies whether information flow can be traced unambiguously and cardinality determines whether complex integration patterns can be faithfully preserved or must be simplified. Architecture governs whether contextual metadata, such as provenance, derivation method, or quality indicators, can be attached to links. Semantic strength implies whether relationship meaning is locally implicit or grounded in standardized vocabularies interpretable without prior schema knowledge. Link depth affects the granularity at which relationships are expressed, from entire documents to individual attributes or geometric sub-elements. Finally, ID scope determines whether identifiers remain valid only within a single file or persist across projects and over time.

These categories do not operate independently. As Table 2 illustrates, concrete linking mechanisms combine them in

characteristic patterns corresponding to the three discourse spaces. Mechanisms in schema-based closed discourse, such as `IFCExternalReference`, or `XLink`, typically exhibit unidirectional linking, limited cardinality, and isolated semantic strength, which severely constrains intention reconstruction to the mere existence of a relationship. In shared discourse, container-based mechanisms such as ICDD linksets and MMC links achieve higher semantic expressiveness through objectified link architecture, explicit directionality, m:n cardinality and standardized semantics within their container schemas, enabling receiving systems to recover relationship type, parameters, and provenance. In open discourse, OWL-based mechanisms combine all high-expressiveness characteristics from Table 1 with globally persistent identifiers, enabling full externalization of sender intention through publicly defined vocabularies that support independent interpretation, validation, and inference.

The following examples demonstrate linking in the three discourse spaces and discuss the respective implications for intention reconstruction.

Closed Discourse: Linking Buildings with Cadastral Parcels

The following Listing 1 shows an example within the IFC data model. A direct reference from an *IfcSite* entity to a cadastral parcel identifier retrieves land ownership information. The cardinality is typically 1:1, occasionally 1:n for connecting parcels. The IFC entity references external object *DESNALK01Pe000RV*, interpretable only within IFC's internal semantics. The link purpose is not explicit; intention must be inferred from metadata, file names, or workflow conventions. The link is unidirectional (cadastral file has no knowledge of this reference), yet well-established in practice.

In a closed discourse, only the information contained inside the schema can be reconstructed. Information outside of this, such as whether the target reference is an object or an attribute, and its meaning, cannot be reconstructed because, unlike the sender, the receiver does not know the schema of the link target. Similarly, the meaning of the link cannot be restored. The sender knows that a building is going to be constructed on the parcel of land to which the link is attached. However, the link does not convey this knowledge, so the recipient cannot understand it.

```

Shared Discourse: Geospatial Linking for Unified Positioning

Listing 2 shows an example link within a container for the exchange of models between project partners. Information about the georeferencing is required to derive knowledge or understand the link. The link is part of the link model in a multi-model container with extended link types by Krischler et al. (2025). Links are stored in a separate file, but are only valid within the container context. In a shared discourse, the recipient can understand the meaning of a link because the link type and its attributes explicitly specify it. Receiving software can interpret the georeferencing intention based on the link type and additional information, such as inner and outer poses. However, the recipient can only interpret link information that is defined within the context. If the sender uses link information from outside the container context, the recipient cannot interpret it. In this example, the information can be used to transform the data into another coordinate system to visualize all geometrical models in the MMC together.

Table 2: Categorization of Linking Mechanisms in BIM-GIS Integration: The different Mechanism are assigned to Discourse Spaces (Disc.) for open, shared and closed

Mechanism	Disc.	Direction	Card.	Archit.	Sem. Strength	Depth	ID Scope
Schema / Encoding-based							
IfcExternalReference	○	unidirectional	1:n	direct	isolated	Object	Global (URI)
GML XLink	○	unidirectional	1:n	direct	isolated (XML)	Object / Property	File / Global (URI)
CityJSON Extensions (lynks schema)	○	unidirectional	1:n	direct	generalized	Object / Property	File
Information Container-based							
MMC Links	◒	directional	m:n	objectified	standardized	File / Object	Container
ICDD Link-set	◒/●	bidirectional	m:n	objectified	standardized	File / Object	Container
Semantic Web-based							
OWL ObjectProperty	●	bidirectional	m:n	objectified	standardized	Object	Global (URI)

Discourse Spaces: ○ closed ◒ shared ● open

Metadata, like format and recording date, can be added for additional information, for example, with the Dublin Core terms ontology. In the open discourse, all information of the sender's intention can be reconstructed, because the meaning of each class and predicate of a link can be retrieved from the web. The sender is not limited to a certain amount of possible link information, like in schemas with a closed discourse.

Discussion: Practical Requirements and Trade-Offs (RQ3)

Different discourse spaces imply distinct practical trade-offs:

Closed discourse offers low implementation effort and broad tool support, but systematically shifts interpretation costs downstream. While well-suited to integration scenarios that are temporally bounded (e.g. a single project phase), organizationally contained (few stakeholders involved), and functionally routine (stable workflows and well-known schemas with little risk of unknown data sets that might necessitate extensions), closed discourse provides only limited potential for reuse of both the linked data and the links themselves. Because link semantics remain implicit and context-bound, the sender's intention, such as why a specific spatial, topological, or geometric relationship was established, cannot be reconstructed without gaps once the link is detached from its original environment. As a result, analytical decisions embedded in the linking process (e.g. spatial analyses, topological evaluations, or transformation derivations) are not reproducible by receiving systems and must be recomputed by downstream actors. This introduces redundancy and constrains the derivation of new knowledge, as inference requires substantial additional effort or manual interpretation, and it raises uncertainty about the dataset as a whole. The interpretation burden therefore remains with human expertise rather than being encoded in a machine-interpretable form, and the contextual knowledge that motivated linking decisions persists only implicitly, relying on external documentation, tacit assumptions, or institutional memory.

Shared discourse balances semantic expressiveness and practical feasibility, making it particularly approachable for industry-oriented BIM-GIS workflows. It enables integration without requiring full data homogenization or migration into a unified semantic model, allowing datasets to remain in their native formats while supporting explicit, structured linking. Integration can therefore be carried out within a bounded, project-specific environment in which a shared "project truth" is established, without generalizing relationships beyond the immediate context unless required. At the same time, reliance on open and standardized container and link models ensures that integration artifacts remain extensible and interpretable for future use. By externalizing sender intention through objectified link structures, such as geometric transformations, topological relations, derivation provenance, or quality indicators, shared discourse reduces redundancy in downstream processing. Analytical results produced during link creation, for example spatial or topological analyses, can be directly consumed by receiving software systems instead of being recomputed, which might lead to amortizing integration effort across multiple stakeholders and project phases. This moderate increase in architectural complexity is justified where recurring integration tasks, cross-organizational coordination, and quality assurance demand a controlled yet flexible semantic environment.

Open discourse offers the highest potential for long-term interoperability, reuse, and machine-supported reasoning, but it also introduces substantial practical barriers for current industry adoption. In contrast to closed or shared discourse, it typically presupposes that data sources are available in RDF, that suitable ontologies (T-boxes) are selected, aligned, or extended for project-specific purposes, and that instance data (A-boxes) are populated accordingly. This form of semantic engineering requires expertise, tooling, and organizational maturity that are not yet widely established in the AEC sector, resulting in significantly higher upfront effort and complexity. Where applied successfully, open discourse enables integration beyond project-specific contexts, allowing links to remain interpretable across organizational and institutional bound-

aries without bilateral semantic agreements. Typical application domains include legal traceability, long-term information retention for asset and infrastructure management, and the consolidation of heterogeneous models across administrative levels such as cities or regions. Moreover, open discourse enables automated reasoning and inference, supporting use cases such as consistency checking, completeness verification, and the derivation of implicit relationships. The investment in semantic infrastructure is therefore justified primarily when links are intended to function as persistent, reusable knowledge assets, enabling machine-accessible representations of sender intention, analytical provenance, and contextual validity constraints at scale.

Conclusion

This study examined the significance of links in BIM-GIS integration from the perspective of the discourse space. It demonstrated that the semantic value and practical utility of links are not determined solely by the technology, but by the context in which they arise and are interpreted. By introducing closed, shared, and open discourse as an analytical framework, the paper provided a systematic basis for comparing heterogeneous link modeling approaches and positioning existing research accordingly (RQ1). This perspective allows integration mechanisms to be evaluated not only by their formal capabilities, but by their suitability for different organizational, temporal, and functional contexts.

The analysis showed that link expressiveness directly affects the ability to reconstruct sender intention and semantic context (RQ2). In closed discourse, intent remains implicit and bound to local schemas or workflows, limiting reproducibility and reuse. Shared discourse partially externalizes intention through objectified links and contextual metadata, enabling consistent interpretation within bounded integration settings. Open discourse fully externalizes semantic intent through globally defined vocabularies and formalized relationships, enabling independent interpretation, validation, and inference beyond project-specific boundaries.

From a practical perspective (RQ3), the three discourse spaces represent distinct trade-offs rather than a linear maturity path. Closed discourse offers low entry barriers but high downstream interpretation costs; shared discourse provides an industry-viable balance between expressiveness and feasibility; and open discourse enables long-term interoperability and reasoning at the cost of substantial semantic infrastructure and expertise. Instead of advocating a single integration paradigm, this paper contributes decision support for selecting appropriate linking strategies based on required semantic depth, reuse potential, and organizational readiness.

A key limitation of this work concerns the validation of link quality and sender intention reconstruction. While the paper shows conceptually how discourse space influences the externalization of semantic intent, it does not define formal metrics to assess how accurately sender intention can be reconstructed by receiving systems. Sender intention is often tacit and context-dependent, making objective evaluation difficult without a clear ground truth. In practice, reconstruction can only be assessed indirectly, for example by evaluating whether links can be interpreted without auxiliary documentation or analytical results reproduced.

Outlook

Future work will focus on the development of an optimized link meta-model capable of operating coherently across closed, shared, and open discourse spaces while remaining compatible with existing standards and domain data models. A meta-model would define a technology-agnostic conceptual core for links, capturing relationship types, scope of validity, sender intention, and contextual metadata independently of their concrete encoding. This enables the same conceptual link to be instantiated in different technical serializations - such as schema-inherent references, container-based link models, or ontology-based representations - depending on project needs, supporting progressive semantic enrichment without forcing premature data homogenization. The proof of whether the choice of closed, shared, or open can be provided technically by ensuring that a receiving software system can interpret the links and use them for analysis and visualization. At the same time, it must be ensured that the chosen link approach is adopted by the software industry and regularly used in real BIM-GIS projects. In parallel, emerging AI-based methods offer promising opportunities to support the improvement of weakly structured or semantically inconsistent datasets and to generate links by automated methods. Potential applications include the normalization of naming conventions, the identification of implicit semantic patterns, and the assisted mapping of project-specific attributes to standardized vocabularies, as well as supporting validation and refinement of link models, e.g. by suggesting missing relations or highlighting inconsistencies.

AI Declaration

During the preparation of this work, the authors used AI tools for grammar and spelling check, paraphrase and reword. After using these tools, the authors reviewed and edited the content as needed and take full responsibility for the publication's content.

TOWARDS A MULTI-DOMAIN SEMANTIC ARCHITECTURE FOR GRAPH-BASED ORCHESTRATION OF DECENTRALISED ADDITIVE MANUFACTURING

Lukas Kirner, Alex Donkers, and Ekaterina Petrova
Eindhoven University of Technology, Eindhoven, The Netherlands

Abstract

Construction-scale additive manufacturing (AM) is often executed in decentralised, multi-actor project environments, where production information is distributed across heterogeneous systems. This fragmentation hinders automation, coordination, and life-cycle traceability. This paper proposes a multi-domain semantic system architecture to support graph-based integration and orchestration of decentralised AM workflows. The architecture separates system topology, functional service interfaces, information requirements, and runtime provenance. Using a concrete 3D printing use case, the approach demonstrates how modular software components can be integrated through a shared digital-twin interface while maintaining end-to-end traceability of generated and consumed artefacts.

Introduction

Construction sectors in many developed countries share persistent structural challenges, including rising costs, long project durations, shortages of skilled labour, and increasing regulatory requirements related to sustainability and life-cycle assessment (Abdelalim et al., 2025; Cabeza et al., 2014). At the same time, the demand for affordable housing and resource-efficient construction continues to grow. These pressures challenge traditional construction methods and motivate the exploration of alternative production paradigms (Kedir and Hall, 2021).

Construction-scale additive manufacturing (AM) such as concrete 3D printing, has emerged as a promising approach to address some of these challenges (Lim et al., 2012; Buswell et al., 2018). By enabling digitally driven fabrication processes for building components, AM offers potential benefits including reduced labour dependency, shorter construction times, and material-efficient geometries (Hager et al., 2016). At the same time, the strong reliance on digital planning, parameterisation, and process control introduces complex information dependencies between design, material definition, and execution.

The implementation of AM on construction scale is usually integrated within temporary, multi-actor project environments. Design, material definition, machine control, and quality assurance are often handled by different stakeholders and supported by heterogeneous software systems. As a result, production-related information is generated across organisational and temporal boundaries, while increasing requirements for documentation and life-cycle assessment demand consistent traceability of design decisions and production-related information (Wu et al., 2016).

While practical challenges that relate to printing hardware and material behaviour are prominent, efficient data management and process coordination represent equally significant hurdles (Jaskuła et al., 2024). Information is frequently exchanged through isolated files, proprietary software tools, or manual handovers, resulting in limited interoperability and weak integration between design, execution, and as-built documentation. These limitations hinder automation, scalability, and the consistent availability of information required for life-cycle assessment (Cabeza et al., 2014).

Semantic models and linked data approaches have been proposed to address these challenges by enabling formal, machine-interpretable representations of entities, relationships, and dependencies across organisational and system boundaries. Graph-based representations are particularly well suited for decentralised settings in which no single system can act as a central source of truth (Pauwels et al., 2017).

Despite this potential, the practical use of semantic approaches in decentralised AM remains limited. Existing ontologies and data models typically address isolated aspects of the process chain, such as geometry, manufacturing activities, or sensor observations (Kirner et al., 2024a), while lacking a coherent architectural separation between system integration, functional interfaces, information dependencies, and execution traces. As a result, semantic models often become either difficult to operationalise or insufficient to support cross-system coordination and traceability.

This paper addresses this gap by proposing a multi-domain semantic system architecture for decentralised AM workflows. The architecture explicitly separates system topology, functional service descriptions, information requirements between modules, and runtime provenance. Using construction-scale concrete 3D printing as a representative use case, the approach demonstrates how existing semantic standards can be combined into an actionable architecture that supports integration, coordination, and end-to-end traceability across the AM process chain.

Related Work

Additive manufacturing

Construction-scale AM transfers layer-wise fabrication principles from industrial AM to the production of building components and, increasingly, full-scale construction, with early work on large-scale automated material deposition such as Contour Crafting and concrete printing systems (Khoshnevis, 2004; Lim et al., 2012). Over the past decade, concrete 3D printing (3DCP) has become the dominant form of construction-scale AM due to its poten-

tial to reduce formwork, enable material-efficient geometries, and increase automation (Buswell et al., 2018).

Typical 3DCP workflows span digital design, toolpath generation, material preparation, and layer-wise deposition with subsequent quality assurance. While geometry-to-machine translation resembles industrial CAM pipelines, construction-scale AM is strongly influenced by time-dependent material behaviour, such as buildability and inter-layer adhesion, which couples digital models, process parameters, and execution (Mechtcherine et al., 2020). Challenges in data management and process coordination include fragmented information flows, limited interoperability, and insufficient traceability of material definitions, parameters, and as-built outcomes (Bos et al., 2016; Jaskuła et al., 2024).

Semantic and ontology-based approaches in AM

To address gaps in data availability, data-centric frameworks in AM focus on the structured capture of process information. Deetman et al. introduce a database framework for 3D concrete printing to store cross-disciplinary process data for analysis and reproducibility focussing on storage and schema (Deetman et al., 2026).

For semantic integration across tools and domains, ontology-driven approaches have been suggested to structure and integrate knowledge in AM. Li and Petzold present a mixture-of-domain documentation framework that captures cross-domain knowledge in a shared knowledge graph to support semantic retrieval and question answering across robotics, materials, and BIM domains (Li and Petzold, 2025). Domain-specific semantic models have also been introduced, for example for wire arc additive manufacturing and composite extrusion, to formalise process knowledge and enable semantic interoperability across tools (Ahmad et al., 2025). Gouttebroze et al. propose a semantic standard and process ontology for additive manufacturing that aligns standard terminology with formal process descriptions (Gouttebroze et al., 2023).

System integration and system-of-systems approaches

The increasing distribution of digital tools in construction has motivated system-of-systems approaches for integrating heterogeneous services. Hagedorn et al. propose a system-of-systems architecture for deploying containerised construction IT services, focusing on modular integration and explicit service interfaces across independently managed components (Hagedorn et al., 2025). In a more general setting, Feng et al. present an ontology-based approach for modelling system-of-systems architectures and operational views to provide a shared semantic foundation for describing interacting systems (Feng et al., 2023).

These approaches address deployment and architectural modelling of distributed systems, but do not explicitly model information dependencies between tools or capture execution-time provenance needed for traceability across workflows.

Methodology

This work develops a multo-domain semantic system architecture to support graph-based coordination and traceability in decentralised construction-scale AM. The methodology to achieve this follows four steps: (I) use-case driven examination of an exemplary AM process chain and involved software systems, (II) identification of coordination and traceability concerns across system boundaries, (III) structuring of these concerns into distinct semantic domains, and (IV) alignment of each domain with existing standards and ontologies to form an extensible architectural framework.

I Use-case driven system examination

To ground the methodology in practice, the approach starts from a representative decentralised AM workflow derived from the EU-funded project "Additive To Predictive Manufacturing" (AM2PM)[1]. The focus is placed on a possible design–material–optimisation sub-workflow that supports predictive and sustainability-driven decision-making, while abstracting from the physical printing process itself. This scoping reflects the intention to examine information dependencies between software modules rather than machine control or sensing.

The considered sub-workflow couples material design, structural optimisation, and life-cycle assessment. A concrete mix design module produces a mix specification that includes, among others, cement content and material properties such as compressive strength. The cement component of the mix is linked to environmental product declaration (EPD) data, enabling the association of embodied CO_2 emissions with the mix composition. These material properties are required inputs for a shape optimisation module, which aims to minimise material usage for a slab structure by exploiting the mechanical performance of both the printed lost formwork and the subsequently poured concrete. Equipment type, staff, material quantities and other practical parameters are assessed in a simulation module. The involved modules and their interactions are illustrated in a simplified manner in Figure 1, where modules interact with a decentralized graph-based integration domain. Brown arrows represent two-way interaction between a module and the integration domain, and contain data conversion. Solid green arrows represent semantic relationships between concepts in a module, whereas dotted green arrows represent mappings between such semantic concepts. An optimization module that feeds a control module is using the integration domain. The latter is not the primary focus of this work.

Based on the material parameters and structural requirements, the optimisation module determines an efficient geometry, which directly influences the amount of material to be printed and cast. Whether material quantities are later measured during printing or estimated through predictive simulation is outside the scope of this work. In-

[1] https://www.am2pm-project.eu/

stead, attention is placed on how the required information is made available and propagated across modules. Given access to both the optimised geometry and the concrete mix specification, a life-cycle assessment (LCA) module can estimate the environmental impact of the slab, dominated by cement-related emissions.

In such a setting, changes in concrete composition affect structural behaviour, geometric optimisation results, material quantities, and downstream environmental assessments. These interdependencies are realised across multiple software modules that operate independently but rely on shared information artefacts.

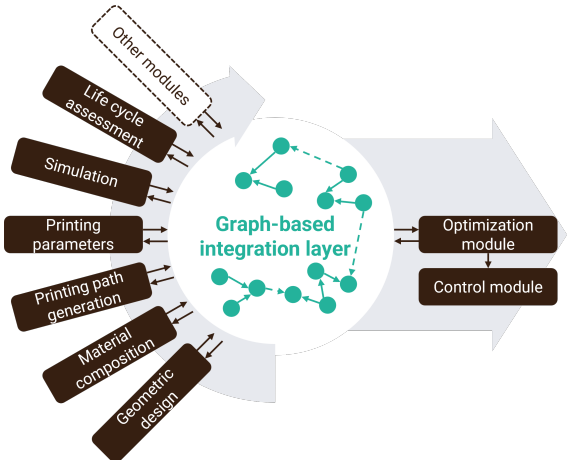

Figure 1: Simplified AM2PM module interaction.

II Coordination and traceability concerns

From the use-case driven system examination, a set of recurring and characteristic coordination and traceability concerns emerge. These concerns arise from the fact that multiple independent software systems contribute to a shared production outcome, while relying on different representations, responsibilities, and temporal perspectives on the same information artefacts.

A first class of concerns relates to information dependencies across system boundaries. Design artefacts, material definitions, optimisation results, and environmental data are produced and consumed by different modules, often at different points in time. Dependencies between these artefacts are typically implicit, making it difficult to determine whether all required inputs are available, which upstream changes necessitate recomputation, or which downstream results are affected by modifications in design or material parameters. Such dependencies are relevant at design time and influence validation, scheduling, and coordination decisions before any execution takes place.

A second class of concerns concerns traceability across execution and decision contexts. Results generated during execution, simulation, or optimisation need to be traceable back to the design-time inputs, assumptions, and configurations that led to them. This traceability extends beyond runtime logging and includes the ability to associate outputs with the specific versions of input artefacts and system configurations that were in effect when they were produced. Without explicit representation of these relations, it becomes difficult to support reproducibility, accountability, and life-cycle assessment in workflows where responsibilities and data are distributed across multiple systems.

Addressing these issues requires a structuring of system-related knowledge that separates stable system descriptions, information dependencies, and execution-time records.

III Derivation of the semantic architecture

The identified coordination and traceability concerns cannot be handled well within a single, undifferentiated semantic model. Design-time dependencies, stable system descriptions, and execution-time records differ in how long they remain valid, who is responsible for them, and how often they change. Treating these aspects in the same way risks either mixing volatile execution data into long-lived system descriptions or failing to represent dependencies that are needed for coordination before execution.

To address this, the proposed architecture separates semantic responsibilities into four domains with distinct scope, temporality, and mutability (see Table 1). The domains distinguish between system structure (*D1*), functional interfaces between systems (*D2*), information requirements and dependencies (*D3*), and provenance records of concrete executions (*D4*). This separation follows patterns observed in the use-case driven examination rather than assumptions imposed by a specific ontology.

By separating these concerns, each domain can be modelled at an appropriate level of abstraction. System topology and interfaces change slowly and support integration, information requirements capture dependencies that must be known before execution, and provenance records document what actually happened. This allows the domains to evolve independently while remaining linked, which is essential in decentralised workflows with multiple interacting systems.

IV Ontology selection and integration strategy

The proposed architecture is instantiated using a deliberately small set of established ontologies, selected for their conceptual fit with individual domains rather than for exhaustive domain coverage. This choice defines a minimal semantic starting point. Fig. 2 shows the integration of these ontologies.

System topology (D1)

At the system topology domain, structural relationships between software components are represented using *SAREF for System* (SAREF4SYST, prefix `s4syst`) (Lefrançois, 2019). It provides explicit concepts for systems, connection points, and connections, making it suitable for modelling decentralised software modules and their integration while focussing on a relatively stable system structure that aligns with the slow-changing nature of topology descriptions.

Table 1: Domain separation and according to scope, temporality and mutability (non-exhaustive).

Domain	Scope	Temporality	Mutability
D1: System topology	system structure	mostly static	slow
D2: Functional description	interface	mostly static	slow
D3: Information requirements	workflow dependency	logical	medium
D4: Provenance and traceability	execution record	historical	immutable

Functional service description (D2)
Functional interfaces are described using the W3C *Web of Things (WoT) Thing Description* (prefix `td`) (Charpenay et al., 2023). Thing Descriptions provide a machine-interpretable, declarative description of interaction affordances exposed by a system, including *properties*, *actions*, and *events*. In this architecture, the Digital Twin interface is represented as a `td:Thing` whose affordances describe access to shared project artefacts (e.g., concrete mix specifications, optimisation results) without prescribing orchestration logic or encoding execution-time provenance. This makes WoT TD suitable for complex, decentralised module ecosystems while keeping the functional contract separated from design-time information dependencies (*D3*) and runtime traces (*D4*).

Information requirements and dependencies (D3)
Design-time information dependencies are captured in the information requirement domain using the IoC Process Ontology (prefix `ioc`) (Kirner et al., 2024b) in alignment with the *WoT* (Charpenay et al., 2023). An `ioc:Process` is aligned with a `td:Thing`, while specific operations are modelled as WoT affordances. Information requirements are specified at the level of these affordances using `ioc:hasInputInformation` and `ioc:hasOutputInformation` to indicate which `ioc:Information` artefacts are required or produced by a given action, independent of their runtime access or generation (e.g. a topology optimisation action requiring a concrete mix specification). Information artefacts are treated as logical coordination objects supporting dependency reasoning, completeness checks, and change impact analysis prior to execution. Artefacts may be described using domain ontologies, but their internal semantics are not modelled at this domain. The separation of D3 from execution-time provenance enables validation and orchestration without reliance on historical execution data. In practice, explicitly modelled information requirements can be validated using SHACL shapes (Knublauch and Kontokostas, 2017). The domain itself may require future extensions by more formal requirement or constraint ontologies.

Provenance and traceability (D4)
Execution-time behaviour and traceability are represented using the W3C Provenance Ontology *PROV-O* (prefix `prov:`) (Lebo et al., 2013). PROV-O provides a standard model for representing activities, entities, and agents, and for expressing how information artefacts are generated, used, and derived over time. In the proposed architecture, provenance is used exclusively to record immutable execution histories, linking concrete runs of distributed modules to the specific input artefacts and system configurations that produced them. This makes PROV-O well suited for auditability, reproducibility, and life-cycle relevant traceability, while remaining strictly separated from coordination and dependency modelling.

Table 2: Overview of used ontologies for the proposed semantic architecture.

Ontology	Main classes and purpose
D1: `s4syst:`	*s4syst:System*, *s4syst:Connection/Point* System topology: software modules and connections (Lefrançois, 2019)
D2: `td:`	*td:Thing*, *td:PropertyAffordance*, *td:ActionAffordance*, *td:EventAffordance* Functional interfaces: interaction affordances and specific endpoints (Charpenay et al., 2023)
D3: `ioc:`	*ioc:Process*, *ioc:Information* Information requirement: Expresses design-time input/output dependencies (Kirner et al., 2024b) validated using SHACL (Knublauch and Kontokostas, 2017)
D4: `prov:`	*prov:Entity*, *prov:Activity*, *prov:Agent* Immutable execution history: Branches with used/generated artefacts and responsible agents for traceability (Lebo et al., 2013)

Cross-domain integration principles
The architecture deliberately avoids merging ontologies or introducing inheritance relations across domains. Each domain defines its own relations and responsibilities, while instances may be referenced across domains when appropriate (e.g. a software system described at the topology domain acting as a provenance agent at runtime). Relations that describe execution-time behaviour are expressed exclusively at the provenance domain. This separation prevents semantic overlap between design-time coordination and runtime history, while allowing referenced domain ontologies to evolve independently.
The selected vocabularies are not assumed to be sufficient in the long term. Instead, the architecture is designed to allow extensions and the integration of additional domain-specific ontologies as requirements evolve. Table 2 summarises the ontologies and standards used at each domain of the proposed architecture and their respective roles.

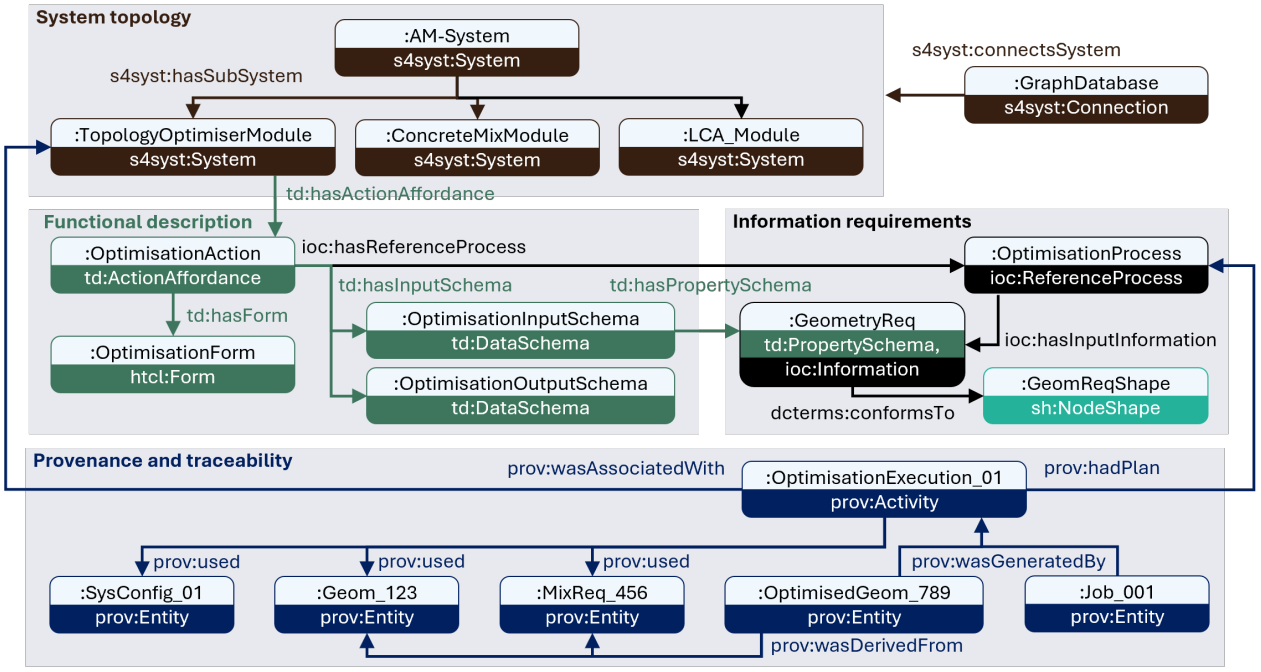

Figure 2: System integration using proposed ontologies, including a demonstrator instantiation

Evaluation and Demonstrator

Having defined the semantic architecture and its ontology alignment, the evaluation demonstrates its instantiation in the AM2PM use case through RDF instances, exemplary SPARQL queries, and a visualised provenance-aware information flow, and presents the semantic model together with its implementation in a platform prototype.

Instance-level semantic model for the AM2PM use case

The system and topology domain (D1) instantiates the Digital Twin Orchestrator as a `s4syst:System` and `td:Thing`. Exemplarily, the material design, topology optimisation, and LCA modules are attached via `s4syst:hasSubSystem`. Interactions between these components are mediated through an explicit `s4syst:Connection`, enabling the model to describe both structural composition and communication paths without mixing functional roles. Each module is additionally a `prov:Agent`, allowing execution responsibilities to be linked directly to provenance records.

The interaction domain (D2) is realised by a `td:ActionAffordance` bound to an HTTP endpoint via `hctl:hasTarget` and `htv:methodName`. The action is linked through `wp4-ext:hasReferenceProcess`, connecting the API operation to the abstract process description. Its payload is constrained by `td:hasInputSchema` and `td:hasOutputSchema`, where inputs such as *:geometry* and *:mixRequirements* are defined as IRIs, enforcing a by-reference data exchange pattern. This separates interface invocation from data ownership and allows the same service interface to operate over distributed or externally managed artefacts.

The information domain (D3) specifies required and produced artefacts independently of execution. The reference process declares its contract using `ioc:hasInputInformation` and `ioc:hasOutputInformation`, linking, for example, to *inst:GeometryInfo*, *inst:ConcreteMixReqInfo*, and *inst:OptimisedGeometryInfo*. Each information object is annotated with `dcterms:conformsTo` to reference a SHACL shape, enabling validation of the referenced resources without embedding the data into the invocation payload. As a result, information completeness and structural validity can be checked before execution and reused consistently.

The provenance domain (D4) models specific process executions as `prov:Activity` and links them to the reference process via `prov:hadPlan`. Used inputs are instantiated with `prov:used`, generated results with `prov:wasGeneratedBy`, and input-result dependencies with `prov:wasDerivedFrom`, making the full derivation chain between input versions and outputs explicitly queryable. Input and output artefacts are represented as `prov:Entity`. As example, revising a concrete mix parameter such as its compressive strength results in a new mix entity that is `prov:used` in a subsequent optimisation run. This leads to a modified optimised geometry, which in turn affects the life-cycle assessment results derived from that geometry. The corresponding result entities can be linked via `prov:wasRevisionOf`, while preserving `prov:wasDerivedFrom` relations to the exact input versions, enabling causal tracing of how changes in material parameters propagate through optimisation and LCA.

Query-based semantic analysis

To demonstrate the usability of the proposed approach, a set of simple questions covering all four domains is answered using SPARQL queries. The queries reflect typical information needs of users and software agents interacting with the Digital Twin system. Listing 1 shows the additional prefixes used.

Listing 1: Additional prefixes for subsequent SPARQL queries.

```
dcterms:<http://purl.org/dc/terms/>
hctl: <https://www.w3.org/2019/wot/hypermedia#>
htv: <http://www.w3.org/2011/http#>
omg: <https://w3id.org/omg#>
sh: <http://www.w3.org/ns/shacl#>
```

The first question addresses the system topology (D1): *Which modules exist and how are they connected?* The corresponding SPARQL query (Listing 2) returns all connected modules with their labels and descriptions and serves as an entry point for discovering the current system structure.

Listing 2: Query for retrieving all connected modules (D1).

```
SELECT ?subsystem ?label ?description
WHERE {
  ?syst s4syst:hasSubSystem ?subsystem;
        s4syst:connectedThrough ?connection.
  ?subsystem rdfs:label ?label;
  dcterms:description ?description;
  s4syst:connectedThrough ?connection .}
```

The second question focuses on the available interaction methods, such as callable API endpoints (D2). Using one of the modules identified in Listing 2, the question is: *Which actions can be invoked on the TopologyOptimiser module and what input do they expect?* The query returns the available actions, for example *inst:RunOptimisationForm*, an HTTP POST form that triggers the topology optimisation. Labels and `dcterms:description` support not only invocation but also discovery of these endpoints, for instance by software agents or agent-based toolchains.

Listing 3: Query to the form for a specific affordance (D2).

```
SELECT ?action ?actionl ?actionDesc ?method ?target
     ?contentT
WHERE {
  inst:TopologyOptimiserModule td:hasActionAffordance
       ?action.
  OPTIONAL {?action rdfs:label ?actionl.}
  OPTIONAL {?action dcterms:description ?actionDesc.}

  ?action td:hasForm ?form.
  OPTIONAL {?form htv:methodName ?method.}
  OPTIONAL {?form hctl:hasTarget ?target.}
  OPTIONAL {?form hctl:forContentType ?contentT.}}
```

The third question addresses information requirements and constraints (D3): *What is the needed content of infromation the input needs to perform the requested action? How must it be sturctured?* Starting from the action identified in Listing 3, the query follows its link to the associated `ioc:ReferenceProcess` (aligned to `prov:Plan`). Using `ioc:hasInputInformation`, it retrieves the strcture of the required information artefacts together with their SHACL-based constraints. The use of D3 and the required domain ontologies to concisely describe the expected data structures is subject to future work.

Listing 4: Query to retrieve information requirements.

```
SELECT ?info ?fieldName ?dataT ?shape
WHERE {
  inst:OptimisationAction ioc:hasReferenceProcess ?
      proc.
  ?proc ioc:hasInputInformation ?info.
  OPTIONAL {?info rdfs:label ?fieldName.}
  OPTIONAL {?info td:datatype ?datatT.}
  OPTIONAL {?info dcterms:conformsTo ?shape.}}
```

The fourth question addresses provenance after a process execution (D4): *Which executions produced which results, and which data influenced these outcomes?* In the example query, the resulting `omg:Geometry` is used as an entry point to retrieve the activity that generated it and the associated execution context. This includes the used input data, the reference process or plan that was followed, and the responsible module (`prov:Agent`), in this case `inst:TopologyOptimiser`. For simulation workflows, this supports comparing outputs produced under the same reference process but with different inputs, enabling systematic analysis of how parameter changes affect the results e.g. for additive manufacturing.

Listing 5: Query to retrieve provenance information after a sucessfull process execution.

```
SELECT ?activityl ?inputs ?result ?agentl
WHERE {
  ?result a omg:Geometry.
  ?result prov:wasGeneratedBy ?activity.
  ?activity prov:used ?inputs;
    prov:hadPlan ?reference;
    prov:wasAssociatedWith ?agent.
  OPTIONAL { ?activity rdfs:label ?activityl.}
  OPTIONAL { ?agent rdfs:label ?agentl.}}
```

The presented questions can be asked independently, for example by different systems or software agents with distinct responsibilities. They can also be applied in the given sequence, progressing from a general understanding of the system, to concrete instructions for its use, to its information requirements and constraints, and finally to the interpretation of its outputs. This progression is essential for supporting simulation workflows and, ultimately, can enable future predictive manufacturing applications.

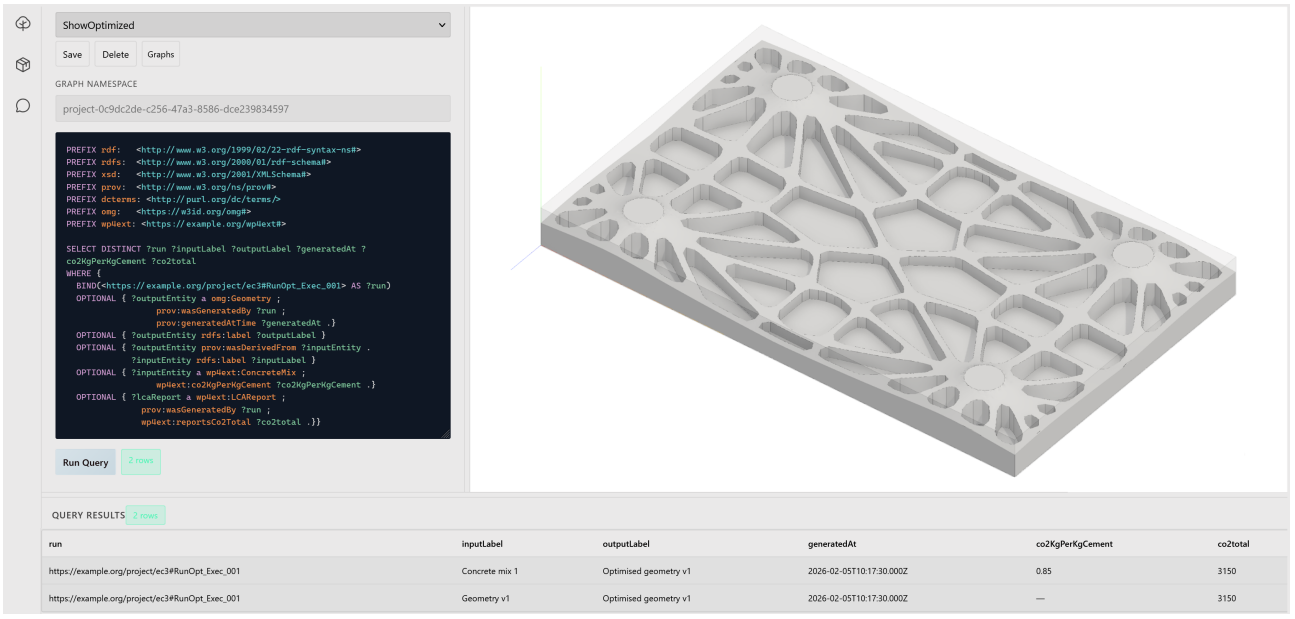

Figure 3: Web platform linking original and optimised geometry to multi-domain semantic data.

Platform-based visualisation and comparison

To demonstrate what the multi-domain semantic architecture can achieve for user-facing applications, the presented exemplary A-Box is stored in a triple store of a linked data–based web platform. The application exposes a query endpoint that can be controlled by its viewer component (see Fig. 3). On the left, a SPARQL query is used to retrieve the output of an optimisation run involving the concrete mixing, topology optimisation, and LCA modules. Here, we focus on the query logic of D3 and D4. The 3D viewer shows in transparent (as hint) the original, non-optimised geometry and highlights the results of the optimised run. Below, the query results are shown in a table, so users can access relevant information about the completed optimisation run, such as its IRI, the used cement mix, the time the geometry was generated and resulting CO_2-equivalent.

Results & Discussion

The evaluation shows that the semantic integration of distributed modules, information requirements, and provenance records enables the comparison of two variants that satisfy the same functional and structural requirements while differing in material usage and CO_2-equivalent emissions, and that a simple web-based 3D viewer can make these differences accessible to users.

Beyond this specific example, queries across domains illustrate how the approach supports typical coordination and analysis tasks, such as discovering available modules, checking required information, and tracing how results were produced. This indicates that the architecture is not limited to a single workflow, but can serve as a general integration pattern to enable system-of-systems approaches. At the same time, the study also reveals clear limitations. The current evaluation is restricted in scale, while the modelling effort is significant, especially for defining information requirements and maintaining alignments between vocabularies. Constraints are currently limited to basic validation and need to be refined to remain both precise and usable in practice. In addition, issues such as governance, trust, and security were not addressed, but may become critical in cross-organisational settings. In short, the approach can be a viable basis for coordination and traceability in decentralised AM workflows, but its practical adoption depends on reducing modelling effort, strengthening constraint definitions, and validating the approach in larger and more heterogeneous settings.

Conclusion

This paper presented a multi-domain semantic architecture for decentralised additive manufacturing workflows. The approach separates system structure, interfaces, information requirements, and provenance. The evaluation shows that this separation supports integration, comparison of results, and traceability across tools. The current work is limited to a prototype and a small use case. Future work will address larger and more distributed system landscapes in AM, where coordination may also involve agentic AI components. Building on this, simulation-based workflows that rely on explicit system and information modelling will be developed, with the goal of supporting predictive manufacturing (PM).

Abstract

Digital twin adoption is hindered by fragmented symbolic and subsymbolic construction data from heterogeneous sources. We propose a hybrid knowledge-graph and vector-database architecture that integrates a GeoSPARQL-enabled RDF store with semantic embeddings to unify technical documentation and support both precise reasoning and fuzzy retrieval. A hybrid RAG workflow on PDF-based data demonstrates improved ranking quality and contextual relevance compared to single-paradigm retrieval. This lays the groundwork for future work on infrastructure-focused digital twins. Comprehensive support for multimodal data and case studies, such as minimally invasive bridge strengthening and scaffold-free robotic assembly, is left as a planned continuation of the research.

Introduction

Digital twins have emerged as one of the most transformative paradigms in engineering, construction, and infrastructure management. They promise to provide a continually updated and data-driven representation of physical assets, enabling predictive maintenance and sustainable rehabilitation. Despite their potential, the integration of digital twins into practical workflows remains limited. A major barrier is the heterogeneity of data sources: engineering projects generate symbolic data (design models, ontologies, metadata) and subsymbolic data (images, sensor readings, point clouds). These data differ in format, structure, and semantics, making unified access and analysis challenging.

Within the Climate-Neutral and Resource-Efficient Construction (CARE) initiative, we aim to address these challenges by developing comprehensive data integration platforms. The goal of this project is to develop a unified data framework, as shown in Figure 1, that ensures both current and legacy construction data comply with the FAIR (Findable, Accessible, Interoperable, and Reusable) principles. By establishing standardized data models, metadata structures, and interoperability mechanisms, the project seeks to enable new automation- and sustainability-focused workflows across rehabilitation and construction processes.

As the first step, this paper presents a prototype implementation of the CARE hybrid symbolic–subsymbolic architecture and assesses its retrieval layer using multimodal documents containing text, tables, and embedded images. The current study aims to validate the architectural foundations and retrieval performance that underpin the broader digital twin vision of the CARE initiative. Support for multimodal data such as IFC models, point clouds, and sensor streams is planned for future work.

Within this scope, the paper addresses the following research questions:

- RQ1: To what extent does ontology-driven alignment improve retrieval accuracy and robustness under incomplete or missing metadata in infrastructure-like document corpora?
- RQ2: How effectively can a hybrid knowledge-graph + vector-database architecture support retrieval for infrastructure digital twins compared to single-paradigm retrieval-augmented generation (RAG) approaches?

Based on these research questions, the following hypothesis is evaluated:

- H1: A hybrid knowledge-graph + vector-database architecture enables more accurate and context-rich retrieval for infrastructure-like document collections than single-paradigm RAG approaches.

These research questions highlight the need for retrieval architectures that bridge heterogeneous construction data. This study therefore evaluates the proposed hybrid approach against non-hybrid RAG methods.

Background and Literature Review

Digital Twins in Infrastructure

Digital twins are virtual replicas of physical assets that integrate real-time data streams with simulation models. In infrastructure, they are used for monitoring bridges, tunnels, and buildings (Gao et al., 2021). However, most implementations remain siloed, focusing on specific data types (e.g., structural health monitoring) rather than holistic integration. This leads to the research question of developing a methodology to integrate various information

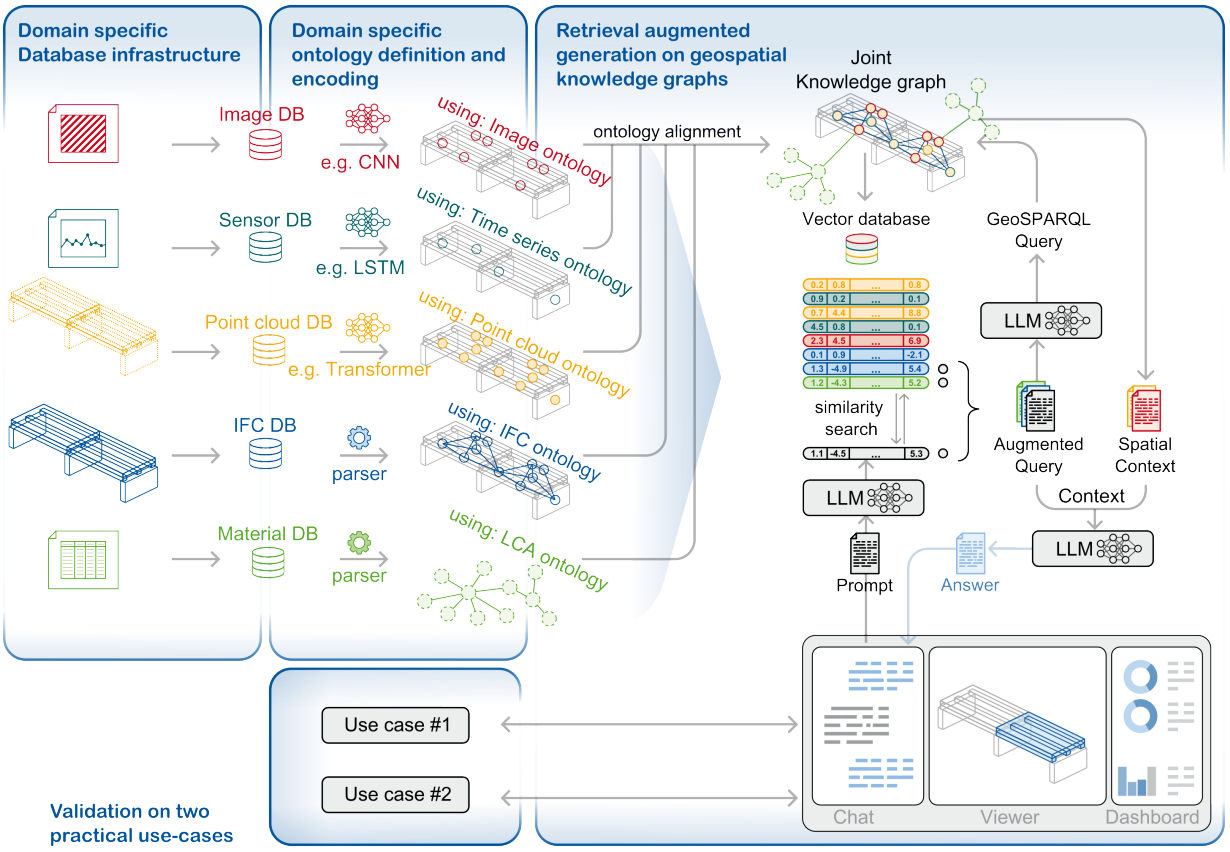

Figure 1: Schematic overview of the CARE Scheme, a hybrid data integration pipeline for construction intelligence.

and simulation models, as well as heterogeneous datasets, into a digital twin, thereby improving the confidence in the integrated simulation model and its predictions (Ye et al., 2019).

Challenges of Data Integration

Infrastructure projects increasingly rely on large, heterogeneous datasets originating from design processes, construction activities, and operational monitoring systems. These datasets differ not only in format but also in semantics, temporal resolution, and uncertainty, creating substantial challenges for integrated data management. A key difficulty arises from the coexistence of symbolic data, including CAD and paper drawings, Building Information Modeling (BIM), ontologies, environmental and geospatial (GIS) data and metadata, and subsymbolic data, such as sensor measurements, site photographs, point clouds, inspection and maintenance records, and time-series data streams (Kaden et al., 2022). Symbolic data are typically structured, semantically explicit, and governed by domain-specific rules, while subsymbolic data are continuous, high-dimensional, and often noisy or incomplete (Pauwels et al., 2017). Integrating these fundamentally different representations requires reconciling discrepancies in granularity, data quality, and interpretability, which traditional database systems are not designed to handle (Platzer, 2025). Conventional relational databases assume stable schemas and consistent semantics, making them poorly suited to the dynamic, multimodal nature of infrastructure data. As a result, workflows often become fragmented: design teams operate within GIS, BIM, or CAD environments, while monitoring systems generate sensor data that remains disconnected from the symbolic representation of the project (Sacks et al., 2018). This fragmentation limits the ability to perform cross-domain analysis, such as automated progress monitoring, structural health assessment, or predictive maintenance. For example, linking point clouds or site imagery to BIM elements requires complex spatial and semantic alignment procedures, which are prone to uncertainty and information loss (Biljecki et al., 2015).

Interoperability challenges further exacerbate the problem. Standards such as Industry Foundation Classes (IFC)[1], City Geography Markup Language (CityGML)[2], and LAS[3] offer only partial solutions, and linked-data mappings like ifcOWL (Beetz et al., 2009) fail to resolve cross-domain interoperability. Inconsistencies in metadata, versioning, and implementation across software platforms hinder seamless data exchange (Gröger and Plümer, 2012). In addition, subsymbolic data sources, particularly those generated by Internet of Things (IoT) sensors or mobile devices, often lack standardized schemata alto-

[1] https://www.buildingsmart.org/standards/bsi-standards/industry-foundation-classes/
[2] https://www.ogc.org/standards/citygml/
[3] https://www.ogc.org/standards/las/

gether, complicating their integration into existing information models.

Recent research emphasizes the need for hybrid data platforms capable of handling both symbolic and subsymbolic modalities (Platzer, 2025). Approaches include graph-based data models, Semantic Web technologies, and machine-learning-based feature extraction, matching, and correlation across domains. These methods show promise in enabling digital twins, which require continuous synchronization between physical assets and their virtual representations (Fuller et al., 2020). However, significant challenges remain, including scalability constraints, inconsistent metadata standards, and the difficulty of aligning machine-interpretable semantics with real-world observations. Addressing these issues is essential for achieving robust, data-driven decision-making throughout the life cycle of infrastructure systems.

Existing Retrieval Augmented Generation (RAG) Approaches

Recent advances in Artificial Intelligence (AI) and data management have enabled the integration of symbolic and subsymbolic data in infrastructure projects. RAG is a method where an AI model retrieves relevant external information and uses it to produce more accurate, up-to-date, and grounded responses. RAG approaches include vector-, keyword-, hybrid, graph-, multi-hop, agentic, structured-data, multimodal, and summarization-centric retrieval methods. Among these, VectorRAG, GraphRAG, and HybridRAG represent the core semantic, structured, and combined retrieval strategies.

While each offers unique strengths, they also exhibit limitations that motivate ongoing research into more unified multimodal architectures.

Knowledge graphs remain a foundational technology for representing structured, semantically rich information. They encode entities and relationships in a transparent, machine-interpretable form, enabling reasoning and complex semantic queries, and add an additional layer of compatibility through ontology-based constraint checking. Emerging work centers on improving knowledge graphs with RAG pipelines. However, they rely heavily on complete and precise metadata; when annotations are missing or inconsistent, their performance suffers.

In contrast, vector databases excel at handling unstructured or subsymbolic data such as images, documents, and sensor streams. They embed data into high-dimensional vector spaces, enabling similarity search and pattern recognition without requiring explicit semantic labels. Still, recent studies indicate that vector-embedding–based RAG approaches underperform compared to GraphRAG and Hybrid GraphRAG (a.k.a. HybridRAG): GraphRAG achieves higher context and answer relevance, while Hybrid GraphRAG attains higher factual correctness (Ahmad et al., 2025). HybridRAG architectures combine vector-based retrieval with knowledge-graph reasoning and large language models (LLMs), enabling systems that leverage both latent similarity and explicit semantics, demonstrating how integrating knowledge graphs into RAG pipelines improves precision, context awareness, and explainability in real-world applications (Yuan et al., 2024). These systems represent an early yet significant step toward multimodal data spaces capable of unifying symbolic and subsymbolic data. However, applications in infrastructure are constantly evolving, with open challenges including ontology alignment, scalable graph construction, and the integration of high-volume sensor data.

In general, recent research indicates that GraphRAG-style hybrid architectures are the most promising path forward (see Table 1). They combine the strengths of knowledge graphs (semantic structure, reasoning) with those of vector databases (pattern recognition, scalability), offering a more holistic approach to data integration. Yet, substantial work remains to adapt these methods to the unique demands of infrastructure engineering, where data heterogeneity, uncertainty, and scale are particularly pronounced.

CARE Data Acquisition

The Climate-Neutral and Resource-Efficient Construction (CARE) Cluster of Excellence (EXC)[4] provides a unifying research environment for developing scalable, interoperable digital twin technologies across infrastructure domains. A central requirement for validating the hybrid symbolic–subsymbolic integration proposed in this work is the availability of real-world datasets that combine structured engineering knowledge with heterogeneous sensor observations. CARE's life-size bridge demonstrator fulfills this role by offering a controlled yet realistic environment in which multimodal data can be collected, aligned, and evaluated (Herbers et al., 2024).

The openLAB[5] research bridge is a 45m, three-span prestressed concrete structure designed explicitly as a full-scale experimental platform. Its construction integrates multiple structural typologies and intentionally embedded damage mechanisms, enabling the systematic study of deterioration processes and monitoring strategies. Each span represents a distinct research scenario: legacy-inspired defects and reduced shear capacity in the first span, state-of-the-art construction with embedded fiber-optic "Smart Tendons" in the second (Richter et al., 2024), and an innovative rapid-assembly system with Ultra-High-Performance Fiber-Reinforced Concrete (UHPFRC) joints in the third. This diversity ensures that the resulting dataset captures a wide range of structural behaviors and material responses relevant to both existing and future infrastructure.

A defining characteristic of the openLAB demonstrator is its comprehensive monitoring strategy, which begins during precast fabrication and continues throughout construc-

Table 1: Comparison of Knowledge Graphs, Vector Databases, and Hybrid RAG Approaches

Criterion	Knowledge Graphs (KG)	Vector Databases	HybridRAG Systems
Data Type Strength	Structured, symbolic, semantic data	Unstructured, subsymbolic data (text, images, sensor streams)	Both symbolic and subsymbolic data
Semantics	Explicit, machine-interpretable	Implicit, encoded in embeddings	Combines explicit semantics with latent similarity
Reasoning	Strong logical and spatial reasoning	Weak; no native reasoning	Enhanced reasoning via KG + LLM integration
Robustness to Missing Metadata	Low; requires complete annotations	High; embeddings tolerate noise	Medium–High; vector retrieval compensates for missing metadata
Explainability	High transparency	Low interpretability	Medium–High (KG-backed explanations)
Scalability	Moderate; graph operations can be expensive	High; optimized for large-scale retrieval	Moderate; depends on pipeline design
Typical Use Cases	BIM integration, geospatial reasoning	Similarity search, anomaly detection, multimodal retrieval	Digital twins, semantic search, multimodal analytics

tion, reference operation, and controlled damage loading. The instrumentation combines global measurements, such as accelerations, inclinations, and environmental conditions, with dense local sensing, including strain gauges, displacement transducers, and nearly one kilometer of distributed fiber-optic sensors (DFOS). The DFOS network provides continuous, high-resolution strain profiles along reinforcement and concrete surfaces, enabling precise detection of cracks, stiffness changes, and localized damage. Beyond sensor streams, the dataset also includes a wide range of engineering data representations essential for digital-twin workflows, such as IFC models, Computer-Aided Design (CAD) drawings, point clouds, image collections, Portable Document Format (PDF)[6] construction plans, and tabular sensor exports (e.g., .csv files). These complementary modalities enrich the symbolic layer with geometric, semantic, and visual context, enabling cross-domain alignment and multimodal reasoning. This multimodal sensing environment produces a uniquely rich dataset that spans symbolic construction metadata, geospatial information, and high-dimensional subsymbolic sensor streams.

For CARE-DS and CARE-DIVE, the openLAB bridge serves as a critical validation case. Its heterogeneous data landscape mirrors the challenges encountered in real infrastructure systems, including inconsistent metadata, varying spatial granularity, and overlapping effects of environmental and structural influences. The demonstrator therefore enables systematic testing of ontology-driven data harmonization, multimodal embedding generation, hybrid retrieval, and uncertainty-aware reasoning. Moreover, integrating all monitoring data into an as-is digital twin provides a reference model against which hybrid queries and RAG-based workflows can be evaluated.

In summary, the openLAB research bridge constitutes a foundational dataset for the CARE ecosystem. Its combination of symbolic engineering knowledge, subsymbolic sensor observations, and lifecycle-oriented digital twin integration provides the ideal environment for developing and validating the hybrid data integration methodologies proposed in this work

Objectives

The overarching objective of this research is to develop a hybrid symbolic–subsymbolic query layer that enables holistic, multimodal data integration for digital twins. This query layer aims to unify structured, semantically rich information (e.g., ontologies, BIM models, geospatial metadata) with unstructured or subsymbolic data sources (e.g., sensor streams, images, point clouds). By bridging these two representational paradigms, the project seeks to overcome current fragmentation in infrastructure data workflows and support more robust, transparent, and scalable digital twin applications (Pregnolato et al., 2022).

This objective reflects the growing need for digital twins that can reason over both explicit engineering knowledge and real-world observations, enabling more accurate monitoring, simulation, and decision-making across the life cycle of infrastructure assets.

Heterogeneous data infrastructures include image, sensor, point cloud, IFC, and material databases. The data is processed via machine learning models and parsers, then semantically aligned using domain-specific ontologies. The resulting representations are fused into a Joint Knowledge Graph, enabling structured data generation and downstream interpretation by an LLM. Outputs are visualized through a dashboard interface that combines chat, a 3D viewer, and analytical components. Lastly, the architecture will be validated across two practical use cases, demonstrating scalable, ontology-driven decision support in infrastructure contexts.

Methodology and Work Plan

The methodological structure of this project is organized around two tightly coupled pillars: The data space, which provides the semantic and data backbone, and the hybrid query interface, which implements the hybrid symbolic–subsymbolic query layer. Each pillar is operationalized through a set of concrete work steps. The data space encompasses the development of the domain-specific data infrastructure and ontology. The hybrid query interface (DIVE) builds on this foundation to implement hybrid retrieval mechanisms and validates them on two real-world

use-cases.
Those two big pillars are further divided into four steps, each addressing a critical component of the hybrid symbolic–subsymbolic data integration framework. They can be sorted like:
Data space: Semantic and Data Infrastructure

- Domain-specific database infrastructure
- Definition and encoding of the domain-specific ontology

Hybrid query interface: Hybrid Retrieval and Application Layer

- Retrieval-augmented generation (RAG) on geospatial knowledge graphs and visualization
- Validation on two practical use-cases

Together, those four steps form a pipeline that spans semantic modeling, multimodal encoding, hybrid retrieval, and real-world validation. The workflow is intentionally modular to ensure scalability, extensibility, and compatibility with future digital twin applications.

Domain-Specific Data Infrastructure

The first work step establishes the project's technical foundation by developing a domain-specific, file-type–aware data infrastructure. Infrastructure data is inherently heterogeneous, spanning CAD/BIM models, point clouds, sensor streams, inspection images, geospatial metadata, and textual documentation. Each modality requires its own storage strategy, indexing mechanism, and metadata model. To ensure long-term accessibility and interoperability, all components of the data space rely on open, license-free formats such as IFC, GeoJSON, LAS/LAZ, and open sensor metadata standards.
The focus of this step is the construction of specialized, modality-specific databases, each optimized for its respective data type—for example:

- a spatially indexed point-cloud store
- an IFC/BIM repository,
- an image archive with embedded metadata
- a time-series database for sensor data.

These stores remain independent at the technical level, preserving their native structure and performance characteristics. Interconnectability is introduced later through semantic identifiers, not by forcing premature unification. This design ensures that downstream components—such as visualization tools (e.g., point-cloud rendering in the viewer) or hybrid retrieval pipelines—can operate efficiently on each modality.
A particular methodological focus lies on representing uncertain geospatial and temporal metadata, which is common in legacy datasets and field-collected information. We investigate unified approaches, including probabilistic spatial envelopes, temporal validity intervals, and fuzzy metadata descriptors. These representations allow downstream processes to reason about incomplete or ambiguous information without discarding valuable data.
The outcome of this step is a fully operational, open, and extensible data space that provides file-type–specific storage and indexing, supports FAIR data principles, and enables seamless interconnectability across modalities. This backbone forms the structural basis for the symbolic and subsymbolic layers developed in subsequent work steps.

Domain-Specific Ontology Encoding and Subsymbolic Modeling

The second work step builds on the data backbone by introducing the hybrid architecture's semantic and subsymbolic layers. Although symbolic representations provide structure and interpretability, they cannot fully capture the richness of unstructured or subsymbolic data such as images, point clouds, or time-series sensor streams. We therefore develop:
Domain-specific ontologies that formalize structural components, materials, interventions, sustainability indicators, and lifecycle processes. Ontology engineering follows established best practices, including a clear purpose and scope, competency questions, ontology reuse when possible, appropriate levels of abstraction, consistent naming, modular design, examples and usage patterns; SHACL-based constraint definitions, and publishing in accessible formats. Alignment with standards such as IFC, GeoSPARQL and SOSA/SSN[7] ensures interoperability with BIM, geospatial, and sensor vocabularies.
Lightweight, domain-tailored encoder models that generate compact embeddings for each modality. Examples include CLIP-style models (Radford et al., 2021) for image–text alignment and DistilBERT-based encoders for textual descriptions (Sanh et al., 2020). These embeddings enable fuzzy semantic search, similarity retrieval, and cross-modal reasoning.
The methodological approach begins with the creation of modality-specific datasets, including annotated images, inspection records, vibration or strain time-series, and textual descriptions. Depending on data availability, different training paradigms are employed:

- fully supervised learning for a well-annotated dataset
- pretraining for image-to-language tasks
- self-supervised learning for large unlabeled texts
- contrastive learning for cross-modal alignment

Each encoder is trained in isolation to ensure modularity and avoid negative transfer. The resulting models are optimized for efficiency, enabling real-time vector generation suitable for integration into vector databases and RAG pipelines down the line.

[7] https://www.w3.org/TR/vocab-ssn/

We also aim to develop an API layer that exposes embedding generation and ontology-based reasoning as services. This ensures that downstream components—such as the hybrid query interface in CARE-DIVE—can seamlessly access both symbolic and subsymbolic representations.
The outcome is a coherent semantic and subsymbolic layer that complements the data infrastructure from the previous step and forms the conceptual foundation for hybrid symbolic–subsymbolic querying.

Retrieval augmented generation (RAG) on geospatial knowledge graphs

The hybrid retrieval layer constitutes the methodological core of the architecture. Its purpose is to combine symbolic reasoning over a geospatial knowledge graph with subsymbolic similarity search in a vector database, enabling retrieval-augmented generation (RAG) that is both semantically grounded and robust to incomplete metadata.
At the symbolic level, domain concepts, structural elements, materials, and spatial relations are encoded in a GeoSPARQL-enabled knowledge graph. This representation supports semantic queries, topological reasoning, and ontology-driven inference, allowing the system to retrieve contextually relevant information even when explicit metadata is sparse or inconsistent. The graph serves as the structured backbone for aligning heterogeneous data sources and for expanding retrieval results with semantically related entities.
At the subsymbolic level, documents and other unstructured data are embedded using lightweight encoder models and indexed in a vector database. Dense similarity search provides fuzzy retrieval capabilities that complement the strict semantics of the knowledge graph. This enables the system to surface relevant content even when terminology varies, metadata is missing, or the user query is ambiguous.
The hybrid retrieval mechanism integrates both layers into a unified query pipeline. Vector search first identifies high-similarity candidates, which are then enriched through graph-based contextual expansion. The combined result set is passed to a large language model for downstream reasoning and answer generation. This design balances precision and contextual richness: vector search ensures broad coverage of potentially relevant content, while the knowledge graph injects semantic structure and domain specificity into the retrieved context.
The key innovation of the proposed approach lies in the tight coupling of semantic graph reasoning with subsymbolic similarity search. Unlike conventional RAG pipelines, that rely solely on vector embeddings, the hybrid architecture incorporates explicit ontology-driven constraints, spatial relations, enabling more interpretable and context-aware retrieval.
Although the present prototype focuses on text-based retrieval, the architecture is explicitly designed to accommodate multimodal extensions. Ongoing work explores the integration of embeddings for images, point clouds, and IFC-based geometric entities, enabling cross-modal retrieval and geospatially grounded RAG workflows. In this context, multimodal representations are aligned within a shared latent space using cross-modal contrastive learning. Modality-specific encoders—such as vision transformers for images and point-based neural networks for 3D geometry—are trained to map corresponding observations of the same structural element to nearby locations in the embedding space while separating non-matching pairs (Sun et al., 2024). This CLIP-style formulation provides a principled mechanism for bridging modality gaps and learning representations that are semantically comparable across data types. While these components are currently under development and not yet evaluated quantitatively, they establish a clear methodological pathway toward future multimodal digital-twin representations, including 2D–3D correspondences, spatially anchored observations, and multimodal retrieval workflows.

Validation and Demonstration

To ensure practical relevance, the system will be validated through two representative use cases: sustainability life-cycle assessment and structural circularity. These scenarios pose distinct but complementary challenges, allowing the framework to be evaluated across different data modalities, analytical workflows, and decision-making contexts. The validation focuses on three dimensions. First, feasibility is assessed by determining whether the system can reliably provide the precise subset of data required for each task, including checks on metadata completeness, cross-modal alignment quality, and the efficiency of retrieving relevant information. Second, robustness is evaluated by testing performance under varying data-quality conditions, such as incomplete metadata, noisy sensor inputs, and ambiguous visual observations. The hybrid architecture is expected to maintain resilience by combining symbolic reasoning with subsymbolic similarity cues. Third, transferability examines whether workflows developed for one asset type can be adapted to other asset types with minimal reconfiguration, a prerequisite for scaling the approach to large assets in the future.

Preliminary Results

The preliminary results focus on validating the retrieval layer of the proposed hybrid symbolic–subsymbolic architecture, addressing RQ1 and RQ2 through an empirical comparison of retrieval strategies on infrastructure-like document corpora enriched with embedded images and tables. The evaluation targets the core architectural assumption that combining ontology-driven graph reasoning with vector-based similarity search improves retrieval quality over single-paradigm approaches.
A first prototype implements a HybridRAG architecture by integrating dense vector search using Qdrant[8] with a structured semantic context stored in a Neo4j[9] graph

Table 2: Comparison between the vector-based RAG, the graph-based RAG, and the HybridRAG

Model/Metric	Query hits	avg. MRR	avg. retrieved
VectorRAG	14.71	0.755	93.1
GraphRAG	17.34	0.699	185.7
HybridRAG	18.83	0.812	93.1

database. PDF-based documents are automatically ingested, segmented, and embedded, with visual content processed through a self-hosted Qwen3-Vl[10] model, before being indexed. Retrieval combines similarity-based candidate selection with graph-driven contextual expansion, after which a self-hosted Ollama Mistral 7B[11] large language model performs downstream reasoning over the retrieved content. To evaluate retrieval performance, HybridRAG was tested on the Open RAG Bench dataset[12], which consists of 1000 PDF documents and 3000 benchmark queries, and was compared against the VectorRAG and GraphRAG baselines. The results are summarized in Table 2. HybridRAG achieves the highest mean reciprocal rank (MRR) and query hit rate, indicating superior ranking quality and retrieval accuracy. These findings directly address RQ1, demonstrating that ontology-driven alignment improves robustness and accuracy when retrieving relevant information from heterogeneous document collections with uneven or incomplete metadata. In relation to RQ2, the comparison shows that while GraphRAG retrieves a broader contextual neighborhood, HybridRAG provides a more balanced trade-off between contextual richness and retrieval precision. By combining explicit semantic structure with subsymbolic similarity measures, the hybrid approach enables more context-aware retrieval than either paradigm in isolation. Overall, the observed improvements support H1, confirming that a hybrid knowledge-graph + vector-database architecture enables more accurate and context-rich retrieval for infrastructure-like document collections. Beyond this validated pipeline, the system is currently being extended to support multimodal capabilities. A Three.js[13]-based 3D viewer has been implemented and connected to the retrieval backend (Figure 2), establishing the technical interface for interacting with geospatial and structural data. In parallel, the document ingestion workflow is being generalized to spatial data sources such as point clouds and IFC models, with early prototyping indicating that geometric entities can be decomposed into semantically meaningful units, embedded using modality-specific encoders, and linked to symbolic graph structures. These developments are ongoing and have not yet been evaluated quantitatively; they demonstrate the architectural readiness of the proposed approach for future multimodal digital-twin applications.

Conclusion and Outlook

This paper presented a prototype hybrid symbolic–subsymbolic retrieval architecture for infrastructure digital twins and evaluated its effectiveness on infrastructure-like document corpora. The results demonstrate that ontology-driven alignment significantly improves retrieval accuracy and robustness under conditions of incomplete or heterogeneous metadata (RQ1). Furthermore, the empirical comparison confirms that a hybrid knowledge-graph + vector-database architecture outperforms single-paradigm RAG approaches in terms of ranking quality and contextual relevance (RQ2). The findings show that integrating knowledge-graph structures with vector-based semantic retrieval yields significantly more accurate and contextually richer access to technical documentation than single-paradigm approaches. These results validate the hybrid retrieval layer as a reliable and scalable foundation for more advanced digital-twin workflows. While the evaluation is conducted within the CARE ecosystem and informed by infrastructure demonstrators such as the openLAB research bridge, the core methodological contributions—ontology-driven data alignment, hybrid retrieval architectures, and RAG-based reasoning—are not CARE-specific. These components are transferable to other infrastructure domains, provided that domain-specific vocabularies and metadata schemas are adapted accordingly. Future work will extend the validated re-

trieval backbone toward fully multimodal digital twins, incorporating IFC models, point clouds, construction plans, and sensor data through cross-modal embedding alignment and geospatial reasoning. Additional validation will focus on operational sustainability use cases, including life-cycle assessment and circularity analysis, as well as on assessing the transferability of the proposed workflows across different asset types. Together, these developments aim to establish scalable, interoperable, and robust digital twin ecosystems capable of supporting data-driven infrastructure management.

Abstract

Digital Twins (DTs) couple BIM and IoT for sustainable building operation, yet many implementations remain siloed, hard to scale, and difficult to interpret. This paper presents a stepwise DT prototype for an environmental-education facility, integrating indoor/outdoor sensing (CO_2, PM, temperature, humidity, occupancy) with a Revit BIM model. A Dynamo–Python pipeline maps cloud time-series to shared BIM parameters, enabling in-model visualization, threshold alerts, and KPI reporting. Initial deployment delivers the sensing-and-display setup and a reusable BIM data schema ready for automated synchronization. The lasting contribution is a replicable BIM-centric implementation method for room- and zone-level monitoring in sustainable cultural buildings.

Introduction

DTs are increasingly recognised as dynamic digital representations that are continuously updated by data streams from the physical asset and used to support monitoring, analysis, and decision-making throughout the lifecycle (Grieves and Vickers, 2017; Fuller et al., 2020). In the built environment, DT research has accelerated as BIM (Building Information Modelling), while rich in geometry and semantics, remains essentially static and insufficient to represent operational conditions required in operations and maintenance (O&M) (Sacks et al., 2020; Jiang et al., 2021). A common response is to integrate BIM with Internet of Things (IoT) sensing, cloud data platforms, and analytics to produce operational DTs capable of performance tracking, anomaly detection, and optimisation (Eneyew et al., 2022).

Despite the rapid growth of BIM–IoT DT prototypes, the literature consistently highlights limitations that hinder repeatability and scaling: (i) interoperability and semantic misalignment between BIM schemas and heterogeneous IoT platforms; (ii) fragile, project-specific mapping between sensor identifiers and BIM elements; (iii) ad-hoc synchronisation pipelines that are difficult to maintain; and (iv) limited support for how stakeholders interpret and act on DT outputs (Pauwels et al., 2017; Boje et al., 2020). Recent literature confirms that these issues remain central, especially where heterogeneous data structures, non-standardised integration procedures, and weak information governance limit the transition from data collection to operational decision support (Tang et al., 2019; Mannino et al., 2021; Liu et al., 2025; Zhang et al., 2025). Several contributions argue that semantic enrichment and standards-aware information management are necessary for DT ecosystems to become reliable beyond prototypes (Boje et al., 2020; buildingSMART International, 2023). Recent work on BIM-IoT-enabled smart and sustainable buildings shows that real-time monitoring, in-model visualisation, and sensor-linked dashboards are increasingly common, but that maintainable integration logic and robust spatial contextualisation remain insufficiently clarified, particularly in existing buildings and operational settings (Valinejadshoubi et al., 2021; Piras et al., 2025). Standards and positioning efforts (e.g., Industry Foundation Classes (IFC) and ISO information management frameworks) stress that DT value depends on disciplined information modelling, governance, and transparent data exchange mechanisms rather than tool-specific integrations (ISO, 2018; ISO, 2018a; buildingSMART International, 2020). This direction is also coherent with ongoing CEN/TC 442 standardisation efforts on digital twins in the built environment, which emphasise the relationship between BIM, structured information, and interoperable exchange environments (CEN/TR 18077, 2024; EN 18162, 2026).

Cultural and educational buildings introduce additional challenges and opportunities. Retrofitting sensing infrastructure in existing museums must minimise invasiveness and accommodate visitor flow, while the DT can simultaneously support operational decision-making and public sustainability awareness through “human-in-the-loop” feedback (Turco et al., 2022). In this context, indoor environmental quality (IEQ), including thermal-hygrometric comfort and air quality, becomes a dual objective: protecting occupants (often children) and turning the building into a learning environment. For particulate matter (PM2.5, PM10) and other pollutants, internationally recognised guideline thresholds provide a robust reference for interpretability and alerting logic (World Health Organization, 2021).

This paper reports a DT setup designed as a progressive, stepwise implementation for a museum Living Lab, the Italian (MAcA) Museo A come Ambiente based in Turin, where sensing infrastructure, data management, BIM preparation, and automated synchronisation are introduced in a controlled sequence. The current phase focuses on the area where the sensing infrastructure and

visitor-facing displays are deployed, so that the end-to-end sensing-data-BIM pipeline can be validated, establishing the technical foundations required for scaling it to the full asset. While the five-layer architecture provides the overall DT framework for structuring sensing, data management, integration, digital representation, and stakeholder interaction in the museum case study, the main contribution of the paper lies in its BIM-centric implementation for maintainable room and zone level monitoring, where spatial contextualisation, progressive deployment, and stakeholder interpretability must coexist. More specifically, the contribution lies in the combination of persistent spatial identifiers, room-zone-level data binding, a writable shared-parameter schema, an incremental snapshot-to-live synchronisation logic, and a dual representation strategy in which BIM supports spatial-semantic contextualisation while external platforms support longitudinal analytics. The paper does not present a generic BIM-IoT monitoring platform, but an early-stage operational DT prototype whose advancement lies in making room-/zone-level climate monitoring more maintainable and interpretable through persistent spatial identifiers, BIM-native contextualisation, and interoperable state transfer. Accordingly, the paper illustrates (i) the BIM model and shared-parameter data schema, (ii) the configured cloud-to-BIM synchronisation pipeline, and (iii) intended use cases together with a KPI-driven evaluation strategy.

Case study and project context

The case study is the Living Lab established at MAcA, which is the first museum in Europe entirely dedicated to environmental issues, offering interactive exhibits, labs, and educational trails aimed at spreading environmental culture and supporting experiential learning. The museum (Figure 1) is in the north-west of Turin and in a post-industrial regeneration area facing Parco Dora with an overall surface of 3,500 square meters, including indoor and outdoor areas. It comprises two architectural bodies, a historic building and a newer volume, connected by an internal garden.

Figure 1: MAcA museum overview

Lying within the Po Valley, a densely populated and industrialised basin, particulate matter (PM) and other pollutants frequently exceed regulatory thresholds due to adverse meteorological and morphological conditions that reduce atmospheric mixing, especially in winter (ARPA Piemonte, 2024). Thus, MAcA is a meaningful testbed for setting up a DT focusing on indoor/outdoor microclimate and air quality awareness. Visitor-facing interpretation can connect measured values to broader environmental challenges, while operational monitoring can support comfort and risk mitigation in crowded educational spaces (World Health Organization, 2021). MAcA also provides an excellent "human–data interaction" environment as its mission explicitly targets schools and families through hands-on education. Furthermore, the museum runs structured programmes designed for school audiences. In 2024 it hosted over 34,400 visitors with 26,400 people coming from schools and groups (Associazione A come Ambiente, 2024). This is particularly relevant for a DT aimed at linking occupancy patterns and IEQ conditions (e.g., CO_2, particulate matter, thermal-hygrometric comfort) as comfort and air quality have both health and educational implications.

The development of the MaCA Living Lab is under the umbrella of the European Project NODES Spoke 4 "Digital innovation toward sustainable mountain", promoting digital technologies and services to improve sustainability and resilience in mountain territories and connected communities (ECS-NODES, 2025a). In particular, the INTERFACE flagship which aims to support the regeneration and repopulation of mountain territories through models sensitive to ecological context and participatory approaches capable of adapting to changing environmental conditions (ECS-NODES, 2025b). The MAcA Living Lab is used as a demonstrator where BIM-IoT integration, data-driven communication and monitoring workflows can be validated in a controlled public building and then transferred to other contexts (e.g., schools, cultural facilities, and tourism infrastructures), consistent with the mission of Spoke 4 (ECS-NODES, 2025a; ECS-NODES, 2025b).

Methodology and DT architecture

This work adopts a replicable methodology to set up a BIM-centric DT for sustainable cultural and educational buildings, combining (i) a stable semantic and spatial backbone in BIM, (ii) a heterogeneous IoT sensing infrastructure, and (iii) an automated synchronisation workflow that collects time-varying measurements into BIM parameters for contextualized interpretation, alerting and reporting. The approach is consistent with DT literature that frames built-asset DTs as layered cyber–physical ecosystems, where separation of concerns supports scalability and long-term maintainability (Fuller et al., 2020; Eneyew et al., 2022), and where semantic enrichment and standards-aware information management are essential to move beyond fragile prototypes (Boje et al., 2020; buildingSMART International, 2023). The long-term target is a whole-building DT, while the deployed implementation focuses on the currently sensorised ground floor as an initial deployment domain to validate mapping rules, data schema, and interpretability before scaling additional spaces. The implementation framework is designed along five steps, better described in the following sub-sections.

1. Sensing and stakeholder interfaces.

2. DT system architecture.
3. BIM model and data schema.
4. Data integration and synchronization pipeline.
5. Intended use cases and evaluation strategy.

Step 1 - Sensing and visualization interface

The first step establishes DT's physical observability and its human-facing interaction points. At this stage, the monitored variables and sensing strategy are selected to capture IEQ and occupancy-related dynamics that are relevant to comfort, air-quality awareness, and operational monitoring. In parallel, the approach defines how the DT will communicate these measurements to different stakeholder groups through appropriate interfaces, ensuring that collected data can be interpreted and acted upon rather than remaining isolated technical signals. Detailed descriptions of the deployed sensing assets and stakeholder interface components are reported in Step 2 within the DT layered architecture. This dual interface setup addresses a common barrier in DT adoption, where monitoring data exists but are not effectively translated into decision support and stakeholder understanding (O'Donnell et al., 2013; buildingSMART International, 2020).

Step 2 - DT system architecture

Step 2 defines the DT architecture as a separation-of-concerns system and specifies the data contract that links physical sensing, cloud time-series identifiers and BIM entities. Currently, the system is framed as an early-stage operational DT prototype, combining a monitored physical environment, a spatial-semantic digital counterpart, updateable data links, and user-oriented interpretative outputs, while live cloud synchronisation is still being progressively activated. Although the current implementation uses Revit and Dynamo as the orchestration environment for BIM-native write-back and inspection, the architecture is not intended as a fully centralised DT repository: longitudinal measurements remain managed in the external time-series layer, while BIM stores selected operational states for spatial contextualisation, traceability, and communication. The DT architecture is structured in five layers (Figure 2).

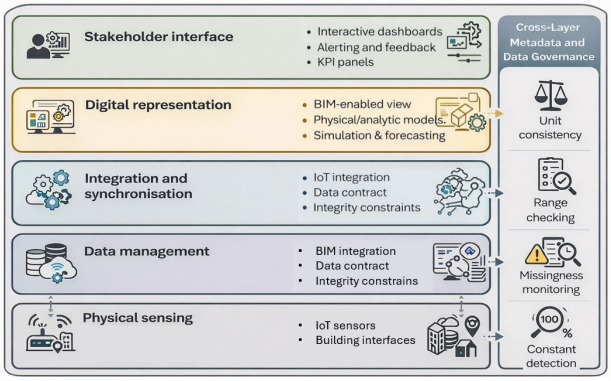

Figure 2: Layered DT architecture and data flow

This separation is widely adopted to support scalability and avoid tight coupling to vendor platforms (Fuller et al., 2020; Eneyew et al., 2022). Several contributions argue that semantic enrichment and standards-aware information management are necessary for DT ecosystems to become reliable beyond prototypes (Boje et al., 2020; buildingSMART International, 2023). In addition, the data contract includes explicit integrity constraints (e.g., unit consistency, range checks, missingness and constant-value detection) to prevent misleading interpretations and to support quality-controlled DT visualisations.

Physical sensing layer

This layer acquires IEQ and occupancy-related signals. The deployed devices measure indoor temperature, relative humidity (RH), carbon dioxide (CO_2), particulate matter (PM2.5, PM10), and occupancy indicators, complemented by outdoor boundary conditions via a weather station. The sensing stack combines KNX building automation devices and LoRaWAN (Long Range Wide Area Network) components to cover both stable IEQ monitoring and dynamic people-flow estimation. Sensor and device types, quantities, and monitored variables are summarised in Table 1 and are deployed across the sensorised domain to capture both environmental state and contextual drivers (occupancy/activity), enabling interpretation of microclimate variation as a function of use patterns. This heterogeneous configuration is designed to support both operational monitoring and educational interpretation by linking microclimate variations to occupant behaviour.

Table 1: Sensing devices deployed in the Living Lab

Sensor type	Qty	Variables measured	Technology
Weather station	1	Outdoor temperature, illuminance, wind, rain	KNX
Outdoor humidity	1	Outdoor RH	Analog (0–10V / 4–20mA) / integration to BMS
Air quality probes	5	PM2.5, PM10	KNX
Indoor multisensors	4	Temperature, RH, CO_2	KNX
Presence/activity sensors	4	Presence/activity, illuminance, noise proxy; (some nodes also expose pressure/dew point signals	KNX
IoT controller/gateway	4	Fieldbus integration (RS485), device bridging metadata	LoRaWAN + RS485
3D ToF people counters	4	People counting / flow direction	LoRaWAN

Data management layer

Sensor measurements are stored as time series in a provider-managed cloud environment. This layer decouples high-frequency ingestion from downstream consumers and provides a single authoritative data source with timestamps and metadata (e.g., sensor identifiers, variable types). The cloud layer decouples sensor ingestion from downstream consumers and supports historical queries and auditing. For the current validation phase, an exported time-series snapshot is used to test the downstream DT linkage. Currently, programmatic access to these cloud time series is under activation. The paper focuses on the integration contract (identifiers, schema and workflow) so that ingestion can be activated without re-authoring the BIM model once API (Application Programming Interface) credentials and endpoints are available.

Integration and synchronisation layer

This layer operationalises the cloud-to-BIM bridge. The proposed workflow is based on Autodesk Dynamo (i.e., visual programming) combined with embedded Python scripts to (i) query the BIM model for persistent space-level identifiers (MAcA_SpaceId), (ii) construct authenticated API requests to retrieve time-series values, (iii) validate and preprocess records (timestamp checks, missing values, unit normalisation, optional aggregation), and (iv) write validated values into BIM shared parameters. The workflow is designed to be inspectable and modular, supporting gradual extension to additional sensors and variables (Eneyew et al., 2022). In the current validation phase, the integration layer operates in a snapshot-based mode using exported time-series datasets. The same modules are designed to transition to authenticated live API queries once endpoints and credentials are available.

In practice, the integration workflow is implemented as a Dynamo graph operating within the Autodesk Revit environment, where Python scripts are used to parse time-series snapshots, apply temporal filters and threshold logic, and write aggregated results directly into BIM shared parameters associated with spaces and zones. The visual programming layer supports transparency and inspection of the data flow, while embedded scripts encapsulate reusable logic for data validation and aggregation.

Digital representation layer

This layer hosts the DT's digital counterpart as a BIM-based operational interface. The Autodesk Revit model functions as the stable spatial and semantic reference where measurements are contextualised, aggregated by zones, and visualised through native constructs such as schedules, view filters and colour-coded overrides. This aligns with research showing that spatially contextualised performance interpretation improves the usability of measured data and supports diagnostics (O'Donnell et al., 2013).

The detailed implementation of the Autodesk Revit model, including modelling scope, shared-parameter schema, sensor-to-model mapping rules, and standards-aware design choices, is presented in Step 3.

Stakeholder interface layer

This layer provides human-facing interpretation for both staff and visitors. The Living Lab deploys five 27-inch displays driven by local mini-PCs, supported by supervision/webserver components, to expose simplified indicators and narratives derived from the monitored variables. This interface layer is treated as integral to the DT ecosystem as it acts as a Human–Data Interaction (HDI) layer that exposes IEQ and occupancy dynamics in near real time, improving interpretability and bridging the gap between measurements and actionability of DT outputs (O'Donnell et al., 2013; buildingSMART International, 2020).

Table 2: summarises the deployed visualization and supervision components

Component	Qty.	Role
LCD monitor (27'')	5	Visitor facing real-time visualisation; staff situational awareness
Mini-PC	5	Local compute for visualisation and interaction
Supervision/energy management software	1	Integration layer; dashboards; device management
Webserver for remote or local interface	1	Remote or local access; integration services

Step 3 - BIM model and data schema

The third step focuses on the design of the BIM model as a semantic backbone for operational data binding and defines a parameter-based data schema to support persistent integration of environmental monitoring information. The BIM model is intentionally developed to prioritise operational interpretability and long-term maintainability rather than geometric detail, in line with operations-oriented BIM practices in facility management contexts (Sacks et al., 2020; Jiang et al., 2021). At the current stage, the model encompasses the sensorised ground-floor spaces, with explicit room and zone definitions to ensure consistent spatial contextualisation, aggregation, and reporting of monitored conditions.

Rather than establishing a one-to-one linkage between individual sensing devices and BIM elements, the adopted strategy associates monitored variables directly with spatial entities. Each space acts as a semantic container for a predefined set of environmental parameters, enabling the aggregation of sensor data at the room or zone level. This approach reduces coupling between physical devices and the BIM model, increasing robustness to sensor replacement, relocation, or changes in the sensing infrastructure, while preserving spatial meaning and continuity of historical records (Pauwels et al., 2017; Boje et al., 2020).

The shared-parameter schema reflects this aggregation-oriented logic and includes space-level parameters

representing monitored environmental quantities (e.g., temperature, relative humidity, CO_2 concentration, PM2.5, PM10, illuminance), along with a timestamp parameter recording the last valid data update. Additional boolean or state parameters are used to encode threshold-based anomaly conditions derived from recent time windows, supporting alerting and reporting without requiring persistent storage of full time series within the BIM environment. This schema enables BIM-native views, filters, and colour-coded representations once synchronised values are written to the model (O'Donnell et al., 2013). The parameters are designed to be writable by external automation scripts, enabling repeatable BIM updates without manual interaction. In the current validation phase, time-series snapshots imported from external data sources are used both to verify data-to-space mapping integrity prior to live ingestion and to test transferability toward open representations, including IFC property sets (ISO, 2018; ISO, 2018a; buildingSMART International, 2020).

The same schema was therefore mapped to a custom IFC property set (PSet_MAcA_IoT) through a DefaultUserDefinedParameterSets configuration, exporting room-level entities as IfcSpace objects with MAcA_SpaceId, timestamp, and selected IEQ variables (Figure 3). In the BAR zone, for example, Z_Bar - CO2, Z_Bar - Temperatura, and Z_Bar - Umidità were exported as Bar_CO2, Bar_Temperature, and Bar_Humidity, while the same logic was replicated for CUPOLA and VERDE. Outdoor variables remain in the time-series layer in the current phase; accordingly, the interoperable exchange model prioritises room-level indoor states through IfcSpace-linked custom properties, while external boundary conditions remain outside the primary IFC export. Currently the prototype focuses on writable implementation logic, stable spatial identifiers, and standards-oriented exchange of selected operational states rather than on bSDD for formal semantic harmonisation.

Step 4 - Data integration and synchronization pipeline

Building on the shared-parameter schema defined in Step 3, Step 4 configures the automated data synchronisation pipeline responsible for injecting time-varying environmental measurements into the BIM model. The workflow is implemented using Autodesk Dynamo in combination with embedded Python scripts and is designed to operate at the space and zone level rather than at the individual sensor level (Figure 4).

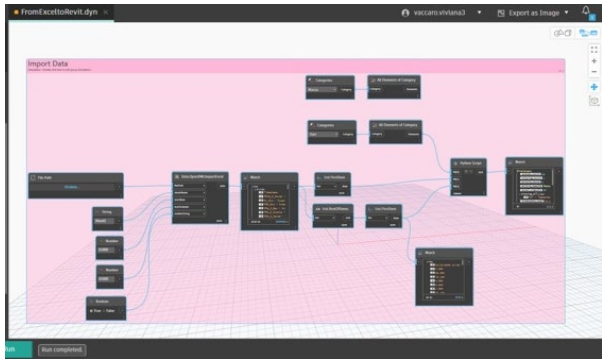

Figure 4: Dynamo based synchronization workflow

This design choice ensures robustness to changes in the sensing infrastructure while preserving the spatial interpretability of monitored conditions.

The synchronisation pipeline performs four main functions: (i) retrieval of structured monitoring data from external sources (currently via spreadsheet-based snapshots, with cloud-based time-series endpoints planned); (ii) temporal filtering and preprocessing of measurements, including timestamp parsing, unit normalisation, and aggregation over configurable time windows (e.g., rolling 24-hour periods); (iii) evaluation of threshold-based conditions to identify anomalous

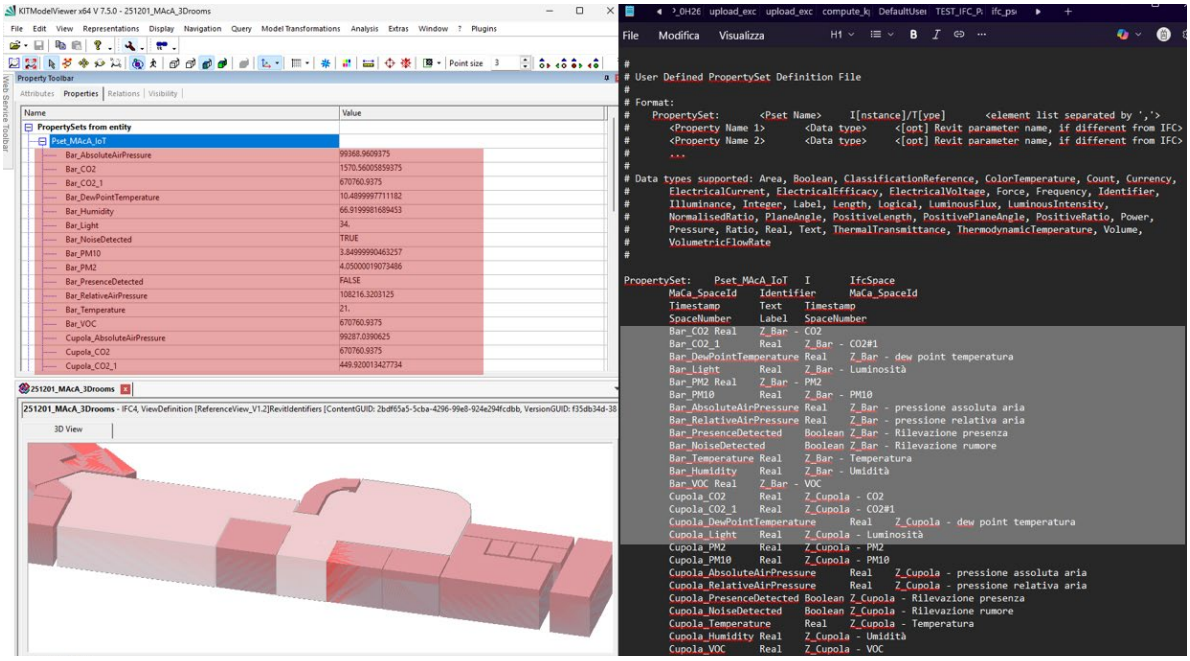

Figure 3: Custom PSet_MAcA_IoT definition and IFC-based export of room-level monitored states

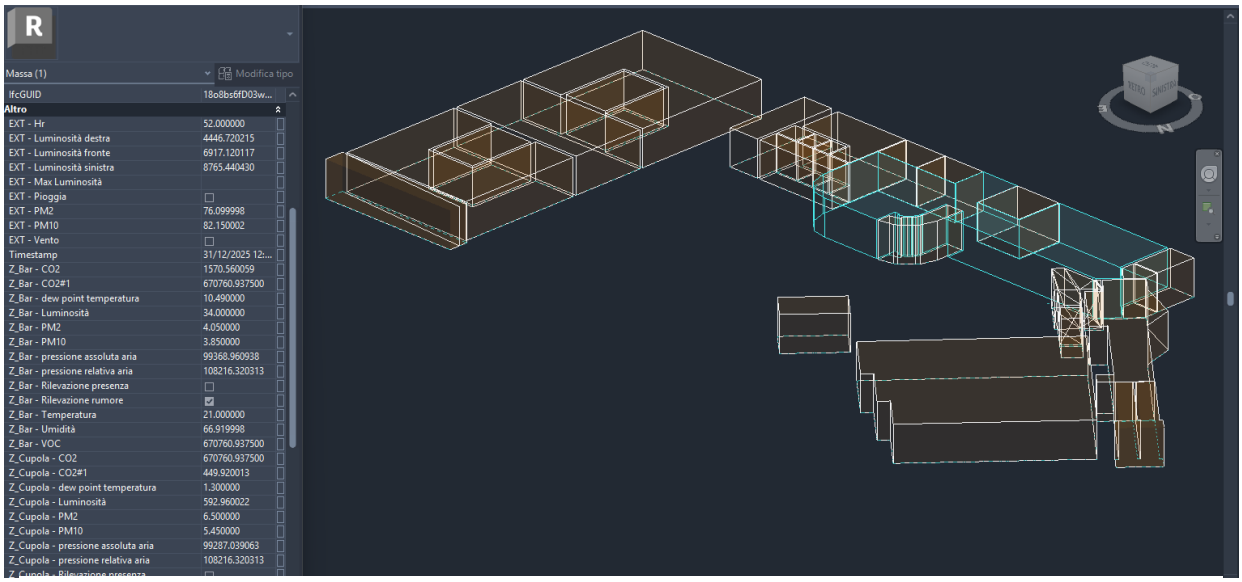

Figure 5: BIM contextualisation of monitoring data via shared parameters

environmental states; and (iv) writing of validated and aggregated values directly into predefined BIM parameters associated with rooms or zones, including measured quantities, last-update timestamps, and alert indicators. Rather than persisting full time series within the BIM environment, the pipeline selectively materialises operationally relevant summaries (e.g., maximum values over the last 24 hours and corresponding alert states). This approach enables BIM-native constructs, such as drafting views populated with automatically generated text-based annotations, view filters, and colour-coded overrides, to function as lightweight operational dashboards, supporting spatially contextualised interpretation of building performance without overloading the model with high-frequency data (Figure 5) (O'Donnell et al., 2013).

Within this workflow, Dynamo scripts directly write alert summaries and exceedance information into dedicated drafting views, allowing the BIM model to function as a self-contained, read-only operational reporting interface without relying on schedules or external dashboards.

At the current stage, live cloud access has not yet been activated; however, the synchronisation workflow is fully implemented and executable. Once data endpoints and authentication credentials are provided, the pipeline can be enabled without requiring modifications to the BIM model or its parameter schema, as the data-to-space association logic is already embedded in the operational configuration defined in Steps 2 and 3. This separation between model structure and data access supports incremental deployment and facilitates the progressive evolution of the system toward a fully operational DT. In this configuration, the time-series layer remains the authoritative source for longitudinal measurements and temporal analytics, while BIM hosts selected synchronised states for spatial-semantic contextualisation and operational interpretation.

Step 5 - Intended use cases and evaluation strategy

The last step of the methodology defines the intended DT capabilities and the evaluation protocol to be applied as integration progresses from snapshot-based validation to live synchronisation. The proposed DT supports three complementary functions: (i) operational observability of IEQ at zone level through continuous sensing; (ii) BIM-centric contextualisation, where monitored values are linked to spatial entities via persistent space-level identifiers (MAcA_SpaceId) and shared parameters; and (iii) stakeholder communication, where technical measurements are translated into readable indicators for educators, visitors, and facility staff. Evaluation is defined as an intended, KPI-driven strategy to be executed once live synchronisation is enabled, structured along three dimensions:

1. Pipeline performance and data reliability: quality criteria for time-series ingestion (latency, completeness, integrity);
2. Spatial correctness and interpretability: SpaceId mapping correctness; clarity of schedules and colour-coded views for staff;
3. Stakeholder usefulness: qualitative feedback on readability, perceived utility, and support to operational or educational decisions.

KPI logic and indicator interpretation will be grounded in recognised guidance for air quality and comfort, while preserving transparency on assumptions and data provenance.

Discussion

The first results support the feasibility of the proposed BIM-centric DT approach. A one-week monitoring excerpt sampled at 15-minute intervals was used as a testbed to verify end-to-end linkage between time-series measurements and the BIM environment, and descriptive statistics indicate meaningful room/zone-level IEQ dynamics. The test confirmed the successful population of shared parameters, timestamps, and alert-related fields from external records, showing that monitored values can be spatially contextualised in BIM without relying on full time-series storage within the model. This is relevant

because the proposed logic reduces dependence on device-specific BIM bindings and supports more robust room- and zone-level interpretation under sensor replacement or reconfiguration. The validation also confirms that data-quality assurance and metadata governance (e.g, covering variable naming, units, channel definitions, and consistent cross-zone mapping) are first-class DT requirements before thresholding logic or public-facing indicators are operationalised (Boje et al., 2020; buildingSMART International, 2023). Accordingly, the workflow incorporates integrity checks on units, ranges, missingness, and constant values to reduce misleading interpretations and false alerts. On the integration side, a proof-of-concept BIM linkage was achieved: DT fields were instantiated as shared parameters in Revit, and a Dynamo-Python workflow was configured and tested to connect the exported snapshot to BIM parameters, enabling automated population and BIM-native representations. This confirms BIM's role as a spatial and semantic backbone for operational data binding, supporting zone aggregation and "where/which space" reasoning that complements conventional dashboards and improves interpretability of measured performance (O'Donnell et al., 2013). In this respect, the contribution is not the generic coexistence of BIM and IoT, but a more maintainable operational logic in which monitored values are bound to persistent spatial entities rather than to device-specific model objects, reducing fragility under sensor replacement or reconfiguration and enabling interoperable room-level state externalisation through IFC. A key implication is that the DT should be implemented as a dual representation system: BIM-based views for spatial traceability and contextual diagnosis, and time-series dashboards for temporal analytics, comparisons, and anomaly cues. Thresholds for alerting and exceedance logic will be anchored to authoritative guidance and widely adopted standards, including WHO guidance for particulate matter (World Health Organization, 2021), (ASHRAE, 2023; ISO, 2025) for thermal comfort, and CO_2 used as a ventilation/occupancy proxy with known limitations (Lu et al., 2022). In this direction, the installed museum screens, currently limited to vendor-default static content, will be progressively repurposed to display curated near real-time dashboards aligned with acquisition frequency, using read-only visualisations, role-based access control, and content governance. Overall, the main scaling challenges are robust metadata and point naming, systematic data-quality assurance, secure and maintainable cloud access, and stakeholder-oriented visual design for public-facing displays.

Conclusions

This paper presented a BIM-centred, stepwise framework for integrating, contextualising, and operationally interpreting environmental monitoring data in a living-lab setting. Through the MAcA case study, the work showed how a DT can be implemented by using BIM not as a passive geometric repository, but as an active semantic interface for spatially grounded monitoring, alerting, and reporting. Rather than pursuing a device-centric or fully control-oriented architecture, the proposed approach intentionally operates at room/zone level, aligning data representation with practical facility-management reasoning and stakeholder interpretation.

The contribution lies not only in the use of a five-layer DT framework, but in its BIM-centric operationalisation for room- and zone-level monitoring, combining persistent spatial identifiers, a writable shared-parameter schema, an incremental path from snapshot-based validation to live synchronisation, and preliminary IFC-based transferability. In the current implementation phase, this approach has been validated through snapshot-to-BIM integration using a Dynamo-Python workflow, confirming that BIM-native views can support early operational interpretation without requiring invasive model re-authoring. The study also indicates that effective DT adoption in cultural or public buildings depends on balancing technical integration with interpretability, governance, and maintainability. In this configuration, BIM is not treated as a fully centralised repository of DT information, but as a spatial-semantic interface coupled with external time-series infrastructures and interoperable exchange mechanisms. Future work will extend live cloud ingestion, consolidate IFC-aligned interoperable exchange, and refine role-based interfaces for operational and public-facing use.

Abstract

Current robotic fleet management in construction primarily relies on 2D maps and geometry-based planners, with limited integration of process context and machine capabilities. This restricts scalability and adaptability in complex, dynamic sites. This paper proposes a semantic voxelisation framework that combines 3D voxel models with knowledge of construction processes, resources, and capabilities using IOC, BOT, and CaSkMan ontologies. The knowledge for capability-aware planning and task scheduling is queried using SPARQL and translated into domains and constraints for the planning framework. The contribution is a unified semantic-to-robotic pipeline enabling context-aware planning and scheduling for holistic fleet management.

Introduction

The increasing adoption of mobile robots and autonomous fleets in construction sites introduces new challenges for planning, scheduling, and coordination in highly dynamic, spatially complex environments. Unlike structured industrial settings, construction sites evolve continuously, involve heterogeneous resources, and impose strong dependencies between space, process, and machine capabilities. Current robotic fleet management systems predominantly rely on 2D geometric maps and local navigation constraints, which limit their ability to reason about volumetric space, task context, and resource suitability at a global planning level.

Parallel to advances in construction robotics, the construction informatics community has developed rich semantic representations of the built environment and construction processes, notably through ontologies such as the Building Topology Ontology (BOT), the Internet of Construction (IOC), and Capabilities and Skill of Machines, CaSkMan (CSS). However, these semantic models are typically used for information management, coordination, or analysis and are rarely integrated directly into task-planning and robotic fleet-management pipelines.

This paper argues that semantic voxelisation can serve as an effective intermediate representation between construction knowledge models and robotic systems. By discretising the construction site into a 3D voxel grid enriched with semantic information about space, processes, and resources, it becomes possible to perform capability-aware reasoning at multiple spatial and temporal scales. Tasks with explicit spatial and resource requirements can be matched against available voxel regions using semantic queries, while the resulting spatial constraints can be projected into representations consumable by robotic middleware such as ROS 2 and also industrial robotics.

Automated planning and scheduling are a branch of artificial intelligence that uses reasoning for generating a sequence of tasks that will lead from an initial state to a desired goal state.

We present a semantic voxelisation framework that integrates IOC, BOT, and CSS ontologies as a reasoning layer for task, process, and resource determination. The framework supports querying feasible workspaces and resource allocations via SPARQL, translating 3D semantic voxel information into 2D navigation costmaps, and providing higher-level inputs for fleet scheduling and task allocation. A prototype implementation demonstrates how semantic reasoning can inform navigation and fleet management decisions without replacing existing robotic planners.

The contribution of this work is a unified semantic-to-robotic pipeline that enables context-aware planning and holistic fleet management in construction environments, bridging the gap between construction knowledge representation and operational robotic systems.

State of the art

Fleet Management and Robotic Navigation in Construction

Current robotic fleet management systems in construction predominantly rely on 2D occupancy grids or topological maps derived from SLAM or BIM floor plans (Vega Torres et al. 2023). These representations are primarily geometry-centric and are decoupled from construction processes, task semantics, and machine capabilities. As a result, navigation and task allocation are typically treated as separate problems, handled by rule-based dispatchers or centralized schedulers (Fragapane et al. 2021).

Semantic Models and Digital Twins

Research on semantic digital twins and Linked Building Data (LBD) has introduced ontologies such as BOT, IFC-derived schemas, and construction process models to describe building topology, assets, and workflows (Boje

et al. 2020). These models are largely used for documentation, monitoring, or offline analysis. While not unheard-of, there are attempts of using semantic data and IFC information for robotic planning such as works from (Crespo et al. 2020) and (Byers and RazaviAlavi 2022).

Limitations of Existing Approaches

Despite progress in robotics and semantic modelling, current approaches remain fragmented across geometric modelling, task planning, and robotic execution, limiting their effectiveness in dynamic construction environments. In particular, the lack of integration between spatial context, process knowledge, and execution frameworks restricts context-aware and adaptive decision-making:

- Spatial representations are largely 2D and static, ignoring volumetric constraints.
- Task planning is largely a manual process and does not explicitly account for site conditions, machine capabilities, or spatial affordances.
- Semantic reasoning is typically disconnected from robotic navigation and scheduling systems, such as ROS2.

This gap motivates a unified representation that bridges 3D space, semantics, and robotic execution.

Methodology

Overall System Architecture

The proposed approach introduces a semantic voxel layer, integrating ontologies from different domains with the Construction Site Voxel ontology as an intermediate representation between construction knowledge models and robotic fleet management systems. The framework integrates a voxelised spatial model of the construction site, semantic annotations using construction ontologies, and a reasoning pipeline to derive task-, resource-, and space-aware planning inputs.

The Construction Site Voxel Ontology, CVX

The **CVX Ontology** provides a semantic representation of construction sites based on voxelised volumetric space. Its primary purpose is to bridge geometric discretisation with construction semantics, enabling capability-aware planning, scheduling, and robotic fleet management. CVX acts as an intermediate semantic layer between building topology (BOT) (Rasmussen et al. 2020), construction processes (IOC) (Kirner et al. 2024), and capabilities and skills for machine capabilities (CSS) (Christian Diedrich et al. 2022), allowing volumetric regions of a construction site to be queried, reasoned over, and translated into robotic navigation and scheduling inputs.

Unlike traditional 2D grid maps or purely geometric voxel models, CVX treats each voxel as a first-class semantic entity, capable of representing spatial location, occupancy state, temporal validity, and process relevance. This enables integrated reasoning over where tasks can be performed, when space is available, and which resources are suitable. An overall concept of the ontology and its links to other ontologies are shown in Figure 1.

cvx:Voxel

The class *cvx:Voxel* represents an atomic volumetric unit of space within a construction site. Each voxel corresponds to a bounded 3D region and serves as the fundamental spatial abstraction in CVX. Voxels are uniquely identified and persist across time, allowing them to be referenced consistently in semantic queries, scheduling decisions, and robotic planning pipelines. The *cvx:voxelAttribute* represents non-tangible, contextual, and informational properties associated with a voxel that are relevant for planning, navigation, and fleet management. Unlike geometric or topological properties, voxel attributes capture dynamic, sensed, or inferred data

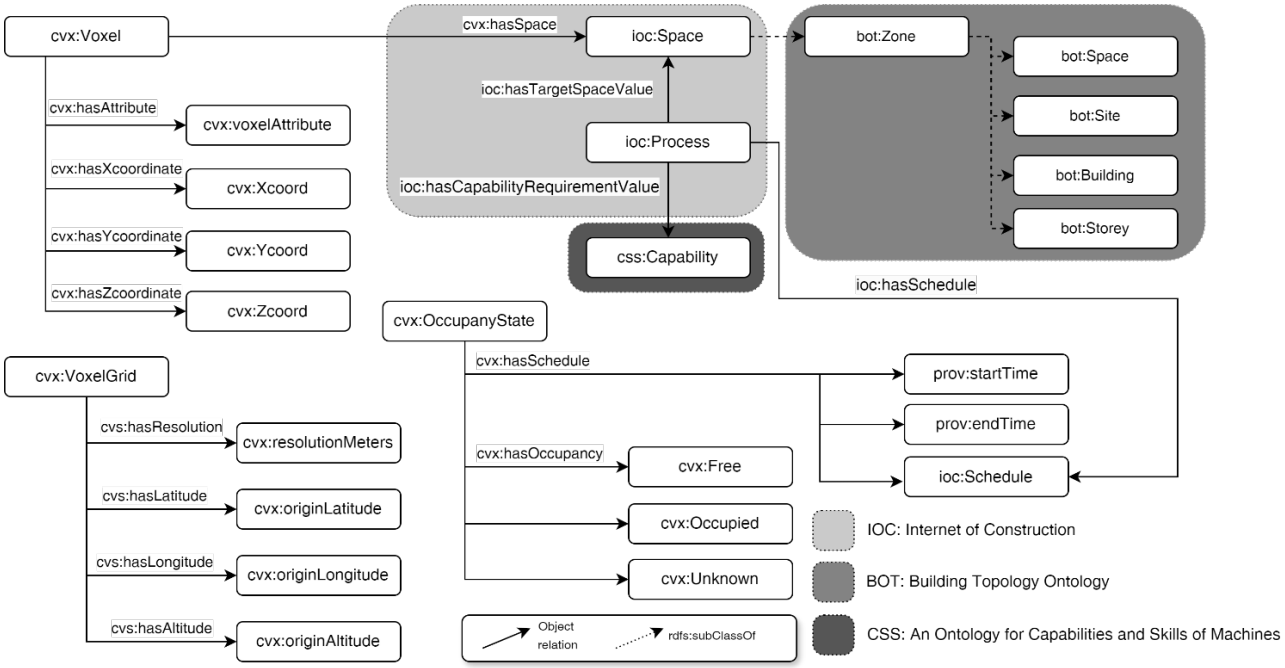

Figure 1: A first CVX ontology concept integrating IOC, CSS and BOT

that may influence robotic decision-making without constituting a physical obstruction.

cvx:VoxelGrid

The class *cvx:VoxelGrid* represents the global discretisation context within which voxels are defined. It captures parameters necessary to interpret voxel coordinates in real-world space. The key properties include *cvx:hasResolution*, specifying voxel size in meters, *cvx:originLatitude*, *cvx:originLongitude*, and *cvx:originAltitude*, defining the spatial reference origin of the grid. This design allows CVX to align voxelised construction sites with georeferenced building and site models, supporting integration with BIM, GIS, and digital twin systems.

cvx:OccupancyState

The class *cvx:OccupancyState* models the usage and availability of a voxel over time. It enables CVX to distinguish between static geometry and temporally evolving construction site conditions. A voxel's occupancy state is linked via *cvx:hasOccupancy* and can take one of three values:

- *cvx:Free* – the voxel is available for traversal or task execution
- *cvx:Occupied* – the voxel is currently in use or obstructed,
- *cvx:Unknown* – the voxel's state cannot be reliably determined.

This tri-state representation reflects real construction environments, where information may be incomplete or uncertain.

Data Storage

Voxel data and associated semantic annotations are persisted in an RDF triple store (e.g., GraphDB, Apache Jena, Fuseki, or Blazegraph) following Linked Building Data (LBD) modelling conventions. Voxels are represented as uniquely identified spatial entities and linked to building topology (BOT), construction processes (IOC), and machine capabilities (CSS). OWL DL axioms are used to capture class hierarchies, spatial affordances, and capability constraints, enabling lightweight semantic reasoning beyond purely syntactic SPARQL queries. SPARQL is subsequently employed for explicit selection and filtering of voxels that satisfy combined spatial, process, and resource conditions. Temporal aspects of voxel occupancy and usage are represented using time-indexed relations, allowing the semantic model to distinguish between current, planned, and historical states of the construction site.

AI-Based Reasoning

Planning Domain Definition Language (PDDL) (Haslum et al. 2019) is employed to model the current construction site state, the intended construction workflow, and the capabilities and status of the robots using the data from the CVX voxel ontology. This symbolic representation enables matching task requirements with available resources and reasoning over spatial feasibility to compute a valid task allocation. The planning output is then translated into an optimized execution schedule, which is consumed by the robot fleet manager. The fleet manager is responsible for low-level execution, including collision avoidance, navigation in dynamic environments, and handling unforeseen on-site changes. In the current implementation, this reasoning is limited to constraint extraction and does not yet include full symbolic plan generation.

Planning Methods

AI-based planning is formulated through two complementary specifications: a domain description and a problem definition. The domain captures the rules of the system, including available actions that are defined by preconditions and effects, objects, and logical predicates that represent world states. The problem specification provides the initial state and the desired goal state (Amer et al. 2021). A planning algorithm operates on both the domain and problem representations to synthesize a sequence of actions that transitions the system from the initial configuration to the goal (Sherkat et al. 2022).

Hierarchical Task Networks (HTN) is a technique that solves complex problems by decomposing high-level, abstract tasks into smaller and executable primitive actions (operators). It uses domain-specific methods to break down tasks, significantly reducing the search space for efficient planning in robotics (Höller et al. 2014). This enables the planner to exploit construction-specific structure and generate solutions that are aligned with established construction practices.

Temporal Planning methods generate action sequences while explicitly accounting for time-related constraints such as action durations, deadlines, and concurrency. These methods enable robots or other agents to (1) adhere to precedence relations such as "Action A must finish before Action B starts" or temporal requirements like "Complete Task before 3 PM", and (2) to coordinate concurrent activities if they do not conflict for optimizing resources. In this context, actions are modelled as temporally extended processes with defined start and end times, finite durations, and effects that may occur at specific time points or continuously over their execution. A combination of numeric and temporal planning can be used to model numeric changes over time, which is useful for resource management (e.g., the battery level) using planners such as OPTIC (Karpas and Magazzeni 2020). A key limitation of temporal planning is that action durations are typically modelled as estimates rather than guaranteed execution times. In real-world construction environments, the actual duration of robotic actions can deviate significantly due to factors such as environmental uncertainty, human intervention, dynamic obstacles, and resource conflicts. These discrepancies necessitate continuous execution monitoring and, when deviations exceed acceptable bounds, the ability to trigger online plan adaptation or re-planning to ensure timely and safe task completion (Staniaszek et al. 2025).

While this section introduces symbolic planning methods such as HTN decomposition and temporal planners (e.g., OPTIC), these are not fully integrated into the current

prototype. The present work focuses on the semantic voxel reasoning layer and its translation into navigation-relevant representations (e.g., costmaps) for execution within ROS2 Nav2. The described planning methods represent a higher-level extension, where the derived spatial and resource constraints can be consumed by external planning frameworks for task allocation and scheduling.

Voxelisation of the construction site to fleet management

Semantic Voxel to Navigation Representation

In the proposed framework, voxels are not treated merely as discretised geometry, but as semantic mediation units between the Linked Building Data layer and fleet-level navigation and task allocation. Each voxel is modelled as a first-class semantic individual with explicit spatial extent and temporal validity, linked to its surrounding context through LBD-aligned relations such as *bot:containsElement* and *bot:intersectsZone*. Rather than encoding navigation logic directly, voxels act as semantic carriers of affordances and constraints. Through reasoning over CVX, BOT, IOC, and CSS, voxels inherit process- and resource-dependent semantics, such as work zones, safety buffers, or machine-restricted areas, with *ioc:process* instances associated with CSS machines and robots so that voxel states are interpreted relative to the capabilities and roles of specific fleet members, rather than as globally fixed occupancy values.

This semantic enrichment allows a voxel to represent not only whether space is free or occupied, but how it may be used by whom and when. For example, the same ground voxel may be traversable for a transport robot, temporarily restricted during a lifting process, or costly under degraded 5G conditions encoded via *cvx:voxelAttribute*. The ontology is queried using SPARQL to extract voxels satisfying fleet-relevant constraints, producing a temporally indexed set of 3D semantic voxels projected into a 2D costmap. Costs are derived from aggregated semantic attributes such as process activity, machine compatibility, or non-tangible signals, making the costmap directly usable by fleet planners while remaining grounded in the ontology. A Hybrid-A* algorithm then finds paths between all feasible start and goal positions for each capable robot, with metrics such as distance, travel time, cost, and battery consumption used to optimise the plan. Task allocation and scheduling are calculated from these estimates, with each robot assigned a priority reflecting task criticality, temporal dependencies, and resource constraints to resolve conflicts in shared or congested areas. Continuous monitoring detects deviations from estimated costs or travel times, enabling dynamic re-planning while ensuring collision-free paths that respect process constraints and overall mission objectives.

Use Case

To evaluate the proposed semantic voxel-based reasoning and planning framework, we consider a representative robotic construction scenario involving a heterogeneous multi-robot team executing a logistic workflow on a construction site for transportation. The use case is designed to simulate real construction environments. Sequential process dependencies, heterogeneous robot capabilities and coordinated multi-robot actions. The scenario considers a dynamic construction site where material handling and safety monitoring are performed by a heterogeneous robotic fleet, consisting of:

- 2 Unmanned Guided Vehicles (UGVs) dedicated to material transport within the site.
- One UGV dedicated to human presence monitoring, ensuring that restricted areas remain free of personnel during automated operations.

The site is represented as a voxelised three-dimensional spatial grid, where each voxel captures semantic, temporal, and environmental properties. The voxel grid forms the basis for navigation planning, task allocation, and safety enforcement. The use case serves as a concrete demonstration of how semantic voxel layer, *cvx* enables context aware task allocation and fleet coordination beyond conventional map-based approaches. In the present prototype, fleet coordination is demonstrated at the level of shared spatial constraints, task-dependent zone reservations, and robot-specific access conditions derived from the semantic voxel model. The validation therefore emphasizes coordination support through task feasibility and time-indexed navigation representations, rather than a full experimental benchmark of decentralized or reactive multi-robot coordination behaviours.

Voxel Grid Generation

The construction site is modelled and discretised into a 3D voxel grid using a custom C# script, in which each voxel represents a bounded volumetric region of space. In addition to geometric information, the script extracts and associates semantic metadata, including building elements derived from IFC models and machine-related information. The resulting A-Box is then translated to Turtle (.ttl) format and uploaded to the triplestore. Each voxel or voxel-based zone is subsequently assigned a contextual state, including:

- Occupancy state (Free, Occupied, Unknown)
- Process allocation (reserved by planned or executing tasks)
- Environmental metadata, i.e., 5G signal strength
- Temporal validity

Voxels are generated deterministically based on grid coordinates and world-space positions, ensuring stable identifiers across different systems. Figure 2 depicts the construction model, and Figure 3 shows the construction site after voxelisation. From this voxelised spatial–temporal representation, a binary navigation map is generated by querying voxels that are semantically classified as free at a specific time instant, as illustrated in Figure 4.

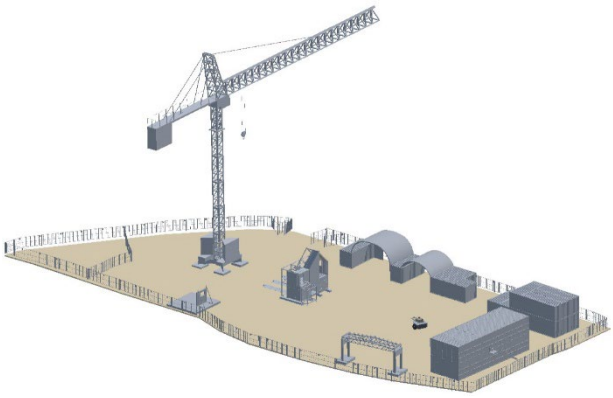

Figure 2: A model of the construction site

Figure 3: A voxelised construction site.

5G Signal Strength as a Spatial Cost Factor

A site-wide 5G signal strength map is integrated into the voxel grid as an environmental attribute. Signal strength varies spatially due to obstructions, distance to base stations, and site topology. This information is used to derive a communication-aware navigation cost map. The on-site signal strength is recorded using a Qualcomm

Figure 4: A 2D costmap queried from the knowledge graph.

SM8450 MTP (Mobile Test Platform), tested on Ericson NR Sub6 RU 3700MHz radio unit. Voxels with weak 5G coverage incur higher traversal cost. Transport UGVs prefer routes that maintain stable connectivity to ensure:

- reliable task updates
- safety monitoring
- remote intervention if required

By representing 5G signal strength as a spatially and temporally grounded attribute, the ontology enables context-aware path planning without hard-coding communication assumptions into the navigation stack. Figure 5, the top left of the figure shows a real test on the testbed using the MTP. On the right of the figure shows the distribution of the 5G signal strength. As tested in this paper (Behjati et al. 2022), it is shown that any Reference Signal Received Power (RSRP) above the value of -79dBM is able to provide a reliable connection for navigation and human observation, it is set that any signal strength less than the value of -80dBm has a high cost in the navigation map as shown in. The data is integrated into the knowledge graph and queried as voxels, the output is shown at the bottom left of Figure 5.

Robots, Capabilities, and Skills

At the semantic level, robots are modelled as resources that provide capabilities, which are realized through skills

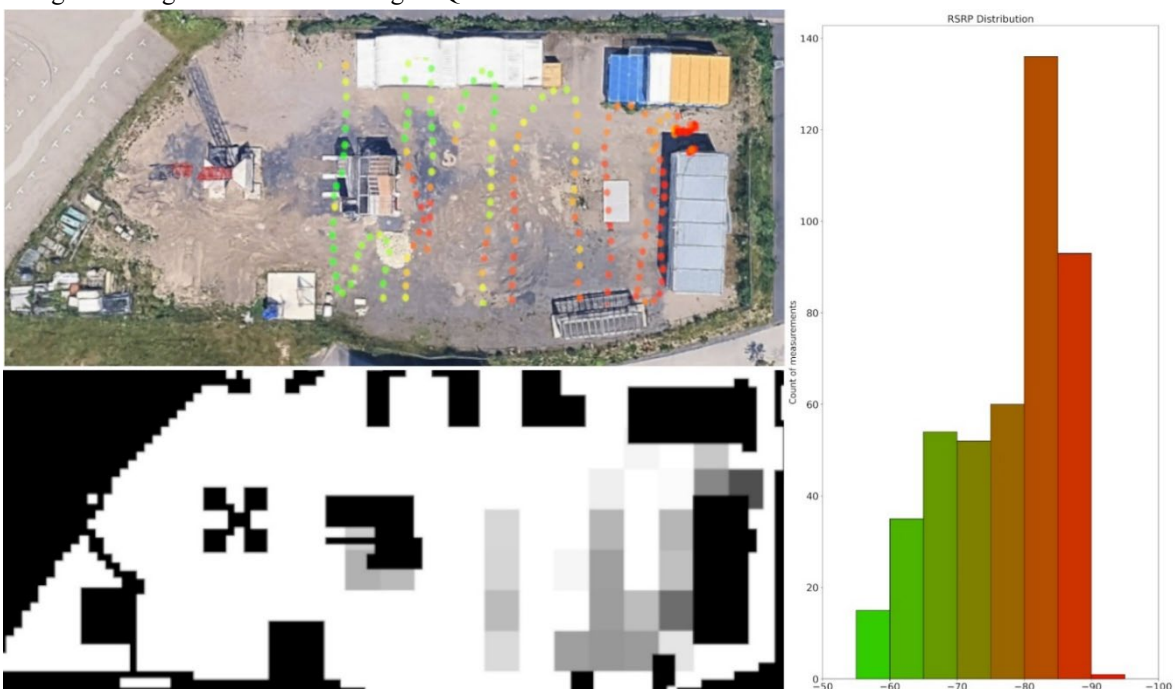

Figure 5: Top, Result of real test of the 5G signal strength on the test site. Bottom, a 2D costmap queried from the knowledge graph with 5G signal strength attribute. Right, a histogram of the data distribution.

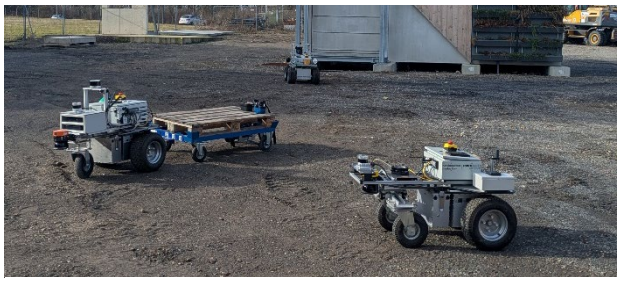

Figure 6: UGVs responsible for transport (left) and human observation

and accessed via skill interfaces. The two transport UGVs provide a Transport Capability, realised through:

- Locomotion skills (for navigation)
- Towing skills (for pallet dragging)
- Payload handling skills (for coupling and release)

The monitoring UGV provides a Safety Monitoring Capability, realised through:

- Locomotion skill (for navigation)
- Perception skill (for human detection)

enabling it to detect human presence within restricted zones. This separation allows tasks to be assigned based on capabilities, while execution selects appropriate skills depending on spatial and environmental conditions. Figure 6 shows the robots that are used for transportation and human observation. The robot on the left has a pallet that the robot can couple to and used to transport items while the robot on the right has an extra 3D LiDAR scanner and on-board computer with GPU for human detection algorithm.

Real-Time Updates and Consistency

The framework supports dynamic construction environments through incremental, event-driven updates of the semantic voxel model. Changes detected from sensors such as camera, LiDAR, or robot feedback are mapped to affected voxels, updating occupancy states, temporal validity (*cvx:hasOccupancy*), and contextual attributes without recomputing the full grid. These updates are propagated to the RDF store. The planning layer maintains consistency through triggered replanning and rolling-horizon execution, where only affected regions are reconsidered. At the execution level, the fleet manager continuously updates navigation costmaps derived from the semantic voxels, ensuring that robot behaviour remains aligned with the latest site conditions while preserving responsiveness.

Spatial-Temporal Map via contextualised working space

The proposed system maintains a spatial-temporal representation of the working space by contextualising spatial occupancy and 5G signal strength within a unified knowledge graph. Occupancy is updated from robotic perception and human-in-the-loop annotations, while communication data is integrated as a dynamic environmental layer. Unlike conventional layered costmaps, these attributes are modelled as first-class semantic entities with explicit temporal validity, enabling consistent querying of historical, current, and predicted site states.

Based on this contextualised representation, robotic task planning and execution are performed using standard frameworks such as Nav2 in ROS2. The knowledge graph acts as an intermediary semantic layer, where relevant spatial subsets are selected via SPARQL queries and lightweight semantic inference to identify regions satisfying task- and capability-specific requirements. These are then translated into navigation-compatible representations (e.g., occupancy grids or costmaps) for a given time horizon and task context, enabling capability-aware task allocation, temporal conflict avoidance, and context-aware navigation where traversal costs reflect both geometric and non-tangible factors.

Voxel-based reasoning refers to the process of evaluating semantically enriched voxels to derive planning-relevant constraints for task allocation and navigation. Each voxel encodes spatial, temporal, process, and contextual attributes, such as assigned processes, zones, machine capability requirements, occupancy state, and 5G signal strength. For example, a transport task requiring a UGV with a specific payload capacity will only be allocated to a voxel route where the associated capability constraints are satisfied, the occupancy state is unobstructed for the relevant time window, and signal strength exceeds the threshold required for teleoperation. This directly shapes both task allocation and the costmap weights used for navigation, meaning semantic voxel attributes are not merely annotations but active inputs for planning.

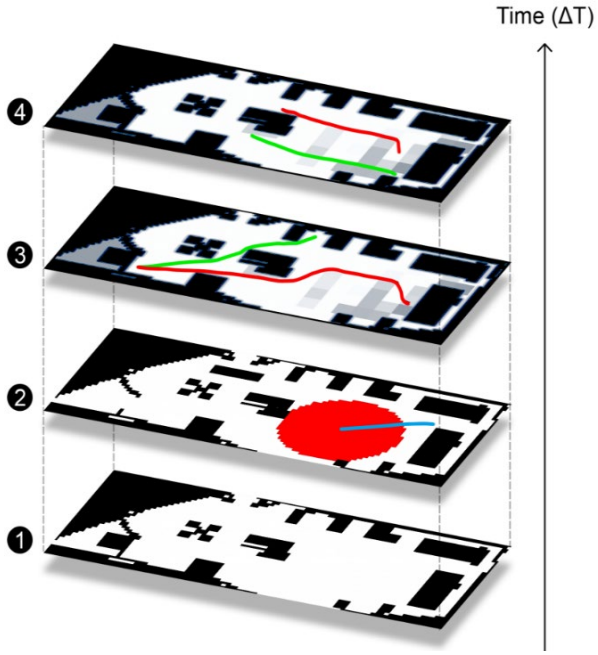

Figure 7: A voxel-based costmap for navigation queried from the knowledge graph at discrete time instance for initial navigation (1), human observation (2) and multiple and parallel processes (3,4).

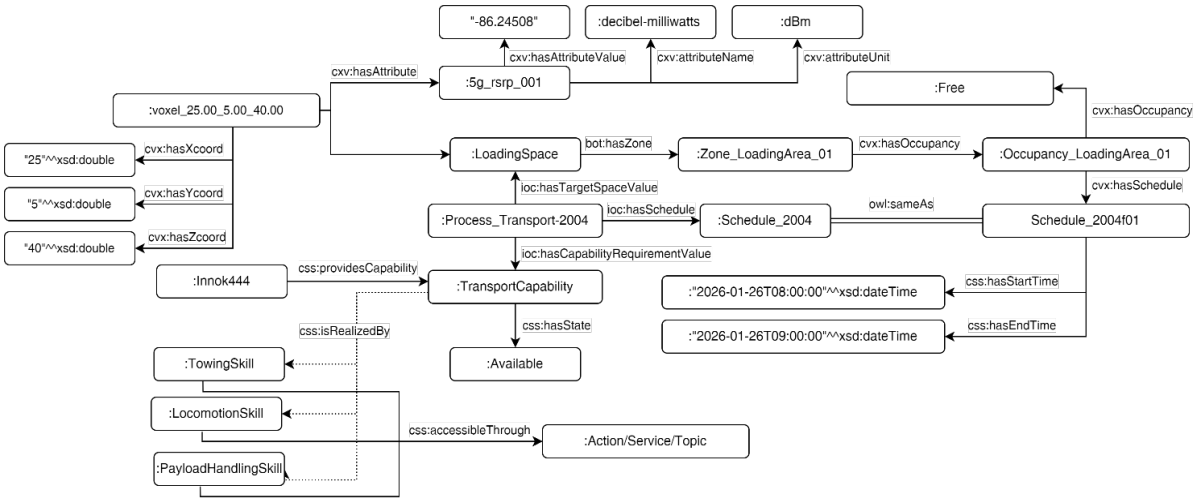

Figure 8: A excerpt of the instantiated voxel, linked to process, zones and machine capabilities.

As tasks are executed, routes, execution states, and temporal dependencies are written back into the knowledge graph, closing the perception–planning–execution loop. This supports continuous refinement of the spatial-temporal model and coordination among multiple agents operating in the same environment.

Figure 7 illustrates snapshots of navigation maps at different time periods. Map 1 shows a conventional binary occupancy map, while Map 2 incorporates human observation zones and a UGV navigation path. Maps 3 and 4 include 5G signal strength with two UGVs assigned transport tasks at different time intervals, where the planner avoids low-signal regions. While the resulting maps resemble layered costmaps (Lu et al. 2014), the key distinction is that this framework generates time-indexed spatial representations, rather than aggregating layers into a single static grid. Figure 8 shows an instance of a voxel linked to an IOC process and BOT zone, with the process associated with CSS-defined machine capabilities.

Conclusion

This paper presents an initial concept for a semantic, spatial-temporal framework for contextualising robotic working spaces in dynamic construction environments. By integrating occupancy states, task semantics, and attributes into a knowledge graph, the proposed approach enables robots to reason over space not only as a geometric entity but as a temporally evolving and context-dependent resource. This allows navigation and transport planning to move beyond static map assumptions and towards situation-aware decision-making.

The contextualised working space acts as a semantic intermediary between perception, planning, and execution. Standard robotic navigation stacks, such as Nav2 in ROS 2, can be leveraged without modification by exporting task- and time-specific spatial representations derived from the knowledge graph. In parallel, execution feedback and transport process updates are written back into the graph, enabling continuous synchronisation between the physical site and its digital representation. This bidirectional coupling supports coordination among heterogeneous agents, including UGVs and human observers, within a shared operational model. However, the current implementation focuses on generating semantically grounded constraints and navigation representations, while full integration with symbolic planning methods such as HTN or temporal planners (e.g., OPTIC) remains part of future work.

By treating spatial regions as first-class semantic entities rather than passive costmap layers, the framework supports traceability, explainability, and extensibility across planning horizons and task types, providing a foundation for planning under real-world constraints common to construction sites, such as dynamic obstacles, intermittent connectivity, and human presence.

Future Works

As a first approach, the proposed framework establishes the groundwork for a structured research roadmap. The following directions outline the planned extensions to mature the system toward real-world deployment. Several extensions can be pursued to further enhance the proposed spatial-temporal framework and broaden its applicability in real-world construction environments.

First, the framework can be extended through formal integration with symbolic planning models, such as Hierarchical Task Networks (HTN) and classical PDDL. Spatial-temporal regions represented in the knowledge graph can be abstracted into planning predicates, enabling high-level task decomposition and constraint-aware reasoning. HTN models are particularly promising for representing construction workflows, where transport, assembly, and inspection tasks follow structured yet adaptable procedures. Such an integration would allow semantic spatial constraints and communication conditions to directly influence task planning and execution at the symbolic level.

Second, the 3D nature of the voxel representation can be further exploited beyond conventional 2D costmap applications. Extending the framework to full 3D spatial–temporal planning would enable coordination of heterogeneous platforms operating across multiple elevation layers, including quadrupedal mobile robots capable of stair traversal, automated cranes transporting materials across building stories, and aerial robots operating in the airspace above the site.

Third, with sufficient data, learning-based occupancy prediction becomes feasible. Graph Neural Networks (GNNs) can be leveraged to model spatial-temporal dependencies between adjacent regions, robotic activities, and construction processes. By conditioning predictions on process states and task progress, the system could anticipate future occupancy changes and proactively adjust navigation and scheduling strategies. This would shift the framework from reactive planning towards predictive and anticipatory behaviour.

Finally, the proposed approach can be generalised into a knowledge-driven AI fleet management framework. By unifying semantic spatial representations, communication context, task models, and execution feedback, the system can serve as a coordination layer for heterogeneous robotic fleets. Such a framework would support dynamic task and resource allocation, and human-robot coexistence across large-scale sites, positioning the knowledge graph as the central decision backbone for adaptive, multi-agent construction robotics. Future evaluation would include explicit multi-robot coordination experiments, such as shared corridor negotiation, synchronized task execution, and conflict resolution in overlapping work zones, to quantify the impact of semantic voxel framework on coordination performance.

STRUCTURAL HEALTH MONITORING OF BRIDGES: INTEGRATING OPENBIM, GIS, AND IOT IN THE BREGANZE BRIDGE CASE STUDY

Idriss Tchaheu Tchaheu ,Francesca da Porto ,Andrea Gennaro, Giorgia Marcellino, Carlo Zanchetta
University of Padua, Italy

Abstract

Current bridge Structural Health Monitoring (SHM) workflows suffer from semantic disconnection, missing metadata validation, and inefficient model-updating. Addressing these deficiencies, this paper introduces a cloud-based platform. The developed workflow uses Information Delivery Specifications (IDS) for metadata integrity, nests sensors and hosts via IfcElementAssembly and IFC model updates using IfcOpenShell. Validated through the Breganze Bridge case study, the platform enables 3D model visualization, sensors measurements plots and threshold-based alerting. The lasting contribution is an OpenBIM SHM framework that integrates metadata validation, sensor-host linking, and threshold evaluation, bypassing proprietary lock-in and the dual-database integration step from model updating workflows.

Introduction

Bridges increasingly require structural health monitoring (SHM) to ensure their safety, operational performance, and long term reliability, particularly as they age and are exposed to growing load demands(Sun et al., 2025). The Architecture, Engineering, and Construction (AEC) industry has seen the widespread adoption of Building Information Modeling(Panah & Kioumarsi, 2021), with recent studies successfully demonstrating the integration of BIM and SHM by using 3D models for sensor placement and data visualization(Biagini et al., 2023; Huang et al., 2024; Li et al., 2022).

However, these BIM-SHM studies prioritize 3D geometric representation without verifying that the model and sensors contain the necessary metadata (properties, materials). Furthermore, although sensors are installed in close physical proximity to structural elements, they remain semantically disconnected entities within the BIM model, lacking formal relationships. Existing workflows typically plot database values without updating the sensor elements in the BIM model itself. Few studies have addressed model updating. Huang et al. (2024) demonstrated updates within Revit using Dynamo, while Marcellino et al. (2025) proposed IFC-based workflow with dual-database integration and file regeneration that may constrain performance for high-frequency updates (e.g., intervals shorter than one hour), requiring appropriate optimization strategies.

This work investigates the development of a cloud-based platform for Structural Health Monitoring of bridges, validated through a real-world case study of the Breganze bridge. The core contribution is a methodology with four integrated components. First, the integration of Information Delivery Specification (IDS) to validate BIM model metadata integrity before integration. Second, semantically nests sensor instances within their host structural elements using IfcElementAssembly, establishing explicit machine-readable relationships that transform sensors from isolated objects into integral components of the monitored structure thereby enabling automated queries and contextual interpretation of monitored elements. Third, updating the IFC model by directly querying the sensor database and modifying the IFC file using IfcOpenShell, thereby overcoming the proprietary lock-in of Revit-dependent workflows and bypassing the dual-database integration and IFC model regeneration step required by prior work. Finaly, visualizes the enriched model and sensor data in a cloud-based platform with BIM-GIS-IoT integration, where users can access the spatial context of the bridge model within the GIS MapLibre open-source interface and switch to other interfaces to interact with the 3D BIM model and visualize sensor measurements enabling to understand and evaluate localized structural element behavior such as displacement and tilt angles as well as environmental conditions including water level, relative humidity, and temperature.

The structure of this paper is as follows: a literature review on SHM, BIM-SHM integration, and BIM-GIS integration for SHM; followed by a description of the adopted methodology; then the presentation of the applied project case study; and finally, the conclusion.

Literature Review

Structural Health Monitoring (SHM)

Structural health monitoring (SHM) is defined as the process of implementing an autonomous damage detection strategy for aerospace, civil, and mechanical engineering infrastructure. It involves the installation of sensors, at key locations along the structure. These sensors monitor a range of variables, including loads, strains, displacements, accelerations, temperatures, and chemical composition of concrete and steel (Figueiredo et al., 2013). SHM has been extensively applied in several

engineering fields to track, identify and measure the responses of structures (Gharehbaghi et al., 2022).

Evolution from Traditional BMS to BIM-Based Monitoring

Despite the availability of monitoring technologies, traditional Bridge Management Systems (BMS) often lack 3D geometric representation and rely on manual data entry (Buuveibaatar et al., 2025). Recent studies suggest that the integration of BIM and SHM provide more sophisticated capabilities for bridge health monitoring addressing the limitations of conventional SHM approaches(Angelosanti et al., 2023; Huang et al., 2024).

Panah and Kioumarsi (2021) highlighted how BIM facilitates SHM by making sensor data accessible, practical, and comprehensible, offering improved means of visualization, interpretation, and documentation. Furthermore, having a 3D model is recognized as essential for BIM-SHM integration. For existing infrastructure, many studies rely on the Scan-to-BIM approach to recreate accurate digital representation for integration with SHM(Biagini et al., 2023; Fawad et al., 2025). As Huang et al. (2024) demonstrated, a 3D virtual model aligned with physical sensors enables precise sensor integration and allows for the colored visualization of strain distribution and residual fatigue life directly within the BIM environment, facilitating a deeper understanding of local bridge component behavior.

However, early implementations of BIM-SHM integration often relied on proprietary formats to build either desktop or web-based platforms. For instance, Li et al.(2022) proposed a BIM-SHM workflow centered on the 3D Revit model as a visual reference, where sensor data from the bridge is managed through a SQL Server database. A Revit plugin developed in C# allow users to view real-time measurement plots in conjunction with the 3D model, rather than updating the model geometry itself. Similarly, Fawad et al. (2023) developed a cloud-based IoT platform for bridge SHM that used a 3D Revit model, where clicking on the represented sensor objects enables access to real-time visualization dashboards for strain, temperature, and acceleration data. Expanding upon previous approaches toward model updating, Huang et al. (2024) employed a methodology utilizing a 3D Revit model, a MySQL database, and MATLAB for processing sensor data. In this framework, Dynamo was used not only to display measurement plots but also to update the instance parameters of sensor elements in Revit with real-time strain and residual fatigue values, ensuring the 3D model remained synchronized with the physical structure. While these studies demonstrate BIM-SHM integration with some plotting measurements and one going beyond to update the model they all share the limitation of relying on proprietary data formats. This dependency creates software lock-in and presents challenges for interoperability.

Among the open standards that support vendor-neutral interoperability across the Architecture, Engineering and Construction (AEC) industry, the sector relies primarily on the Industry Foundation Classes (IFC) standard used to represent both geometry and semantic data. Originally developed with a focus on buildings, the schema has evolved to integrate infrastructure domains as well. This evolution is reflected in the IFC 4.3.2 release published in 2023 by buildingSMART International, which introduces several bridge types and their associated structural elements (Teixeira et al., 2024). In 2024, IFC 4.3 became officially ISO 16739-1:2024. Despite the international recognition and widespread adoption, recent research highlights limitations of IFC bridge applications. Teixeira et al. (2024) point out that many commercial structural analysis software tools still lack full support for importing IFC bridge models; to prevent data loss, they propose a dedicated tool for interpreting bridge element semantics, geometry, and material properties. Additionally, Nakamura et al. (2025)observe that IFC does not currently provide schemas for maintenance and inspection information essential for bridge management. Lee et al.(2025) further notes that the IFC schema lacks definitions for the entities and property sets needed to integrate national design standards, as in the case of elements such as joints and approach slabs particularly common in Korean bridges, leading to the definition of custom extensions to meet local infrastructure requirements. Alongside these limitations in IFC bridge applications, the IFC schema also fails to represent the overall sensor network of an SHM system. Smarsly & Tauscher (2015) noted that while basic sensor types can be mapped, monitoring-related information such as the configuration, interaction protocols, and network topologies of sensors cannot be formally described using standard IFC entities. To address this gap, they proposed a conceptual approach for extending the IFC object model for semantic modeling of monitoring-related information. Building on this work, Theiler & Smarsly(2018) proposed the IFC Monitor schema extension, which defines dedicated entities for sensor nodes, sensor networks, and SHM systems, along with an enumeration for network topology. Their extension demonstrates that IFC can be expanded to represent not only individual sensors but also the topological structure of sensor networks. However, despite this advancement, the validation of the IFC Monitor remains limited on a laboratory-scale prototype of a shear frame structure, rather than a real building or infrastructure asset.

BIM-GIS Integration for SHM

While BIM-based SHM approaches have demonstrated advantages in visualizing and managing sensor data, their limitation lies in the lack of geographical context. As Bjelotomić Oršulić et al. (2024) argue, the integration of GIS and BIM is becoming increasingly important for the digitalization of the built environment. In the context of infrastructure monitoring, Gao et al. (2024) highlight that GIS integration into a digital platform allows operators to examine a structural element in the BIM model while simultaneously assessing its spatial context through the GIS interface. This spatial awareness is important for effective SHM.

Malekloo et al. (2020) conducted a comparative analysis of standalone GIS, standalone SHM, and integrated SHM-GIS approaches across multiple criteria, including structural damage assessment, spatial analysis, database management, decision-making, risk assessment, scalability, and cost. They demonstrated that while GIS alone lacks structural damage assessment capabilities and SHM alone lacks spatial analysis, their integration unifies all evaluated functionalities into a single, comprehensive framework for bridge management.

Methodology

The proposed methodology integrates IFC model, GIS, and sensors into a unified web-based platform for bridge SHM. While lightweight formats such as JSON offer advantages for web-based data integration over IFC files and have been used successfully used for BIM-IoT integration(Chatsuwan et al., 2025), few research work rely on IFC.JSON. Moreover, converting the original IFC-STP to IFC.JSON adds an additional step to the workflow and potential semantic loss. Therefore, IFC is adopted as the data backbone throughout the entire workflow.

The workflow comprises four sequential main stages as illustrated through the IDEF0 process map in Figure 1. The First stage consists of the definition of information requirements and model production, where both human-readable and machine-readable information requirements are defined using the Information Delivery Specification (IDS) standard. These specifications formally declare which properties and attributes must be present in the

BIM model to support SHM integration. With the human readable specification, a digital representation of the bridge, including its sensor instances, is developed in Revit and exported to IFC4.3 the most recent open standard for infrastructure data exchange.

Following the model production, the second stage involves the model validation and semantic enrichment. The exported IFC model is validated against the machine-readable specification using the IFCTester tool within BonsaiBIM. If validation fails, the tool displays the non-compliant elements and properties. Corrections are made either by directly editing the properties in BonsaiBIM and saving the IFC model, or by returning to Revit to adjust the model, re-exporting it to IFC, and re-running the validation. This iterative process continues until the model successfully passes the compliance check. After model validation, semantic enrichment is performed to establish explicit, relationships between sensors and their host structural elements. Addressing the lack of explicit sensor-host relationships in the current IFC 4.3 schema, this methodology adopts IfcElementAssembly as a pragmatic modeling pattern to nest sensors within their structural hosts, enabling meaningful machine-readable relationships and automated queries. To achieve the semantic nesting, a custom metadata property is attached to each host element, declaring which sensor instances belong to it. A script then parses this metadata, matches sensors to their respective hosts. The resulting assembly preserves the spatial context of the host element while linking sensors as integral components of the monitored element.

Moving to third stage of the methodology, the database system adopted to store the sensors is a relational database implemented on MySQL. Having the static IFC model and sensor values stored in the database, the model is updated with significant sensor readings using a MySQL python connector in conjunction with IfcOpenShell. Embedding important sensor readings into

the IFC model within each IfcSensor instance generates a temporally consistent view of the element status over a specific period of time. This allows users to select a sensor in the 3D model, inspect its properties, and assess localized element behavior or environmental conditions without reviewing the measurement plots.

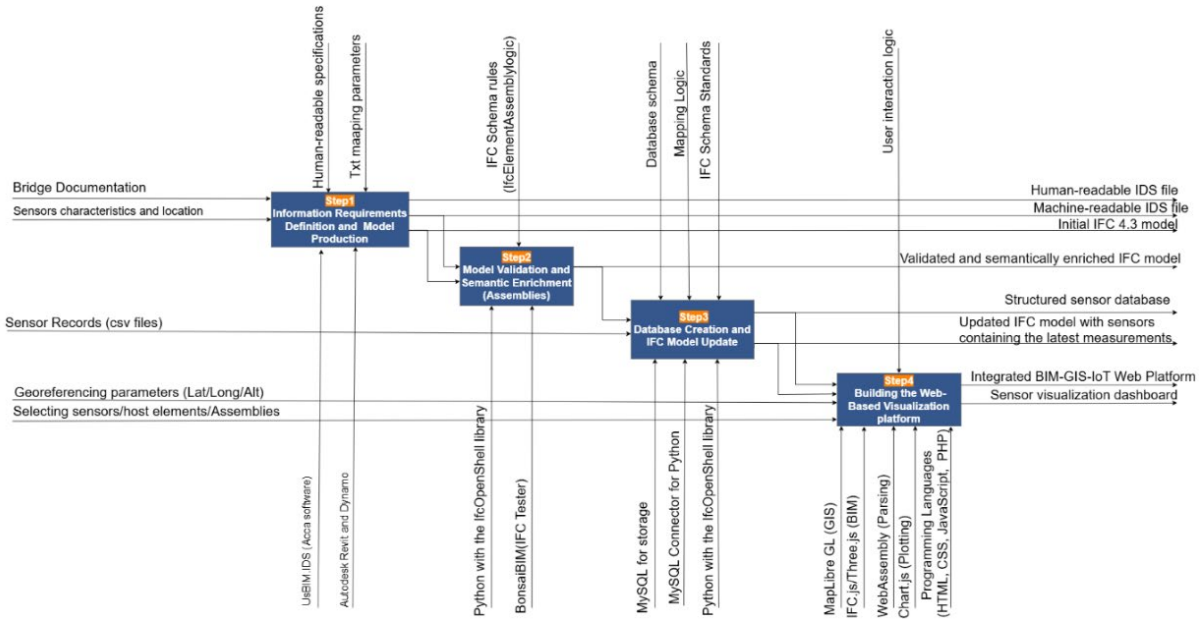

Figure 1:Process map of the methodology adopted

Finally, a web platform is developed to enable the integration of GIS, IFC model, and sensors following a three-tier client-server architecture. The architecture is structured into three distinct layers, the frontend layer serves as the client-side interface for user interaction and visualization; the backend layer manages server-side processing and the logic required for data retrieval; and the database layer provides the environment for data storage and management.

Result and Discussion

Case Study Context and Model Validation

The project case study is a reinforced concrete arched bridge. Various sensor types are installed at different locations on the bridge, including accelerometers, potentiometers, inclinometers, temperature sensors, water level sensor, and thermohydrometer. Prior to bridge model production, the human and machine-readable specifications was defined using the Information Delivery Specification (IDS) standard through the usBIM.IDS tool. Figure 2 illustrates the human-readable requirements defined for the accelerometers sensor metadata.

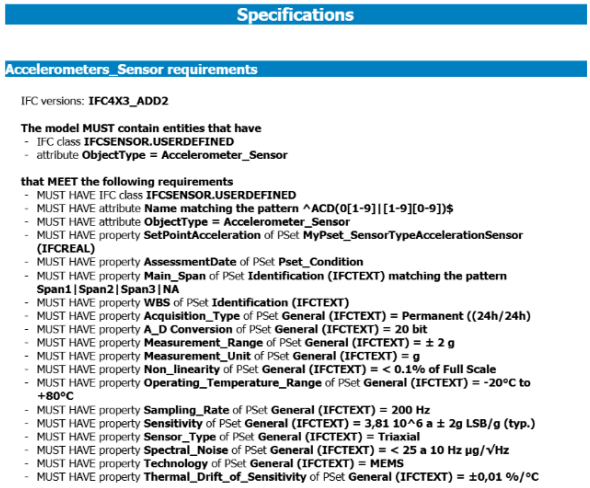

Figure 2: Human-readable requirements defined for the accelerometer sensor metadata

Following the information requirements definition, the 3D bridge model including sensors and metadata from the human-readable specification was created in Revit then exported to IFC4.3, and audited against the machine-readable requirements using IFCTester in BonsaiBIM. Figure 3 presents the validation outcome for the accelerometer sensors. The results demonstrate that the model successfully passed all compliance checks, thereby verifying that the sensors correctly adhere to the defined information requirements.

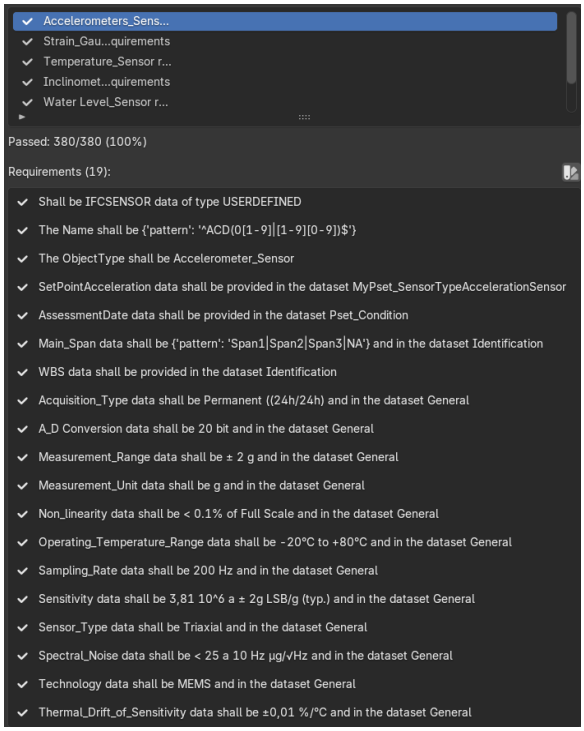

Figure 3: Human-readable requirements defined for the accelerometer sensor metadata

Semantic Linking

Following the successful validation of the model, the next step is to aggregate sensor elements with their hosts under IfcElementAssembly. An initial inspection of the IFC model within widely used BIM viewers, such as BIM Vision and BIMcollab Zoom, confirms that the physical and hierarchical relationships between the host elements and their associated sensors are not natively reflected.

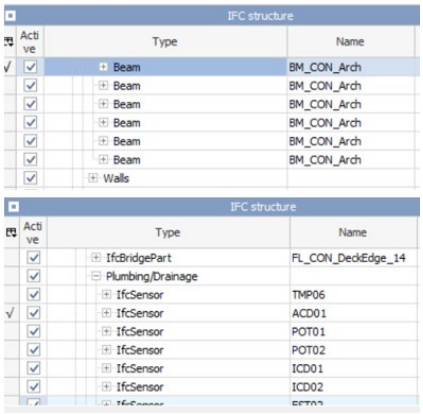

Figure 4:Beams and sensors elements hierarchical representation

Figure 4 displays the default spatial-tree representation, where beams and sensors appear as separate groups without any explicit semantic linkage. To address this, the adopted approach relies on metadata added to each host element to identify which sensors must be grouped with that specific element. This information is provided through the property “Sensors_Instances_Hosted” within the “Data” propertyset of the host element, as illustrated in Figure 5.

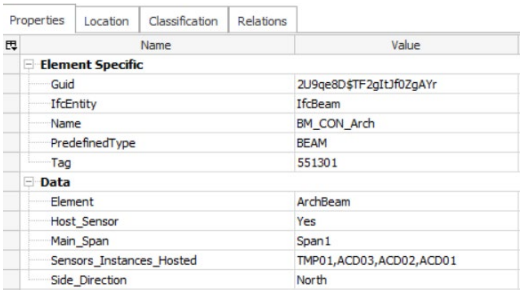

Figure 5:Identification of "Sensors_Instance_Hosted" property to establish linkage between sensors and their host

The overall workflow adopted to aggregate sensors to their host using IfcOpenShell library is illustrated in Figure 6.

Figure 6:Workflow to semantically link sensors and host element

The entities of the IFC model are iterated, and sensors and potential hosts are categorized into two groups. All IfcSensor entities are indexed by their Name attribute and Globally Unique Identifier (GUID) and stored in a dictionary. Then, during the matching phase, a list of candidate host entities is iterated, and retrieve the value of the custom property "Sensors_Instances_Hosted". This value is parsed into a list of unique identifiers, each cross-referenced against the sensor index to map each sensor directly to its specific host element. Finally, the matched elements (host element and its corresponding sensors) are aggregated into an IfcElementAssembly.The developed script successfully establishes a semantic link between sensors and their host. The result demonstrates interoperability compatibility across different BIM viewers, as shown in Figure 7 (BIM Vision) and Figure 8 (BIMcollab Zoom), where sensors (ACD01, ACD02, ACD03, TMP01) and their host element (BM_CON_Arch) are now grouped together under the assembly (BM_CON_Arch_ASB_12).

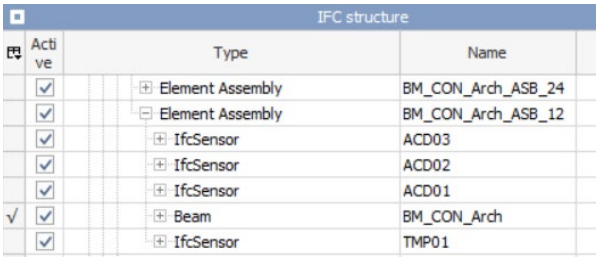

Figure 7:Resulting IfcElementAssembly of a beam element with sensors within BIM vision

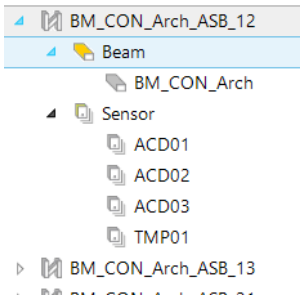

Figure 8:Resulting IfcElementAssembly of a beam element with sensors within BIMcollab Zoom

Database and Model Updating

The relational database designed on MySQL for storing sensor data is illustrated by the entity-relationship model represented in Figure 9.

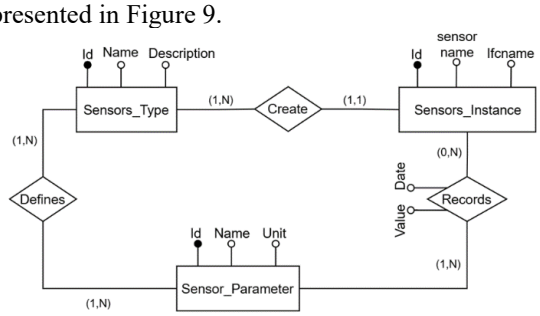

Figure 9:Entity relation model for the sensors database

The data model is organized around three core entities: Sensor_Type, representing the device category; Sensor_Instance, representing the specific physical devices installed on the structure; and Sensor_Parameter, which defines the measured physical quantities. Additionally, the "Records" relationship functions as a transactional entity, storing time-series measurements for each sensor instance

Regarding the IFC model update of IfcSensor instances with significant readings, they are updated with the latest, minimum, and maximum values over the synchronization interval, along with their respective timestamps. The workflow adopted to perform the operation is illustrated in Figure 10.

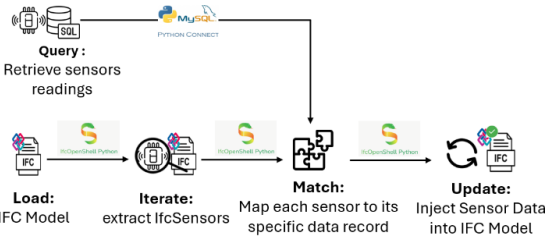

Figure 10:Workflow to update the IFC model with sensor reading

The script developed using IfcOpenShell performs the update as follows. First, the script queries the database to retrieve the values from the appropriate tables. Next, loads the IFC model and iterates through its entities to extract all IfcSensor elements.

During the matching and update phase, the script maps each sensor name from the database to the corresponding IfcName of the sensor within the model. Finally, the model update is performed by injecting the new measurement values and timestamps into the specific IfcProperty fields. The synchronization interval is one hour. Values are overwritten with each update and historical data is not retained within the IFC file. Instead, the complete time-series history is stored in the relational database. Identical IFC sensors that do not receive new sensor data are bypassed and remain untouched. The implementation of this approach is highlighted at Figure 11 and Figure 12, where Figure 11 presents the initial state of a potentiometer sensor (POT01) with default displacement value.

Web Platform

To make the enriched model accessible, a three-tier web platform was developed as illustrated in Figure 13.

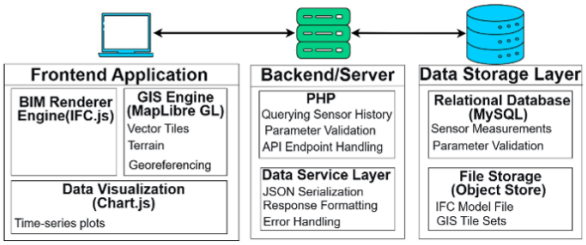

Figure 13:Updated property of the POT01 sensor

The architecture utilizes a MySQL database for data storage, a PHP backend for data processing, and a JavaScript-based frontend. To achieve BIM-GIS-IoT integration, the user interface leverages MapLibre for geospatial rendering, IFC.js for native 3D BIM interaction, and Chart.js for plotting sensor measurements Figure 14 illustrate the bridge model within the GIS context.

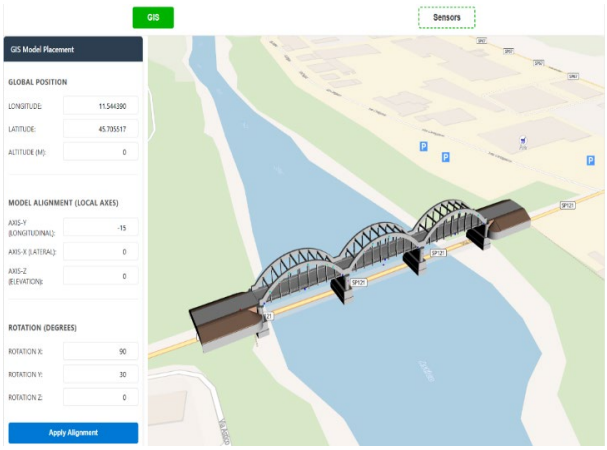

Figure 14:Bridge model into the GIS context

The sensor management interface provides 3D visualization, visibility filtering and element property inspection. Additionally, by interacting with the bridge geometry, users can retrieve measurement data; double-clicking a specific sensor or host element automatically generates the corresponding measurement plots for detailed analysis, as illustrated in Figure 15 for the case of an inclinometer being double-clicked.

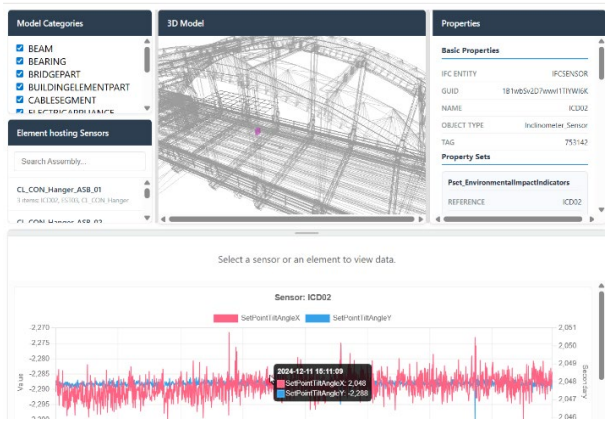

Figure 15:Data plot of an inclinometer measurements by double clicking on the sensor in the 3D model

Similarly, the list of host elements and their semantically nested sensors under IfcElementAssembly is provided in a dedicated window. Selecting an assembly automatically highlights the host element and displays plots for all associated sensors.

Furthermore, a threshold evaluation system was developed for static measurements to visually identify structural host elements exceeding predefined limits within a specified timeframe. Figure 16 shows the 3D model where host elements below the limit appear in green, while those above the threshold are highlighted in red

Figure 16:Threshold-based highlighting of bridge elements in the 3D model

The threshold manager dashboard illustrated in Figure 17 allows users to input threshold values and timeframes, displaying which inclinometer sensors that exceed or remain below the five-degrees limit.

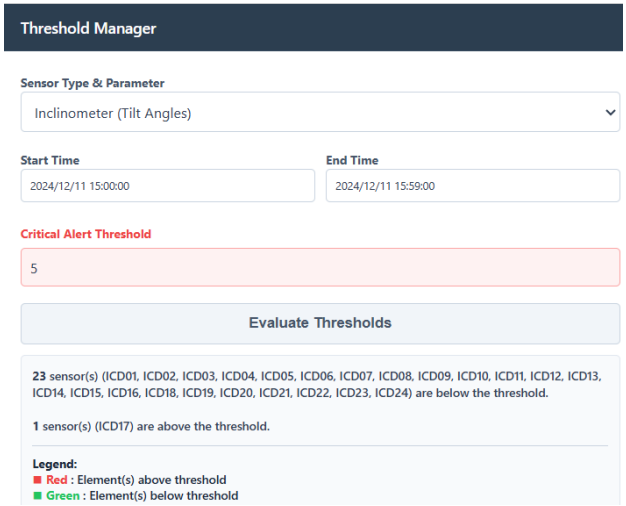

Figure 17:Threshold Manager showing inclinometer sensors above and below the critical limit

Conclusion

This study addressed critical needs identified in both literature and practice by implementing a web-based platform that integrates BIM, GIS, and IoT sensors for bridge monitoring. The platform integrates model checking using Information Delivery Specifications (IDS) to ensure data quality prior to integration. Furthermore, the use of the existing IfcElementAssembly entity links sensors with their host elements, enabling meaningful, machine-readable relationships that support automated querying. The proposed workflow also eliminates the reliance on proprietary data formats and dual-database synchronization for the model updating of IfcSensor instances. By injecting significant measurement values directly into the sensors, generates a temporally consistent view of the host element or environment status over a specific period. This allows users to select a sensor in the 3D model, inspect its properties directly without needing to review a separate measurement plots window. In addition, visualizing the bridge model within the GIS environment provides essential spatial context, while the sensor management interface allows users to interact with the 3D model and plot sensor measurements for detailed analysis. The platform enables the evaluation of both localized element behavior such as displacement tracked via potentiometers and tilt angle measured by inclinometers on specific structural elements and contextual environmental conditions, including relative humidity, temperature, and water levels. Additionally, a threshold-based alert system automatically highlights host elements in the 3D model when sensor readings exceed predefined limits, providing intuitive visual warnings. Nevertheless, some limitations must be noted. Because the semantic linking relies on exact metadata matching, the process can fail if sensor names are missing or incorrect. Future studies could therefore incorporate spatial collision detection algorithms to link sensors to elements based purely on their physical 3D location. Furthermore, while direct static sensor measurements provide a good understanding of localized element behavior, the global structural assessment remains incomplete, future research could integrate experimental data from Operational Modal Analysis (e.g., natural frequencies and mode shapes) with numerical FEM data to evaluate global structural behavior. Despite these current limitations, the proposed workflow provides a highly reliable, open-standard foundation for bridge SHM leveraging openBIM.

Acknowledgments

This work was conducted as part of the Indice Project, Task 2.3, Deliverable 2.3.1, focused on defining Digital Twin solution based on openBIM and IoT protocols. Gratitude is expressed to the BIM team of ITS Engineering Company for their support.

Abstract

Building operations account for major global energy use, yet decarbonisation is hindered by fragmented data silos. This paper presents a utility-aware knowledge graph developed for multi-scale residential energy modelling. By leveraging Linked Data principles and the DDIM server, the framework integrates building-level performance data with national electricity distribution networks. Using Ireland as a case study, the methodology semantically associates 2.3 million residences with over 46,000 low-voltage transformers through a novel enrichment process. This scalable approach enables planners to perform complex queries for grid capacity analysis, bridging the gap between individual building physics and urban-scale energy simulation.

Introduction

Building operations accounted for 30% of global energy consumption in 2021 (Skillington et al., 2022; Bacheva and Raposo Grau, 2025). Ireland, like many countries, is on-track to miss decarbonisation goals, a potential significant cost to the exchequer (Environmental Protection Agency, 2025). Ireland is also suffering a housing crisis, with development of residential stock failing to meet demand (Social Justice Ireland, 2025). Infrastructure problems, such as insufficient electricity supply capacity, are a contributing factor to both of these issues (Irish Academy of Engineering, 2025). Data-driven decisions are now vital to address the issues of global warming, building comfort and stock availability (Skillington et al., 2022). By fusing various information sources, such as building data, energy infrastructure and population data, and applying Machine Learning (ML), planners can perform sophisticated analyses, to identify energy performance trends and optimize large-scale carbon reduction strategies (Ali et al., 2021a).

Access to accurate information is of fundamental importance to all stakeholders in this process, including planners and policy makers (Madnick et al., 2009). The information that must be managed is, however, complex and heterogeneous, both in content and organization (Bonilla et al., 2019). Information sources are dynamic, evolving, and multifaceted; information can be distributed across multiple sources providing related, yet heterogeneous collections of data that inform utility companies, planners and other stakeholders (Boddy et al., 2007). National and district level views of the same entities are managed by separate formats and systems, requiring expensive data reorganization in order to extract relevant information for planners and policy makers (Swan and Ugursal, 2009; Nacht et al., 2023). Together these issues describe rich, timely data sources whose utility is diminished by their disjointed and heterogeneous nature. This work presents an approach that seeks to overcome these difficulties and increases the value of data by integrating diverse sources into a homogeneous data source that can be extended to include new sources as they become available (Li et al., 2019).

Several advances have enabled solutions to these problems. Linked data provides a mechanism to interlink disparate datasources and interrogate them using semantic queries - that is queries that are of associative and contextual nature (Li et al., 2019). Linked data allows all relationships in a datastore to be explicitly defined. This facilitates the development of flexible queries, and admits reasoning about both data and their relationships (Ngomo et al., 2014). Linked data also permits the integration and exchange of data from a variety of sources and domains (Consoli et al., 2017). Digital twins for multi-scale energy modelling integrate Linked Data and ML to bridge the gap between building-level physics and urban-scale dynamics. Linked Data, utilizing RDF and ontologies, provides a semantic framework to unify heterogeneous data sources, such as IoT sensors, GIS, and weather APIs, ensuring interoperability across scales. Meanwhile, ML models accelerate simulations by acting as surrogate models for complex thermodynamic equations. By training on historical and real-time semantic data, these twins enable predictive analytics for grid stability and demand response. This synergy allows for a "glass-box" approach where data remains structured and searchable, while ML provides the computational power to optimize energy distribution in complex, multi-layered environments (Santos et al., 2025).

This research paper details the creation of a utility-aware knowledge graph designed to improve multi-scale energy modelling within the built environment. By utilizing Linked Data principles, the authors successfully integrate fragmented datasets involving building characteristics, population statistics, and electrical grid infrastructure. The study specifically demonstrates this approach

in Ireland, connecting millions of residential properties to their nearest low-voltage transformers to create a unified view of energy demand. This framework addresses the problem of functional silos by allowing planners to perform sophisticated, data-driven analyses of decarbonisation strategies and grid capacity. Ultimately, the methodology provides a scalable solution for integrating heterogeneous information sources to support sustainable urban planning across different jurisdictions.

The paper is organized as follows. First, the background explores functional silos in the energy modelling domain and the application of Linked Data and standardized ontologies. The methodology then details the development of the utility-aware knowledge graph, focusing on the core context and the DDIM server used for managing data fusion. A central component describes the enrichment process that semantically links building assets to low-voltage electricity distribution networks. The results section examines the national-scale graph generated using Irish datasets, including GeoDirectory and ESB Networks. The study's capabilities are then validated through competency questions that demonstrate sophisticated reasoning. Finally, the paper discusses the methodology's global scalability before concluding with future research directions.

Background

Multi-scale residential energy-modelling is significantly hindered by functional silos, which are compartmentalised operating units isolated from their environment (Ahmad et al., 2018; Ali et al., 2021b). These silos result in horizontal fragmentation between project disciplines and vertical fragmentation between individual building and district-scale representations (Ali et al., 2024; Balaji et al., 2016). Data integration remains a vexing problem because building information is complex, dynamic, and distributed across multifaceted sources in incompatible formats (He et al., 2023). Planners frequently encounter data inconsistencies and a lack of standard building identifiers, leading to property discrepancies across datasets (Hoare et al., 2022; Pauwels et al., 2017). Access to high-quality energy data is further restricted by privacy and protection policies, which may exclude critical information or compromise its quality through anonymisation (Pritoni et al., 2021; Rasmussen et al., 2021). These hurdles necessitate tedious manual data reorganisation and collection efforts that are both time-consuming and costly (Sood et al., 2023; Tardioli et al., 2017). Consequently, these integration issues create a persistent gap between detailed building energy modelling and traditional urban planning practices (Wang et al., 2024; Wu et al., 2024).

Linked Data principles address the persistent challenge in multi-scale residential energy-modelling of functional silos by providing a mechanism to interlink disparate, heterogeneous data sources into a unified "Web of Data" (Pauwels et al., 2017; Hoare et al., 2022). By utilizing the Resource Description Framework (RDF) and unique Uniform Identifiers (URIs), this approach admits semantic queries of an associative and contextual nature, allowing all relationships in a datastore to be explicitly defined (Hoare et al., 2022; Bizer et al., 2009).

The sector has operationalized this through standardized ontologies:

- BOT provides a lightweight core for building topology (Rasmussen et al., 2021).
- Brick standardizes building automation metadata (Balaji et al., 2016).
- SAREF enables interoperability among smart appliances (Daniele et al., 2015).

A significant practical application is the use of federated SPARQL queries to integrate Ireland's national transmission grid data with residential housing stock archetypes (Hoare et al., 2022). This allows for utility-aware, multi-scale reasoning where data owners maintain local control while planners perform national-level scenario exploration for decarbonisation (Hoare et al., 2022).

Utility information in Linked Data is represented through specialized ontologies that bridge the gap between building-level assets and national infrastructure (Hoare et al., 2022). While standard building schemas like Brick often lack grid-specific concepts (He et al., 2023), extensions such as `SARGON` incorporate electrical grid automation by mapping CIM and IEC 61850 data models into RDF formats (Haghgoo et al., 2020).

Crucially, this information is structured using a hierarchical *common context* spine; individual buildings are semantically linked to geographical small areas and then to transmission nodes (Hoare et al., 2022; He et al., 2023).

Methodology

We now turn to describing the development of a utility aware knowledge graph (KG) to support multi-scale energy modelling. The KG is structured by defining a number of common contexts to create vertical hierarchies of relationships between represented entities and horizontal relationships to define equivalence between disparate representation of the same physical entities. While exemplified using the Irish context (and relevant datasets), the approach can be applied across jurisdictions where suitable datasets are available. Having described the common context, the process used to integrate building and electricity distribution network information is described. The section will conclude with a brief description of DDIM server, used to manage the data fusion and access process.

Core context

A graphical representation of the context model along with the organization of this project's data through the use of the ontology are shown in Figure 1 (A). The ontology is deliberately sparse to maintain clarity. An entity represents some physical entity or space in time. Each instance

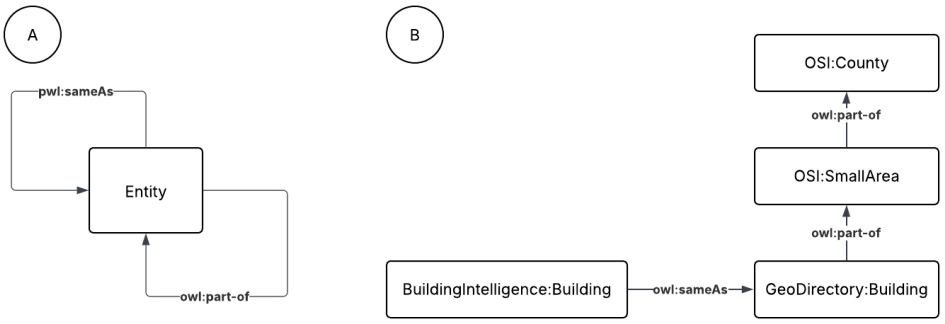

Figure 1: A. Context model and B. Relationships to data sets used in this project

of an entity is described by a class, for example, a building, region or nation. Together, these classes describe a set of layered contexts, each representing a different scale. Information sources are associated with some entity in each layer. This association with context allows sources to be intra-connected at a particular scale, and inter-connected between scales. Figure 1 (B) illustrates the use of the context model to place buildings in geographical hierarchies and relate building representations to each other across datasets. Equivalence is expressed using the *owl:sameAs* relationship; we use the relationship to denote that buildings in different datasets represent the same physical entity (Halpin et al., 2010). The use of *owl:sameAs* can give rise to semantic ambiguity where datasets' properties lists overlap. This issue is overcome by assigning a source authority ranking for datasets as they are added to the graph. This feature is provided through the DDIM's data upload forms. Hierarchies are created using the *owl:part-of* relationship. In Figure 1 building representations are in the geographical context of a small area which in turn is part of a county. In this way, various transitive relationships can be created to support aggregation and other analysis operations over geographical contexts.

Managing data fusion and access

The Dynamic District Information Model (DDIM) (Project, 2023a) is used to mine and manage relationships between the siloed data sources. For this project, the DDIM uses the core context to defined relationships between geographical areas and locations to provide a common context between data sources. This context is captured through a knowledge graph defiend in Neo4J (with NeoSemantic plugin). The server supports forms based no-code implementation of the graph, where forms are used to upload datasets and create owl:sameAs and owl:part-of relationships between columns in the uploaded data. the The server implementation consists of three key functional areas:

- Creation of 'Core Spines' (describe by the context model) using a form based process integrates uploaded information. These spines allows information to be associated with entities in various contexts, facilitating querying across these spaces;
- A series of interfaces to allow client software to query (through RESTful or SPARQL based interfaces);
- A DCAT compliant data catalogue;

The server is implemented using the Django Framework (Project, 2023b) with RESTful (DjangoRESTful, 2023) extensions. This framework also provides user management and security. Neo4J and NeoSemantic (Project, 2023a) is installed within the same domain. Queries are submitted through the Django server to this database.

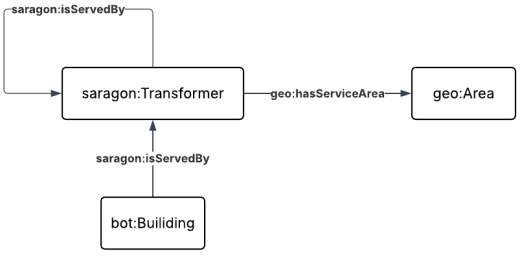

Figure 2: Additional graph structure added post enrichment.

Enriching KG with building/LV relationships

We now examine the steps taken to integrate building and electricity distribution network information. In this instance, the information used was provided by ESB Networks as part of their *Capacity Heatmap for Network Planning* tool (ESB Networks, 2026). This provides a wealth of information about the location and capacity of transformers on the Irish electricity distribution network. One purpose of the Capacity Heatmap is to guide customers who wish to make a new connection to the network. In this use, customers are advised to locate the transformer closest to the required connection; we employ the same heuristic in this work. Low Voltage (LV) transformers were associated with building data (from Geodirectory (GeoDirectory, 2022a)) and areas representing each transformer's serviced area were created using the following steps:

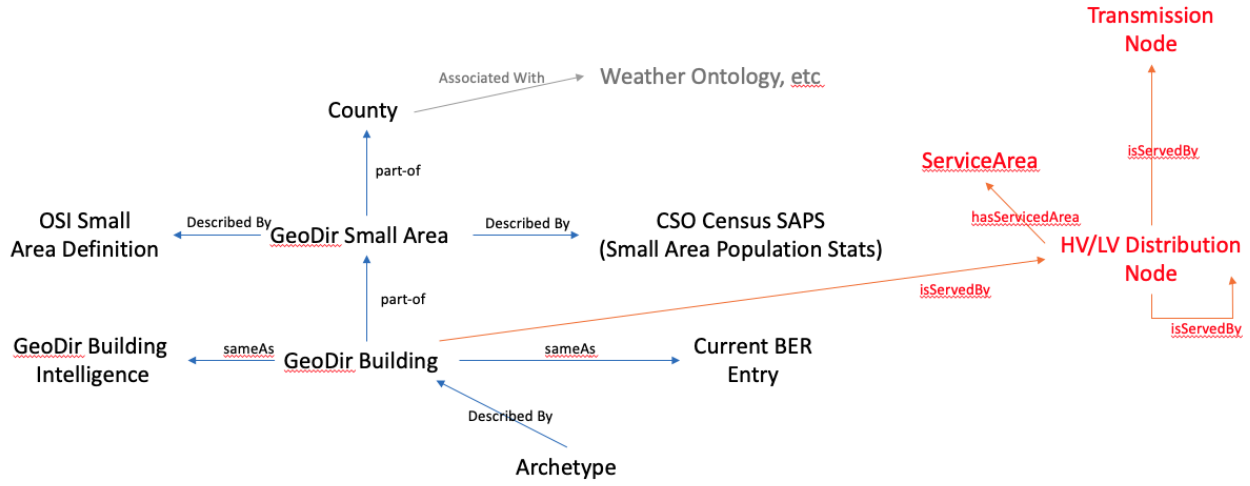

Figure 3: Representation of relationships between datasets in National Scale Residential Energy Graph. Elements added as part of the enrichment process are shown in red.

1. Entity definitions

Let B be the set of buildings:

$$B = \{b_i \mid i = 1, \ldots, n\}$$

where $b_i = (\mathbf{p}_i, \mathscr{C}_i)$, with $\mathbf{p}_i \in \mathbb{R}^2$ as coordinates and $\mathscr{C}_i$ as characteristics.
Let T be the set of transformers:

$$T = \{t_j \mid j = 1, \ldots, m\}$$

where $t_j = (n_j, \kappa_j, \mathbf{l}_j)$, with n_j as name, κ_j as capacity, and $\mathbf{l}_j \in \mathbb{R}^2$ as location.

2. Relationship assignment

For each building b_i, the closest transformer t^* is found via:

$$f(b_i) = \arg\min_{t_j \in T} d(\mathbf{p}_i, \mathbf{l}_j)$$

This establishes the relation $(b_i, \text{isServedBy}, f(b_i))$.

3. Geometric representation

The service area for transformer t_j is defined by the convex hull of the points S_j it supplies:

$$S_j = \{\mathbf{p}_i \mid f(b_i) = t_j\}$$

$$\text{CH}(S_j) = \left\{ \sum_{k=1}^{|S_j|} \alpha_k \mathbf{p}_k : \sum \alpha_k = 1, \alpha_k \geq 0 \right\}$$

4. Knowledge graph insertion

The graph $\mathscr{G}$ is updated such that:

$$\mathscr{G} \in \{(b_i, \text{isServedBy}, t_j), (t_j, \text{hasServiceArea}, \text{CH}(S_j))\}$$

These steps were implemented as a Python script which output two files, a text file containing Cypher queries to create a relationship between each building and the transformer that it is served by. The second output file is a GeoJSON (Internet Engineering Task Force (IETF), 2016) formatted definition of the convex hull defined areas that describes the area containing buildings serviced by a transformer. In the Irish context, 46,527 transformers were associated with over 2.3 million residences.

Figure 2 shows the structure of the developed graph extension when the LV/Building relationship process is processed. Transformers and their associated connections to buildings are described using the SmArt eneRGy dOmain oNtology (SARAGON) (Haghgoo et al., 2020) ontology. Transformers can be served by higher voltage transformers and in turn serve buildings. Each transfomer is also associated with a geographical area representing the convex hull described by the buildings it serves. This area can be used for visualisation and other purposes.

Results

This paper continues by examining the generated utility aware graph. The data sources and resulting graph structure will be described in the Irish context before examining the outputs Building/LV enrichment process. The convex hull outputs will be described before a number of competency questions will demonstrate the complexity of queries that the knowledge graph can inform. Finally, the potential to use this methodology in other jurisdictions will be discussed.

Structure of knowledge graph

The DDIM and core context were used to create a national scale residential energy graph for Ireland. The graph structure is used to inform energy modelling. Subsequently, the graph was enriched to include information about the Irish electricity distribution network using the steps described a-priori. Development of the graph followed the following steps:

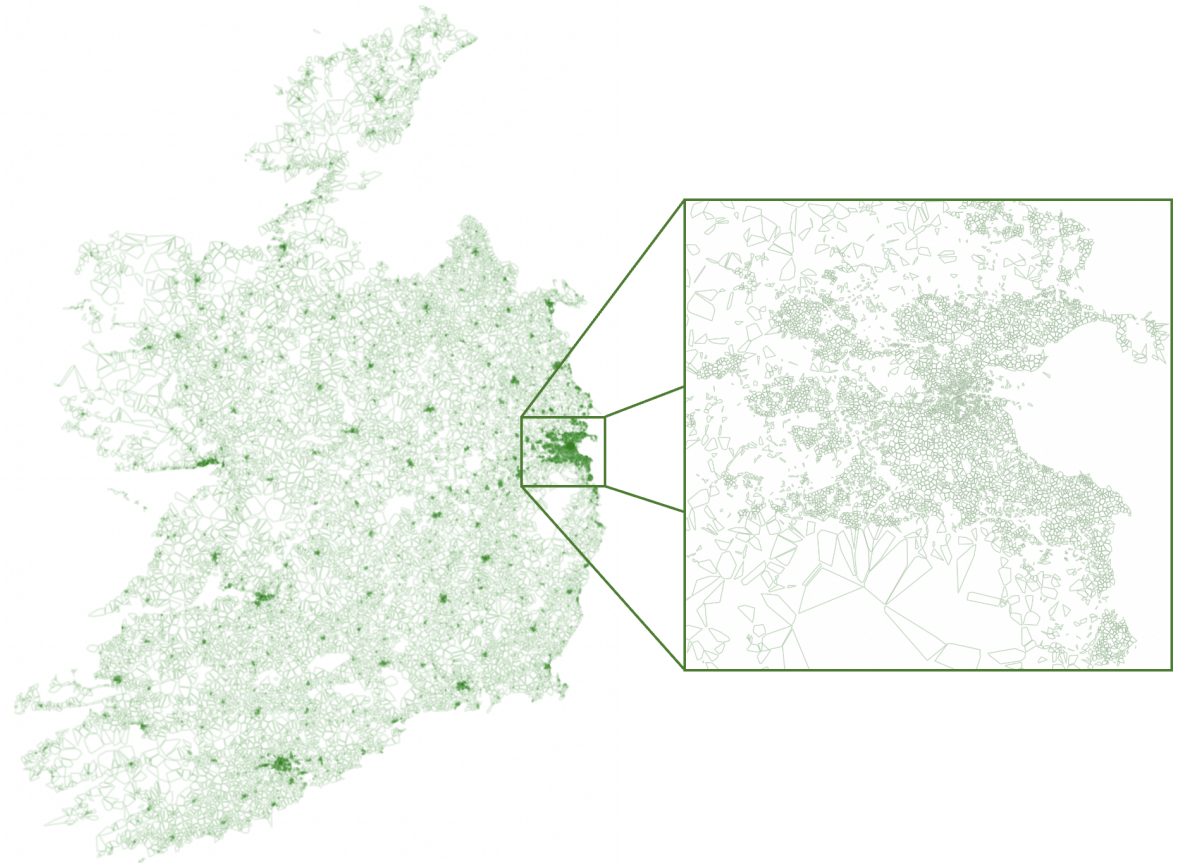

Figure 4: Map generated from presentation of derived convex hulls representing areas served by LV transformers. Clusters of smaller areas correspond to urban areas with higher densities of residential properties.

- Collection of relevant data sources.
- Identification of vertical and hierarchical relationships that could be exploited to support dataset fusion using the core context.
- Creation of the graph using the DDIM server.

The following datasets were identified:

- Geodirectory's *GeoAddress (GeoDirectory, 2022a)* and associated *BuildingIntelligence (GeoDirectory, 2022b)* – comprehensive list of approximately 2.3 million buildings, including location information and residential building properties. BuildingIntelligence includes energy modelling relevant information, for example, heating fuel.
- SEAI's *National BER Research Tool (SEAI, 2023)* - contains anonymised data used to calculate buildings' EPC certificate. The database contains data collected during building surveys. There are entries for approximately 60% of the Irish residential building stock.
- Irish Central Statistics Office (CSO) *Small Area Population Statistics (SAPS) (Office, 2022)* – 15 themes describe various statistics garnered from the CSO's census. These include socio-economic information about housing, commuting, motor cars and other energy modelling resources.

The Knowledge Graph contains other relevant information, including geographic area definitions from Ordinance Survey Ireland and developed building archtypes.

The DDIM was used to create the graph structure shown in Figure 3. Horizontal *same-as* relationships were identified between, building representations in the BER, GeoAddress and Building Intelligence datasets. Each building (represented by the GeoAddress entry) was associated with a building archtype. A vertical *core context* was created where each building was placed in the context of a small area using part-of relationships. Small areas were similarly placed in counties. These geographic contexts were chosen as they are widely used by various data providers. However, finer grained contexts including streets and townlands could also have been created.

The graph was subsequently enriched by creating associations between buildings and transformers (shown in red in Figure 3). Having followed the process described a priori. This added nodes for each transformer and a representation of the area they serve. Relationships between building representations and transformers were also created.

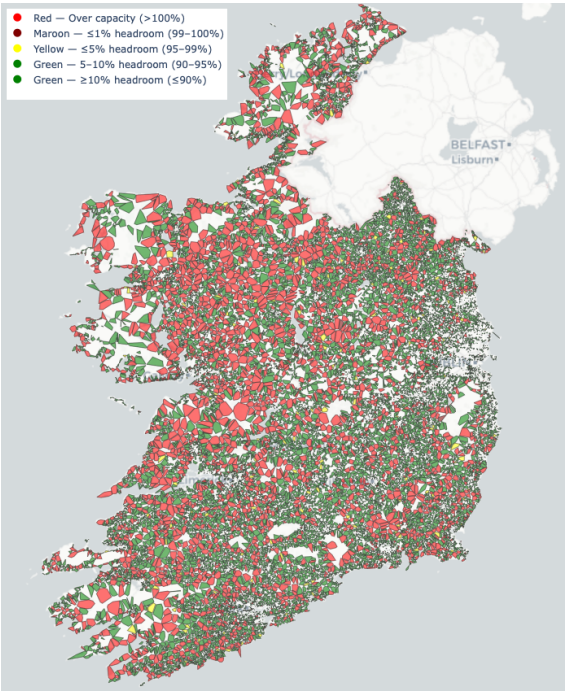

Figure 5: esults of multiscale energy modelling for scenarios including heatpump and EV adoption by residential households.

Visualising the relationships between LV transformers and buildings

Figure 4 presents a visualisation of the areas served by individual LV transformers at various scales. A distinct contast exists between urban areas characteristed by denser clusters of smaller areas and remote low-population areas (west coast and mountainous areas such as South of Dublin). This becomes more apparent when the map is zoomed to an urban areas such as Dublin (inset, Figure 4. As these areas are defined as GeoJSON polygons, colours can be assigned to each area depending on the form of analysis applied; for example, the visualisation can be used to show which LV transformers will experience capacity issues under various scenarios. The use of GeoJSON is also advantageous as web-based interfaces can be created dynamically zoom in and out across multiple-scales.

An example of this application is shown in Figure 5. In this isntance, building characteristics (fabric, occupancy and heating system) are aggregated into representative archetypes and converted to hourly electricity demand. Electrification scenarios such as heat-pump adoption and EV charging are applied as behavioural state changes within the housing stock. The resulting demand is spatially allocated to low-voltage substations, allowing feeder peak load and transformer overload to be calculated.

Competency questions for knowledge graph

Scoping and design of the KG was guided by developing numerous competency questions (Keet and Khan, 2024). These questions were also used to validate the capabilities of the graph. We now present two of these along with their results to demonstrate the ability of the KG to reason in sophisticated ways about knowledge relevant to multi-scale energy modelling in Ireland.

CQ1: Average residential buildings per LV node

The following Cypher query was used to report on statistics related to this query:

```
MATCH (b:Building)-[:NEAREST_LV_STATION]->(
lv:LVStation)

WITH lv, count(b) AS buildingCount

RETURN avg(buildingCount) AS
avgBuildingsPerLVNode,
min(buildingCount) AS minBuildings,
max(buildingCount) AS maxBuildings,
count(lv) AS totalLVNodes
```

The average number of connections was found to be 47.0 buildings per LV node with a standard deviation of 44.5. In total 42,235 LV nodes were found to supply at least one residential building. This can be explained by some LVs supplying commercial buildings and the use of the nearest LV to a building heuristic.

CQ2: Aggregate connectivity summary

Provide a summary table that describes overall connectivity between LV nodes and residential buildings.

```
MATCH (lv:LVStation)
OPTIONAL MATCH (lv)<-[:NEAREST_LV_STATION]-
                        (b:Building)
WITH lv, count(DISTINCT b) AS buildings

OPTIONAL MATCH (lv)-[:SERVES_SMALL_AREA]->
                        (sa:SmallArea)
WITH lv, buildings, count(DISTINCT sa) AS
                            smallAreas

OPTIONAL MATCH (lv)-[:HAS_ARCHETYPE_COUNTS]
->(ac:ArchetypeCounts) WITH lv, buildings,
smallAreas, count(DISTINCT ac) AS
                          archetypeNodes
WITH buildings + smallAreas +
     archetypeNodes AS totalConnections

RETURN avg(totalConnections) AS
avgConnectivity, min(totalConnections)
AS minConnectivity, max(totalConnections)
AS maxConnectivity, percentileCont(
totalConnections, 0.5) AS
medianConnectivity
```

In summary, overall connectivity is described thus: average 53.9, median 41.0, range 0–619. The sophistication of the query and its ability to bridge disparate siloed information sources is demonstrated.

Applying this methodology in other jurisdictions

The methodology is designed for global scalability. Access to appropriate datasets represents the greatest challenge. For example, in the United Kingdom, access to GeoPlace's National Address Gazetteer would yield a dataset of addresses equivalent to GeoDirectory, while EPC data can be accessed through the Department for Levelling Up, Housing & Communities' Energy Performance of Buildings Data datasets. By mapping these and other datasets to common contexts, the no-code form based approach used by the DDIM allows domain experts to create utility-aware knowledge graphs in any jurisdiction. Larger datascales at national level are supported by the ability of the DDIM to operate as a federated node in distributed deployment. Using building archetypes further enables national-scale energy simulations for diverse decarbonisation planning.

Conclusions

This paper addresses the fragmentation of AECOO data silos by developing a utility-aware knowledge graph (KG) for multi-scale residential energy modelling. By leveraging Linked Data principles and the Dynamic District Information Model (DDIM), the research successfully integrated building-level characteristics with national electricity infrastructure. The methodology was validated in the Irish context, semantically linking 2.3 million buildings to 46,527 Low Voltage (LV) transformers through a novel automated enrichment process. Results from competency questions demonstrated the KG's ability to perform sophisticated reasoning, revealing an average of 47.0 residential buildings served per LV node. This framework effectively bridges building physics with urban-scale dynamics, offering a globally scalable approach for planners to optimize grid capacity and decarbonisation strategies. Future work will focus on integrating real-time sensor data and machine learning to enhance predictive analytics for grid stability

TOWARDS AN INDUSTRY-ACADEMIA COLLABORATION FRAMEWORK FOR THE DEVELOPMENT OF DIGITAL GEOSPATIAL SURVEYING MICRO-CREDENTIALS

Brian Graham[1], Bryan Hallissey[1], and Shane Murtagh[2]
[1]South East Technological University, Waterford, Ireland
[2]KOREC Group, Dublin, Ireland

Abstract

The geospatial surveying sector is undergoing rapid digital transformation, intensifying demand for advanced digital skills amid widespread workforce shortages and declining education pathways. Micro-credentials have emerged as a flexible solution for targeted, industry-aligned upskilling, yet their effective development requires structured collaboration between Higher Education Institutions and industry. This paper proposes a conceptual framework for designing Digital Geospatial Micro-Credentials through an Industry–Academia Collaboration model, synthesising multidisciplinary literature and preliminary action research. The framework integrates key drivers, collaborative patterns, and outputs, offering a foundation for future validation and enabling responsive approaches to developing digitally skilled geospatial professionals.

Introduction

The Architecture, Engineering & Construction (AEC) sector is currently undergoing a major digital transformation. Known as Construction 4.0, this paradigm shift is seeking to enhance efficiency, productivity, sustainability, safety, and collaboration (Build Up, 2024). In a study of Construction 4.0 adoption in Australia, Siriwardhana et al. (2025) identified the integration of several key technologies including BIM, IoT, digital twins, AI, AR/VR, Blockchain, Robotics, 3D Printing, Big Data and Drones. EU policy initiatives such as public procurement mandates are attempting to overcome the challenges associated with Construction 4.0 which include high initial investment, training needs, and resistance to change (Build Up, 2024). The geospatial surveying sector is also undergoing a profound transformation driven by digitalization. Traditional methods are being replaced by advanced technologies such as LiDAR, UAVs (drones), AR/VR, GNSS, and cloud-based GIS platforms. These tools enable faster data collection, higher accuracy, and real-time processing, allowing surveyors to deliver dynamic, interactive spatial models rather than static maps. To integrate effectively with Construction 4.0, modern geospatial surveyors need strong digital skills, spatial awareness, geodetic knowledge, interdisciplinary collaboration and proficiency in advanced tools like reality capture, GIS software, and data management systems (Trimble, 2025).

Geospatial Skills Shortages

The challenges associated with the rapid digital transformation of the geospatial sector is further exacerbated by a significant skills shortage which has existed for many years, with de Róiste (2014) and Masum et al. (2017) highlighting this issue in Ireland, New Zealand, Australia, and the United States. This problem persists with the most recent report from the Society of Chartered Surveyors in Ireland (SCSI) suggests a continued shortage of land surveyors in Ireland (Murphy, 2023), with both Site Engineers and Setting Out Engineer listed on Irish Government's Critical Skills Occupations List (DoETE, 2024). Martin (2024) suggests that the significant deficit in the number of geospatial professionals in Ireland is due to several factors including a lack of knowledge of geospatial surveying as a discipline, that it is not a protected professional title and the declining number of secondary students entering education programmes. Similarly, the global geospatial industry is facing a critical shortage of skilled surveyors due to an aging workforce and insufficient new entrants (Trimble, 2025). This is further compounded by a decline in surveying education programmes, with the SCSI and the Council of European Geodetic Surveyors as recently as October 2025 expressing *"serious concern over the trend of various universities across Europe closing their educational programmes related to land surveying."* They continue by stating that *"future professionals must have access to high-quality, innovative education and training."*

Higher Education & Micro-Credentials

The higher education sector is also facing growing challenges due to rapid technological change, evolving professional needs in the workplace and the digital transformation of society (Urem et al., 2025). This has expedited the demand for short, targeted, flexible upskilling/reskilling beyond traditional degrees (Walsh Shanahan & Organ, 2022; Islam, 2025). Employers are increasingly seeking immediately applicable digital skills, pushing Higher Education Institutes (HEIs) toward workforce-aligned modular learning (Urem et al., 2025). Micro-credentials, which are defined differently across contexts but share common goals: upskilling and reskilling to meet rapidly changing digital skill demands, provide an opportunity to address such challenges. They

are short, flexible, industry-aligned learning units that can stack toward higher qualifications, supporting lifelong learning through competency certification (Moore et al., 2025). In this regard, both Islam (2025) and Walsh Shanahan & Organ (2022) emphasize the potential for developing micro-credentials in collaboration between academic institutions and industry stakeholders to guarantee workforce alignment, ensure relevance and uptake, meet market needs and foster innovation.

Opportunities in Digital Geospatial Education

Siriwardhana et al. (2025) advocates for the integration of Construction 4.0 concepts such as digital surveying technologies into formal education through collaboration between industry and academia. The potential benefits of industry-academic collaboration (IAC) for geospatial education are also highlighted by de Róiste (2014: 187), who states that it is: *"likely to lead to a greater professionalization and therefore a wider recognition of both the industry and those working in it. The benefits of gaining a qualification (after* employment*) or re-skilling in emerging areas need to be sold to both employees and their organisations."* This is confirmed by Cox (2025) who highlights the shift from traditional classroom-based models to flexible, hybrid, work-integrated learning pathways that align with industry needs. Trimble (2025) also cites the potential of IAC with an emphasis on micro-credentials, and continuous professional development to prepare a digitally skilled geospatial workforce.

Towards a Conceptual Framework?

The rapid digital transformation taking place within geospatial surveying sector, coupled with a significant skills shortage and a decline in formal education programmes, points towards a need for the development of upskilling opportunities for existing professionals within the AEC industry. Through a systematic literature review of 56 peer-reviewed articles on micro-credentials in HE published between 2015 and 2021, Ahsan et al. (2023) found that micro-credentials enhance employability through alignment with market needs, improving graduate employability and bridging skills gaps. They also suggested that micro-credentials be co-designed with industry to ensure relevance and acceptance, thus confirming the importance of IAC. According to Iatrellis et al. (2024), this trend highlights the need for structured, sustainable frameworks to support micro-credential programs and adapt to the changing educational landscape. With micro-credentials gaining traction as a potential solution in delivering enhanced digital skills, this research seeks to establish if an IAC framework for micro-credential design can effectively close the digital geospatial skills gap. This will be achieved by adopting a conceptual research design aimed at synthesizing existing theoretical and scholarly perspectives to create a new Conceptual Framework (CF) for the development of Digital Geospatial Micro-Credentials via IAC, based upon ongoing action research which is being led by South East Technological University (SETU) and KOREC Group, a geospatial surveying services provider in Ireland. In building a CF for multidisciplinary phenomena (i.e. digital geospatial surveying, micro-credentials and IAC) linked to different bodies of knowledge, the approaches proposed by both Jabareen (2009) and Waller (2022) have been adopted in the present study (as outlined in Table 1).

Table 1: Development of a Conceptual Framework

Present Study	Jabareen (2009)	Waller (2022)
Review of Multidiscipline Literature	Mapping sources Extensive reading and categorizing of selected data	Review: literature/themes/ theory
Main Concepts Arising	Identifying, naming, deconstructing & categorizing concepts	Reflect: what are the main concepts/issues?
Relationships and Integration	Integrating concepts	Relationships: what are their relationships?
Reflection & Synthesis into CF Diagram	Synthesis, resynthesis, and sensemaking	Reflect: does the diagram represent it sufficiently?
Validation of CF	Validating the conceptual framework	Review: check it with theory, colleagues, stakeholders, etc.
Revision of CF	Rethinking the conceptual framework	Repeat: review and revise it to see if something better occurs

The intention of this paper and associated conference presentation is to encourage a review, validation and revision of the framework as a work in progress to ascertain *"whether the proposed framework and its concepts make sense not only to the research but also to other scholars and practitioners" (Jabareen (2009: 54).* The paper is structured to reflect the work of both Jabareen (2009) and Waller (2002), with a Literature Review (multidisciplinary literature and main concepts arising), followed by the Development of Conceptual Framework (integration and synthesis into diagram). It is anticipated that further validation and revision of the CF will take place as the research progresses in future. The aim of the CF is to integrate currently disconnected bodies of knowledge—digital geospatial surveying, micro-credential design, and industry–academia collaboration—into a coherent model that can guide HEIs and industry partners in the structured co-development of digital geospatial micro-credentials.

Literature Review

Utilizing relevant scholarly and industry sources, the following review seeks to understand the underlining issues relating to the geospatial surveying profession, the

role of micro-credentials in higher education and the nature of Industry-Academia Collaboration (IAC), leading to the identification of the main concepts arising.

Geospatial Surveying

Geospatial (land) surveying is the science of collecting, analyzing, and presenting spatial information about natural and built environments. Surveyors measure land and sea areas to map boundaries, features, and terrain for purposes such as GIS, construction, and legal disputes. The field is highly technological, using GNSS, LiDAR, drones, and 3D modelling across three main pathways: land, engineering (setting out buildings & infrastructure), and hydrographic (marine) surveying (RICS, 2023). Geospatial professionals are defined by de Róiste (2014) in terms of acquiring, integrating, analyzing, interpreting, presenting, managing, and distributing spatial and temporal information, as well as developing related equipment, software, and services. A major study of geospatial skills in the UK identified "Surveyors" as one of six geospatial occupational subgroups with an emphasis on capabilities including land surveying, field surveys, topographic surveys, use of survey instruments and advanced technologies such as LiDAR (Frontier Economics, 2020). In terms of the Land Surveying profession, CICES (2023) defines the core specialist competences as follows:

1. Undertake and produce topographic surveys using appropriate methodologies and controls
2. Proficient use of surveying instruments (including total stations, GNSS, laser scanners, levels, utility mapping tools, photogrammetry & drones)
3. Understand Geometric Principles
4. Geospatial Data Processing & Deliverables

According to Frontier Economics (2020), typical job titles include Land Surveyor, Utility Surveyor, Hydrographic Surveyor, and Site Engineer, spanning sectors such as Architecture, Engineering and Construction (AEC), geographical information, environmental services, land administration and management, cultural and natural heritage and renewable energy.

In discussing the evolution of the surveying profession, Masum et al. (2017) note the significant impact of technology from the introduction of electronic instruments in the 1960s to GPS in the 1990s and more recent advances with laser scanning and photogrammetric data capture. Geospatial skills encompass a broad range of technologies, including spatial modelling, surveying, Global Positioning Systems (GPS), Geographic Information Systems (GIS) as well as traditional cartography techniques (de Róiste, 2014). Digital transformation of the geospatial surveying sector is continuing at pace, with reality capture (SLAM and 3D laser scanning); cloud-based data management and AI & automation being the key technologies driving change (Trimble, 2025). Recent industry surveys have confirmed that digital skills are in highest demand for geospatial technology professionals, including data capture/collection; data processing & analysis; and data visualization (Frontier Economics, 2020). Siriwardhana et al. (2025) emphasizes that workforce skills are a critical enabler for successful Construction 4.0 adoption, arguing that digital transformation in construction requires a shift from traditional skill sets to advanced competencies such as digital literacy, data analytics, computational and parametric modelling, programming, and AI integration.

Status of Geospatial Education Programs in Ireland

The current offering of geospatial related education in Ireland is dominated by post-graduate programmes (NFQ Level 9) in GIS/Geoinformatics at University College Dublin, University College Cork, Maynooth University and Technological University of Dublin. In terms of full-time undergraduate programmes, there is a 1-year full-time Level 5 Certificate in Geospatial Technology delivered by Cork ETB, while the long-running full-time BSc (Hons) in Geospatial Surveying (Level 8) at TU Dublin was paused in September 2024. At present, TU Dublin is developing a Geospatial Survey Technician apprenticeship, a 2-year Level 6 qualification, in collaboration with the SCSI (Martin, 2024). This shift towards geospatial education programmes at Level 5, 6 and 9 points to a significant gap in educational opportunities at Level 7 and 8. With an ongoing lack of new students entering geospatial education programmes, it is suggested that HEIs focus on providing new upskilling/CPD opportunities for current professionals in industry (Masum et al., 2017; de Róiste, 2014). *"CPD is particularly important in a field that is so deeply influenced by technological innovation. Developments in GNSS, laser scanning, drone-based photogrammetry, and remote sensing continue to reshape workflows and methodologies. Without structured and accessible professional development pathways, there is a risk that skills gaps will widen and sector growth will be constrained" (Cox, 2025: 3).*

The main concepts arising from geospatial literature include skills & competencies, digitalization, key stakeholders, industry needs, skills shortage & gap, opportunities for HEIs, and the potential for IAC.

Micro-Credentials in Higher Education

Micro-credentials present the higher education sector with an opportunity to address the market's demand for flexible upskilling; *"as employers and job seekers become more aware of employment-enhancing micro-credentials programs, demand for such short-term upskilling opportunities is expected to increase" (Yildirim et al., 2025: 538).* A relatively recent innovation in the education landscape, micro-credentials are short, focused, quality assured learning programs that concentrate on specific competencies and skills. They are modular, portable, stackable, and are validated through transparent, reliable assessment and quality assurance (Islam, 2025; Moore et al., 2025; Pawilen et al., 2022). Micro-credentials are offered by diverse providers including universities, commercial entities, and professional bodies. This versatility enables micro-credentials to serve both formal education and workplace learning (Moore et al., 2025).

Table 2: Micro-Credential Categories

	Skill Credential	Micro-Credential Module	Short Learning Programme
Learning Effort/Time	1-25 hours 0 ECTS	25-150 hours 1-5 ECTS	150-1500 hours (stacked)
Award & Assessment	Open Badge Non-Formal Learning	Formal Learning with Assessment	Formal Learning with Assessment
Quality Assurance	None	Often External QA	Always External QA
Learning Outcome	Specific Competence	Acquisition of Learning Outcomes	Career Progression Goals
Pathway	N/A	Often Mapped to Qualification Framework	Always Mapped to Qualification Framework

Both employers and learners place significant value on the validation of micro-credentials for workplace recognition, with traditional academic credentials seen to be more trusted (Ashcroft et al., 2021). Walsh Shanahan and Organ (2022), suggest that the use of ECTS can help to standardize workload and recognition of micro-credentials, recommending a minimum of 5 ECTS for formal recognition. Indeed, Ahsan et al. (2023) found substantial evidence of research which examines integration of micro-credentials into formal curricula. Micro-credentials can function as standalone, credit-bearing courses or be integrated into formal qualifications. Sargent et al. (2023) found that they may appear as optional or compulsory components within traditional programs or as stackable micro-credentials, where multiple related short courses combine to form a recognized award (e.g., Graduate Certificate). Qualifications incorporating micro-credentials include traditional certificates, diplomas, and degrees. This trend reflects growing interest in modular learning pathways that allow learners to accumulate credits toward larger qualifications (Sargent et al., 2023). Micro-credentials are typically categorized in terms of learning effort/time, learning outcomes, assessment methods, quality assurance and pathways to further learning, with 3 categories identified as outlined in Table 2 (Camilleri et al., 2022; Walsh Shanahan and Organ, 2022; Urem et al., 2025). Iatrellis et al. (2024) identified the critical roles and responsibilities of key stakeholders within the micro-credentialing ecosystem as follows:

- **HEIs:** design, develop, and deliver micro-credentials; ensure academic standards, industry relevance, and quality assurance.
- **Industry Partners:** identify workforce skills and co-design micro-credentials; provide practical training opportunities.
- **Regulatory Bodies:** accredit and recognize micro-credentials; ensure consistency, quality and alignment with national frameworks.
- **Students and Learners:** provide feedback to refine relevance and effectiveness; participate in content co-creation for career and educational goals.
- **Quality Assurance Agencies:** evaluate programs against standards; recommend continuous improvement, shaping evaluation criteria.
- **Professional Bodies:** advocate for recognition and validation within industries.

For HEIs, micro-credentials offer several benefits, according to Pawilen et al. (2022): increase visibility and build their brand, attract diverse learners through unique and alternative courses, and appeal to these individuals to enroll in their formal education programs. Ahsan et al. (2023) identified several challenges associated with implementing micro-credentials in higher education including student acceptance, institutional readiness, technology gaps, employer recognition, logistical complexity and quality assurance. Employer awareness of micro-credentials is still low but growing, with traditional academic credentials remaining more trusted. Key factors influencing employer acceptance include industry validation, alignment with job needs, prior experience with credential issuers, and the issuer's reputation, credibility and quality assurance (Ashcroft et al., 2021). This presents a significant opportunity for higher education to lead in this area, with Yildirim et al. (2025: 552) stating that *"this shift could enable more flexible learning pathways, responsive curriculum design, and stronger alignment with lifelong learning and workforce development priorities."*

The main concepts arising from the micro-credentials in higher education literature include nature & categories of micro-credentials, development of skills & competencies, addressing industry needs & rapid digital transformation key stakeholders, course development/curriculum design, opportunities for HEIs, and the potential for greater IAC.

Industry-Academia Collaboration (IAC)

Aligning academic curricula with industry needs has long been a challenge for both educators and practitioners (Mahalingam, 2024), with Ahmed et al. (2022) suggesting that bringing in industry experts to assist in developing the curriculum can help to bridge this gap. Both Karanja and Malone (2022) and Mahalingam (2024) suggest that the co-creation of a curriculum with industry can prove beneficial in terms of improving the quality and relevance of academic programmes, whilst equipping graduates with the skills and knowledge required by industry. The most important outcomes of collaboration with industry were identified by Valiente Bermejo et al. (2022) as bridging the gap between academic education and industry requirements, enhanced graduate employability and strengthened research partnerships. Real, structured partnerships are more effective in driving innovation, with previous research demonstrating that open and networked innovation strengthens the potential of participating organizations (Esangbedo et al., 2024). From a digitalization perspective, Akash and Venuraj (2024) note the importance of IAC in terms of integrating state-of-the-

art technologies into the educational curriculum, an area where HEIs are often found to be lacking.

According to Esangbedo et al. (2024), IAC has been widely studied across different countries, including the UK, USA, and Japan. *"IAC is trending as a strategic framework necessary to bridge the increasing gap between the academic programmes and the emergent requirements of the industry" (Akash and Venuraj, 2024: 3).* A review of literature indicates a variety of frameworks, under various guises, focused on collaboration between academia and industry for curriculum development. These frameworks emerged from a number of different disciplines including business (Mahalingam, 2024); Software Engineering Ahmed et al., 2022); Sustainable Development Goals (Akash and Venuraj, 2024); Manufacturing Engineering (Valiente Bermejo et al., 2022); Information Technology (Junaini et al., 2008); and Industry 4.0 (Esangbedo et al., 2024). Mahalingam (2024) developed the industry-driven curriculum (IDC) framework which focuses on bridging the gap between academic curricula and industry requirements through frequent workshops. Key activities on the framework include identifying industry needs, mapping competencies, gap analysis on learning outcomes, course content, schedule of activities and assessment strategies, and developing a competency-based curriculum. Regular follow-up and updates post-workshop are essential in maintaining engagement with industry, whilst also demonstrating the incorporation of feedback can enhance trust and collaboration throughout the process (Mahalingam, 2024). An Academia-Industry Collaboration Plan (AIC) engineering process model is presented by Ahmed et al. (2022), which suggests that effective communication and collaboration in the early stages of engagement is critical for the transformation of proposals into practical applications, leading to a clearly defined "Finalized Collaborative Agreement." Akash and Venuraj (2024) proposed a framework for IAC which aligns student skill development with real-world requirements. It emphasizes dynamic, iterative collaboration between educational institutions and industry to continuously improve and adapt curricula, incorporate emerging technologies, upskill faculty, thereby enhancing relevance, employability, and responsiveness to evolving market demands. Valiente Bermejo et al. (2022) presents a model for university-industry collaboration in curriculum design and delivery, specifically applied to manufacturing engineering courses. A core element of this model are regular workshops with industry partners in developing, teaching, evaluating and improving the course. An Academic-industry smart synergy model was proposed by Junaini et al. (2008) with industry input in terms of market demand and curriculum development being seen as important to delivering relevant educational programs and a competent workforce. According to Esangbedo et al. (2024) research on IAC generally falls into three categories: Drivers (factors that motivate collaboration), Patterns (how collaborations are structured) and Outputs (results and impacts of collaboration). It is evident that collaboration between industry and academia in curriculum design can lead to significant benefits for both parties. To ensure strategic alignment, the reviewed IAC frameworks suggest that regular communication, collaboration and feedback is essential to ensure the development of competencies, curriculum, content, and assessment which leads to relevant courses that deliver the skilled graduates required by industry.

The main concepts arising from the IAC literature include addressing rapid digital transformation and industry needs, bridging the skills gap, collaboration and communication, key stakeholders, curriculum design and opportunities for HEIs.

Developing the Conceptual Framework

Having identified the main concepts arising from literature, the next stage in the development of a CF involves identifying relationships and integrating concepts, followed by reflection and synthesis inro a CF diagram. It is evident from the main concepts arising that there are a number of overarching concepts that cut across the three domains including digital transformation, skills shortages and educational gaps, micro-credentials for flexible learning and IAC as an enabling mechanism.

Relationships and Integration

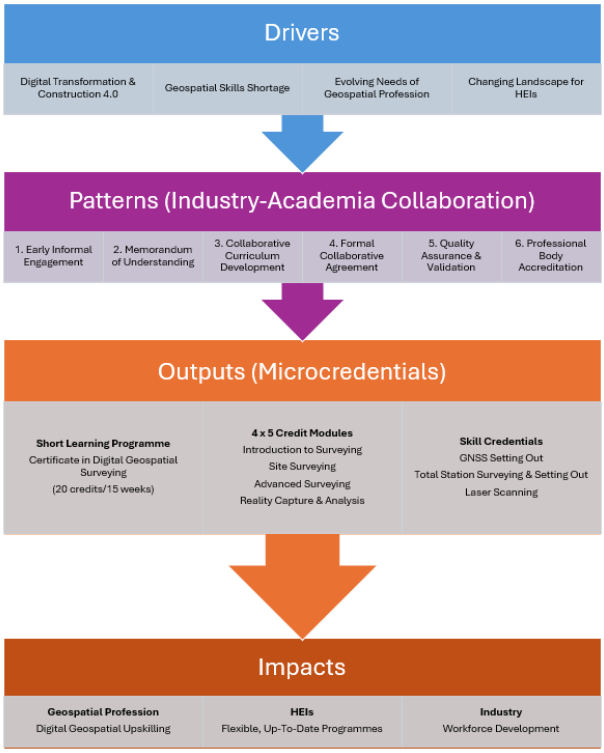
The main concepts arising from each of the three literature topics were reviewed and analyzed using a matrix, allowing for identification of relationships between geospatial surveying, micro-credentials and IAC. Jabareen (2009: 54) suggests that *"this phase reduces the number of concepts drastically and allows us to manipulate to a reasonable number of concepts."*

Table 3: Integration of Concepts

Drivers (factors that motivate collaboration)	Patterns (how collaborations are structured)	Outputs (results and impacts of collaboration)
Digital Transformation & Construction 4.0	Industry-Academic Collaboration	Opportunities for HEIs
Decline in Geospatial Education	Active Engagement from Key Stakeholders	Benefits for Industry
Evolving Needs of Geospatial Profession	Key Stages/Activities	Digital Geospatial Micro-Credentials
Changing Landscape for HEIs	Curriculum Design/Course Development	Upskilling of Geospatial Profession

The matrix was developed by listing all identified concepts from each literature strand and grouping them based on conceptual proximity. Concepts were iteratively merged, eliminated, or re-named to achieve parsimony, consistent with Jabareen (2009). Through this analytical process, concepts were refined and integrated using the three categories of IAC research as identified by Esangbedo et al. (2024, namely: Drivers (factors that motivate collaboration), Patterns (how collaborations are

structured) and Outputs (results and impacts of collaboration). These three categories form the basis for integration as they are widely used in IAC studies and enable the structured organization of complex multi-stakeholder processes. This led to the integration and refinement of concepts as evidenced in Table 3 below.



Reflection and Synthesis

Utilizing the information in Table 3, along with reflecting upon a number of Conceptual Frameworks considered as part of the literature review for both IAC and micro-credentials, this stage sought to synthesize this information into a visual representation of the emerging CF. The framework illustrates how sector-level drivers—such as Construction 4.0 digitalisation, geospatial skills shortages, evolving professional expectations, and shifts within HEI create a clear need for structured Industry–Academia Collaboration (IAC). These forces collectively shape a six-stage collaboration pathway that includes:

1. **Early Informal Engagement:** initial conversations between industry partners and the HEI where needs, interests, and emerging skill gaps are explored; builds trust and determines if collaboration is worthwhile.
2. **Memorandum of Understanding:** once mutual interest is established, partners formalise intentions through a non-binding agreement. This clarifies roles, expectations, and broad collaboration objectives without locking in detailed commitments.
3. **Collaborative Curriculum Development:** industry and HEI teams work together to design curriculum content, define competencies, shape assessments, and ensure learning aligns with real-world technologies and workflows. This stage is central to ensuring relevance and authenticity.
4. **Formal Collaborative Agreement:** partners move from intent to commitment through a binding agreement covering governance, responsibilities, IP considerations, resource inputs, scheduling, and shared oversight of teaching and assessment.
5. **Quality Assurance & Validation:** the collaboratively designed programme undergoes internal HEI QA processes; external assessor review, NFQ alignment and institutional approval, ensuring academic integrity and compliance.
6. **Professional Body Accreditation:** to review and endorse the programme or micro-credentials, confirming industry recognition and signalling credibility to learners and employers.

From these collaboration patterns emerge tangible outputs, including a 20-credit Certificate in Digital Geospatial Surveying (NFQ Level 7), four 5-credit modules, and skills-focused micro-credentials (e.g., GNSS, Total Station, Laser Scanning). These outputs impact across three domains: upskilling the geospatial profession, enabling HEIs to remain flexible and current, and strengthening industry workforce development. The proposed micro-credentials will be underpinned by competencies drawn from established geospatial frameworks (e.g., CICES competencies). Assessment is expected to follow practice-based tasks focused on data capture, processing accuracy, and applied problem-solving. A blended delivery model is envisaged, combining online preparation with equipment-based practical sessions co-delivered by KOREC Group staff. Evaluation in later phases of the research will consider indicators such as learner uptake, completion, employer recognition, and evidence of workplace application. These assumptions are preliminary but outline the pedagogical direction supporting the proposed IAC-driven micro-credential design.

Figure 1: Emerging Conceptual Framework

Future Work

The CF presented reflects the first iteration of a dynamic and ongoing collaborative process between SETU and KOREC Group. Currently, the IAC is at the Collaborative Curriculum Development stage, with an outline of the micro-credentials (output) in place. It is anticipated that the IAC CF will act as a catalyst for further development of both the framework and the micro-credentials with additional research involving:

- Validation focus groups with SETU & KOREC staff
- Interviews with surveyors/employers for input
- Cross-checking with existing frameworks

It is anticipated that empirical research will lead to the validation of a more robust IAC framework which might have applicability in other AEC contexts/professions.

Conclusions

This paper addresses the urgent challenge posed by the rapid digital transformation of the geospatial surveying profession and the lack of flexible educational pathways to develop required digital competencies. Existing literature on geospatial skills, micro-credentials, and Industry–Academia Collaboration (IAC) highlights a

persistent misalignment between evolving industry needs and traditional higher-education provision. In response, this study develops a conceptual framework for Digital Geospatial Micro-Credentials, grounded in multidisciplinary evidence and iterative action research between an Irish HEI and a Geospatial Surveying Services Provider. In terms of a novel contribution, the framework synthesises three previously disconnected domains: (1) digital and professional changes in geospatial practice, (2) micro-credentials as agile, workplace-aligned learning mechanisms, and (3) IAC frameworks that emphasise co-design and continuous feedback. Structured around a Drivers–Patterns–Outputs logic, it clarifies the motivations for collaboration, the mechanisms through which it should occur, and the expected impacts on workforce development. This integration contributes a coherent framework that addresses skills shortages, curriculum relevance, and the need for adaptive educational offerings. Limitations include its basis in secondary literature and early-stage partnership activity, requiring further empirical validation, as well as its initial grounding in the Irish geospatial context, which may affect broader applicability. Future work should test the framework in additional sectors, regions, and educational systems to strengthen generalisability. Next steps involve validating and operationalising the framework through co-design workshops, practitioner interviews, focus groups, and pilot micro-credential evaluation. These activities will refine framework components and identify enabling conditions for effective IAC in digital skills development, with potential extensions to national qualification systems, accreditation processes, and European micro-credential initiatives. In conclusion, this study offers a significant first step toward addressing the digital geospatial skills gap through a structured, collaborative, and evidence-based approach to micro-credential design. By integrating previously siloed literatures, the framework provides a foundation for developing relevant, responsive, high-quality upskilling opportunities aligned with the realities of a digitally transformed AEC sector, with further refinement expected as the research progresses. Future work will operationalise and empirically evaluate the pedagogical dimensions of the framework, including competency mapping, assessment design, delivery modality, and indicators of success such as uptake, completion, employer recognition, and workplace impact. These activities will strengthen the framework's validity and ensure its practical applicability in addressing digital geospatial skills shortages, with the potential to address wider challenges relating to the integration of Construction 4.0 technologies into formal education through collaboration between industry and academia.

OBJECT-LEVEL MULTI-DIMENSIONAL ANALYSIS OF LEVEL OF INFORMATION REQUIREMENTS ACROSS PROJECT LIFECYCLE

Pablo Martinez[1] and Marzia Bolpagni[1]
[1]Northumbria University, United Kingdom

Abstract

Optimizing multi-purpose specifications requires understanding information requirement overlap and burden distribution, yet systematic object-level analysis remains absent. This study introduces a hierarchical 12-KPI framework quantifying geometrical, alphanumerical information, and documentation requirements across 80 objects, 22 purposes, and five lifecycle phases using 5,048 specifications. The key contributions include: (1) a validated three-archetype hierarchy with distinct temporal signatures; (2) the identification of universal objects as multi-purpose integration points; (3) the quantification of purpose-specific uniqueness challenging consolidation assumptions; (4) an interactive dashboard enabling evidence-based Exchange Information Requirement optimization. This object-purpose-phase granularity advances systematic BIM specification from aggregate analysis to decision-support frameworks for practitioners.

Introduction

The adoption of the ISO 19650 series as international standards for information management using BIM creates expectations for standardised information delivery across project stakeholders (Abanda et al., 2025). This regulatory push, occurring alongside intensifying BIM mandates, creates substantial pressure for comprehensive, multi-purpose implementation serving diverse information needs throughout building lifecycles (Mitera-Kiełbasa & Zima, 2024). Each construction phase requires information in different forms, and what is required changes with the activities performed. Information models must simultaneously serve design coordination, regulatory compliance, energy analysis, cost estimation, construction planning, and facility management, each potentially requiring different information requirements as specified by stakeholders.

ISO 7817-1:2024 addresses this through the Level of Information Need (LOIN) framework, structuring requirements across three components: geometrical information (detail, dimensionality, location, appearance and parametric behaviour), alphanumerical information (properties and attributes), and documentation (deliverable files). Although "LOIN" is an acronym to be avoided in projects, it is used here for simplicity. The standard also introduces purposes, the specific reasons for information exchange, as the main organising principle for requirement specification. However, implementing LOIN requires decisions about which purposes to include, which building objects to specify for each, and how requirements evolve across phases from design through operation (Lindholm et al., 2025; Liu et al., 2023).

Despite extensive BIM research, systematic understanding of information requirements at object-purpose-phase granularity remains limited. Existing studies analyse requirements at aggregate levels, treating purposes as monolithic without examining variation across object types. Cavka et al. (2017) developed comprehensive owner requirement frameworks but did not differentiate by object. Krijnen and Tamke (2015) analysed implicit knowledge in models using machine learning yet focused on model-level patterns. Patacas et al. (2020) evaluated IFC and COBie for asset management but aggregated across objects. Phase-based studies investigate limited purpose sets or restricted object types (Noardo et al., 2020), and recent infrastructure work acknowledges substantial cross-discipline and cross-phase variation but lacks systematic object-level quantification.

More recent work has begun to operationalise LOIN. Malla et al. (2023) proposed a structured approach aligned with ISO 7817-1 yet remained at the purpose level without disaggregating by object. Lindholm et al. (2025) demonstrated LOIN-driven exchange connected to production planning, confirming applicability but limiting analysis to a single purpose context. EU-funded projects such as BIM4EEB and DigiChecks produced LOIN-based templates for energy retrofitting and regulatory compliance respectively, but address domain-specific purposes without cross-purpose comparison (Rathnasinghe et al., 2022). Quantitative or KPI-based assessment remains scarce: existing metrics focus on model maturity or compliance scoring rather than characterising the structure and distribution of requirements. To date, no comprehensive analysis examines how requirements for specific objects vary across multiple purposes and lifecycle phases.

This gap prevents evidence-based optimisation of multi-purpose specifications. Practitioners selecting purposes for Exchange Information Requirements (EIR) face unanswered questions: Do different purposes require fundamentally different information for the same objects, or do requirements largely overlap, enabling duplicity across models? Which objects accumulate the heaviest specification when multiple purposes converge? Can

shared baseline specifications satisfy multiple purposes, or are requirements genuinely purpose-specific? How do these patterns evolve from preliminary design through facility operation? Without systematic object-level evidence, decisions rely on institutional experience, vendor recommendations, or conservative over-specification, none enabling sustainable data-driven optimisation balancing coverage against practical constraints, overcomplicating BIM implementation and reducing data management efficiencies.

This study addresses this gap through systematic multi-dimensional analysis at object-purpose-phase granularity. This paper examines standardized information delivery purpose specifications across building object types and project phases aligned with RIBA Plan of Work 2020 (PoW), quantifying geometrical, alphanumerical, and documentation requirements for discrete object-purpose-phase sequential combinations. This granular approach enables investigation of requirement variation patterns, multi-purpose object utilization, and consolidation potential not addressable through aggregate analysis. An interactive dashboard complements the analytical framework, supporting practitioners in exploring purpose combinations and assessing marginal contributions for project-specific specification decisions.

This analysis addresses five research questions:

RQ1: How do information requirements vary across purposes, phases, and object types?

RQ2: What is the distribution of geometrical, alphanumerical, and documentation requirements across information delivery purposes?

RQ3: Which building objects exhibit highest information specification burden across multiple purposes?

RQ4: To what extent do individual objects support multiple information delivery purposes across project phases?

RQ5: What is the uniqueness of purpose-specific requirements at object-phase granularity?

Methodology

Data Source

The analysis utilized all 22 standardized information delivery purposes from BIMids, an industry-academic collaboration platform that supports the implementation of ISO 19650 series and ISO 7817-1 standards in construction projects. BIMids is maintained through collaboration between industry practitioners and academic researchers, with specifications developed through expert consensus and aligned directly with ISO 7817-1 LOIN component structures. It represents the largest publicly available multi-purpose LOIN specification dataset, providing systematic coverage across building object types, project phases, and information delivery purposes, supporting its relevance as an empirical basis for cross-purpose analysis. Each purpose specifies information requirements for building object types across three LOIN components (geometrical, alphanumerical, and documentation) and five project phases mapped to RIBA PoW 2020: Phase 1-PD (RIBA 0-2: Strategic Definition through Concept Design), Phase 2-FD/AUT (RIBA 3-4: Spatial Coordination through Technical Design), Phase 3-FP/TEND (RIBA 4-5: Tender through Early Construction), Phase 4-EXE/ASB (RIBA 5: Construction), Phase 5-OPE (RIBA 6-7: Handover through Use).

The dataset encompasses 80 building object types spanning architectural (door, window, wall, etc.), structural (beam, column, slab, etc.), and MEP (duct, pipe, lift, etc.) disciplines. In the end, a dataset is created comprising 5,048 requirements: 2,443 geometrical, 1,866 alphanumerical, 739 documentation (distributed across 2,603 object-purpose-phase combinations).

Interactive Dashboard

To enable practical application, an interactive web dashboard was developed to enable data access and serve as a combinatory playground for practitioners. The tool embeds all 22 purposes with complete object-level data (5,048 requirements) enabling offline browser-based analysis. Implementation uses vanilla JavaScript and Chart.js for universal compatibility.

Users may select purposeful combinations, and the dashboard shows the variability in information requirements based on the delivery purposes. For unselected purposes, the dashboard displays a marginal score (new requirements added) and uniqueness percentage (proportion not already covered by selected purposes), ranking recommendations by contribution value. The intended workflow follows four steps: (1) select initial information delivery purposes reflecting project requirements; (2) review real-time KPI updates showing cumulative coverage, component distribution, and object-level burden for the selected set; (3) evaluate the marginal contribution panel, which ranks unselected purposes by new requirements added and uniqueness percentage; and (4) iterate by adding or removing purposes until the desired coverage-to-overhead balance is achieved.

The dashboard supports exploratory investigation of purpose combinations, helping practitioners make evidence-based decisions about EIR specifications while visualizing information overhead implications.

LOIN-based KPIs

To address the research questions systematically, a hierarchical framework of KPIs operating at three analytical levels is proposed: purpose level (characterizing overall information delivery needs), object level (identifying integration points where multiple purposes converge), and combination level (quantifying granular requirement patterns). This hierarchical structure enables investigation from macro-patterns (which purposes are geometry-dominant?), through meso-patterns (which objects serve most purposes?), to finally micropatterns (how much do purposes overlap for specific objects in specific phases?). Figure 1 illustrates this

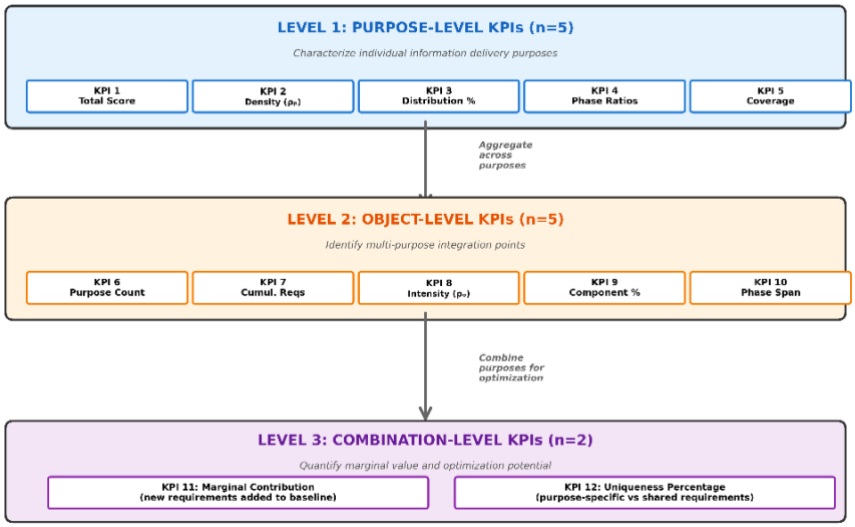

Figure 1. Hierarchical framework of LOIN Key Performance Indicators (KPIs).

hierarchical relationship and the specific LOIN KPIs proposed at each level.

Purpose-Level KPIs. For each purpose (p), five indicators characterizing its overall information requirements are defined.

Total Information Score: it quantifies information requirements burden.

$$S_p = \sum_{o \in O_p}(G_{p,o}w_G + A_{p,o}w_A + D_{p,o}w_D) \quad (1)$$

where (O_p) is the set of objects specified by purpose (p), and ($G_{p,o}$), ($A_{p,o}$), ($D_{p,o}$) represent geometrical, alphanumerical, and documentation requirement counts for object (o) in purpose (p). (w) are weighing coefficients given to each type of information purpose to model different management burden – external file references versus embedded geometrical or alphanumerical data. The default weighting adopted in this study assigns equal weights to geometrical and alphanumerical components and a reduced half weight to documentation. This choice reflects two considerations. First, ISO 7817-1 treats geometrical and alphanumerical information as structurally parallel LOIN components, both requiring embedded model data authored and maintained within the BIM environment, whereas documentation requirements reference external deliverable files with lower authoring overhead per specification. Second, in the absence of empirical evidence quantifying differential management burden across component types, equal weighting represents the most neutral baseline assumption, avoiding a priori bias toward either spatial or property-based specifications. The sensitivity of results to alternative weighting schemes is discussed in Section 5.

Information Density: this is the normalised score by object count, revealing the specification intensity per object.

$$\rho_p = S_p / |O_p| \quad (2)$$

High density purposes impose heavy specifications per object (intensive); low density purposes show broad but shallow coverage (extensive). This metric complements the Total Information Score as purposes can have high scores through either intensive specification of few objects or extensive specification of many objects.

Component Distribution Percentages: this KPI reveals information specialization for each purpose:

$$\%G_p = \frac{\sum_o G_{p,o}}{\sum_o (G_{p,o}+A_{p,o}+D_{p,o})} \quad (3)$$

with analogous definitions for ($\%A_p$) and ($\%D_p$). This KPI enables deterministic approaches to understand how burden is distributed across purposes, i.e. there may be geometrical-dominant purposes if ($\%G_p$)>0.5.

Phase Allocation Ratios: this KPI indicates temporal distribution of each purpose's information requirements across project phases.

$$R_{p,\phi} = \frac{|C_{p,\phi}|}{|C_p|} \quad (4)$$

where ($C_{p,\phi}$) is the set of requirements for purpose (p) in phase (ϕ), and (C_p) are the total requirements for purpose (p). This reveals whether purposes concentrate in design, construction, or operation phases.

Object Coverage: this KPI ($|O_p|$) simply counts the number of objects per purpose, indicating scope breadth versus narrow specialisation.

Object-Level KPIs. Purpose-level indicators aggregate requirements, but obscure which specific objects bear heaviest specification burdens. Object-level KPIs address this by aggregating across all purposes mentioning each object. For each object (o), it is defined:

Purpose Count: this KPI indicates multi-purpose utilization.

$$N_o = |\{p: o \in O_p\}| \quad (5)$$

Objects with a large (N_o) identify critical multi-purpose integration points requiring coordinated information management.

Cumulative Requirements: this KPI sums specifications across all purposes. This reveals absolute specification burden accumulated when multiple purposes converge on single object.

$$R_o = \sum_{p:o\in O_p}(G_{p,o} + A_{p,o} + D_{p,o}) \quad (6)$$

Information Intensity: this KPI provides a symmetric metric to purpose-level density, normalizing cumulative requirements by purpose count.

$$\rho_o = R_o / N_o \quad (7)$$

This reveals average specification burden per purpose using the object. High intensity objects are heavily specified by each purpose, whereas low intensity objects are lightly specified despite appearing in many purposes. This symmetry with (ρ_p) enables comparative analysis: purposes with high density specify many requirements per object; objects with high intensity accumulate many requirements per purpose.

Component Intensity: this KPI analyses cumulative composition of object information, revealing whether object specifications emphasise over geometry (coordination), properties (performance), or documentation (compliance).

$$I_o^G = \frac{\sum_p G_{p,o}}{\sum_p (G_{p,o} + A_{p,o} + D_{p,o})} \quad (8)$$

with analogous definitions for (I_o^A) and (I_o^D).

Phase Coverage: this KPI identifies object lifecycle span.

$$\Phi_o = \left|\{\phi: \exists p, o \in O_p\}\right| \quad (9)$$

distinguishing objects serving only single phases from those persisting through project lifecycle.

Combination-Level KPIs. The most granular level examines individual object-purpose-phase triplets (o, p, ϕ), enabling investigation of requirement overlap and consolidation potential.

Uniqueness: this KPI quantifies purpose-specific requirements versus shared requirements.

$$U_{o,p,\phi} = \frac{1}{|O_p| \times |\Phi_p|} \sum_{o\in O_p, \phi\in\Phi_p} \frac{\left|R_{o,p,\phi} \setminus \cup_{p' \neq p} R_{o,p',\phi}\right|}{|R_{o,p,\phi}|} \quad (10)$$

where ($R_{o,p,\phi}$) is the set of requirements for each triplet of information, averaged across all object-phase combinations where requirements exist. High uniqueness indicates genuine purpose-specific needs requiring dedicated specifications; low uniqueness suggests consolidation opportunities through shared baseline definitions.

Marginal Contribution: this KPI measures the incremental value of each information set when adding a new purpose to a baseline set.

$$M_{p'} = \frac{\left|R_{p'} \setminus \cup_{p\in P_{base}} R_p\right|}{|R_{p'}|} \quad (11)$$

where (R_p) represents all the requirements for purpose (p). This efficiency metric enables evidence-based purpose prioritisation during EIR specification. Purposes with high (M_p) contribute substantial new information, while those with low (M_p) largely duplicate selected purpose information.

Analytical Framework

The analysis employs a progressive validation framework advancing from descriptive pattern identification through multivariate confirmation, structured in five complementary phases. Descriptive analytics will first establish empirical patterns through univariate distributions and bivariate relationships, identifying three purpose archetypes based on component composition (geometrical, alphanumerical, and documentation dominant), universal objects spanning multiple purposes, and temporal requirement concentration patterns. These descriptive findings generate hypotheses requiring statistical validation: whether archetype classifications represent natural groupings versus arbitrary thresholds, whether the proposed 12-KPI framework provides complementary versus redundant measurements, and whether patterns generalize across analytical dimensions.

Multivariate validation is then employed through four methods testing different framework aspects. Correlation analysis (Pearson r across the 12×12 KPI matrix) assesses indicator complementarity, where low-moderate within-level correlations confirm coherence without redundancy. Cronbach's alpha validates internal consistency at each level, where low alpha combined with weak cross-level correlations confirms a multidimensional complementary design rather than a unidimensional redundant scale. Principal component analysis then reveals dataset dimensionality, reducing the 12 KPIs to combined orthogonal components and demonstrating archetype clustering in multivariate space, empirically validating natural groupings. Finally, temporal profile analysis extends validation to the lifecycle dimension, revealing archetype-specific phase concentration patterns that transcend component and object composition differences.

Methodological triangulation across five analytical phases provides convergent validation unavailable through single-method approaches. Patterns identified descriptively (archetype classification, universal objects, phase concentration) receive confirmation through correlation structure, dimensional reduction, and temporal differentiation. This progressive framework—descriptive hypothesis generation followed by multivariate statistical validation—strengthens confidence that findings represent genuine data structure rather than analytical artifacts, supporting framework generalizability beyond the BIMids case study.

Reflecting on the research questions established, RQ1 (requirement variation) is addressed through purpose-level KPIs via descriptive analytics and temporal profiling. RQ2 (component distribution) is addressed through descriptive analytics and PCA archetype validation. RQ3 (object specification burden) is addressed through object-level KPIs via descriptive analytics and correlation analysis. RQ4 (multi-purpose object coverage) is addressed through correlation analysis and PCA. RQ5 (purpose-specific uniqueness) is addressed through combination-level KPIs via descriptive analytics and dashboard implementation.

Results

Descriptive Analysis

This section addresses RQ1–RQ4 through descriptive characterisation of purpose archetypes, object-level burden, and lifecycle patterns. Analysis of LOIN component distribution across 22 purposes reveals three distinct purpose archetypes (see Figure 2). Geometrical-dominant purposes (n=15, 68%) allocate majority requirements to spatial specifications: '2D documents' (100% geometrical, 374 requirements total) and 'Clash detection' (96.5% geometrical, 342 requirements) exemplify purposes where 3D spatial representation is paramount. Alphanumerical-dominant purposes (n=5, 23%) prioritize property data: 'Maintenance' (57.8% alphanumerical, 552 total requirements) focuses on operational parameters including schedules, warranties, and performance thresholds. Documentation-dominant purposes (n=1, 5%) emphasize deliverable files: 'Minimum requirements' (59.4% documentation, 1,130 total) establishes comprehensive baseline spanning all components but emphasizing document deliverables.

Total information requirements vary substantially: 'Minimum requirements' (1,130) and 'Maintenance' (552) impose heaviest specification loads, while specialized purposes like 'Programming' (5) and 'Access management' (43) target narrow scopes with low demand.

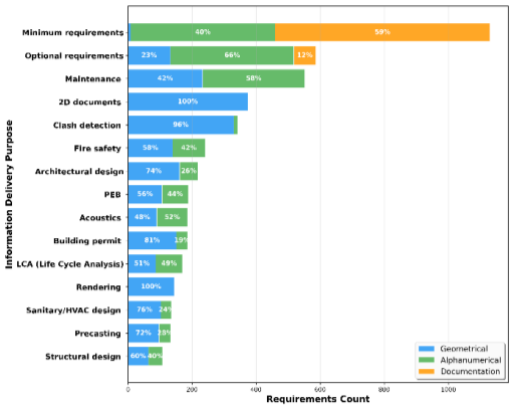

Figure 2. Top 15 component distribution by purpose.

Object-level aggregation identifies universal building elements supporting multiple purposes (see Figure 3). Core architectural objects accumulate highest cumulative requirements: door (172 requirements across 16 purposes), window (148, 16 purposes), ramp (133, 15 purposes), space (125, 17 purposes), slab (122, 14 purposes). These objects function as integration points because they serve multiple purpose archetypes: geometrical-dominant purposes require spatial properties for coordination, alphanumerical-dominant purposes specify performance attributes, and documentation-dominant purposes demand compliance deliverables.

Space achieves highest purpose count (17) spanning spatial programming through facility management; door and window support 16 purposes each. In contrast, specialized MEP equipment serves 1-4 purposes only. Analysis reveals 29 objects (36%) support 10+ purposes each, identifying critical targets for standardization and information quality management.

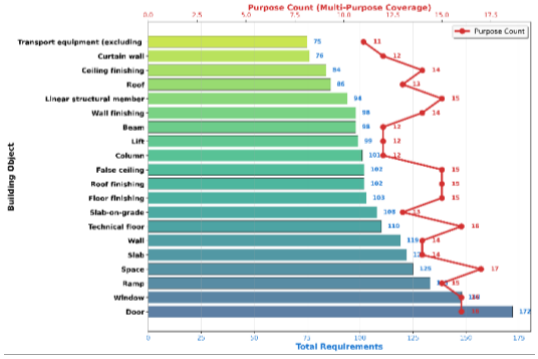

Figure 3. Top 20 object analysis by total requirements and multi-purpose coverage.

Requirement distribution across phases demonstrates progressive intensification (see Figure 4). Phase 1 specifies 660 requirements, escalating to 2486 in Phase 2 (+277%), 3784 in Phase 3 (+52%), peaking at 4750 in Phase 4 (+26%). Phase 5 surprisingly denotes fewer requirements at 3485 (-27%) for operation and use. Note that there is quite a balanced G-A-D distribution across project phases.

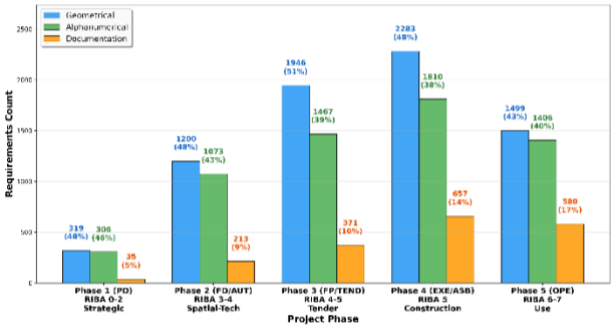

Figure 4. Lifecycle requirement intensification by component.

Correlation Analysis

This section validates KPI complementarity underpinning all five research questions, with relevance to RQ3 and RQ4 (object-level structural relationships). Correlation analysis across hierarchical levels reveals predominantly weak to moderate inter-correlations, supporting complementary nature of the proposed indicators (see Figure 5). However, some can be noted: 1) there is a significant positive correlation ($r > 0.9$) between (N_o) and (R_o) and (ρ_o) and (Φ_o) denoting structural relationships between KPIs (as expected based on their equations); 2) there is a moderate negative correlation ($r = -0.399$) between total information score and uniqueness demonstrating the cumulative nature of information requirements and duplicities existing in practice; and 3) there is a significant positive correlation ($r > 0.9$) also between ($R_{p,\phi}$) and (ρ_o), which may indicate a structural pattern in information requirement distribution across project lifecycle.

When looking at the cross-independence of the KPIs (purpose level vs. object level), there is a minimal

correlation between them (median $|r| = 0.22$). This confirms that the bi-level KPI definition captures different dimensions of LOIN integration and validates the hierarchical approach.

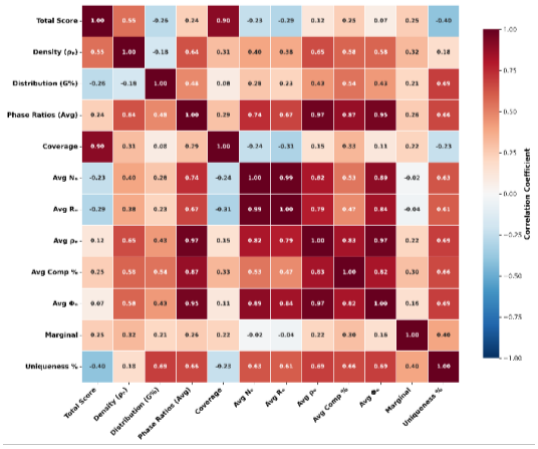

Figure 5. Correlation matrix for the 12 proposed LOIN KPIs.

The Cronbach's alpha results show internal consistency for purpose-level KPIs as they demonstrate low inter-item correlation (α=0.19), confirming multi-dimensional measurement where each indicator captures distinct information aspects. Object-level KPIs show moderate consistency (α=0.56), reflecting structural relationships (e.g., multi-purpose objects accumulate requirements) while maintaining conceptual distinctiveness. Low within-level alpha combined with weak cross-level correlations (median |r|=0.22) validates the framework's multi-dimensional design: indicators provide complementary rather than redundant information, justifying the 12-KPI structure.

Principal Component Analysis

Principal component analysis on all 12 KPIs reveals concentrated variance structure with first three components explaining 87.4% (PC1: 52.3%, PC2: 22.7%, PC3: 12.4%), demonstrating efficient framework dimensionality. PC1 presents existing object-level lifecycle complexity ($\overline{\Phi_o}$: 0.392, $\overline{\rho_o}$: 0.391), separating purposes with sustained cross-phase object engagement from phase-concentrated specifications. PC2 captures purpose scope (Total Score: 0.595, Coverage: 0.540), distinguishing comprehensive from specialized purposes. PC3 emphasizes component archetype (Geom %: 0.599), with purposes clustering in multivariate space according to archetype classifications (see Figure 6). This emergent clustering validates the three-archetype framework: purposes classified by component thresholds demonstrate multivariate similarity within groups and dissimilarity across groups, confirming natural rather than arbitrary categorization. High PC1 variance (52.3%) suggests object-level temporal patterns dominate purpose variation, informing optimization priorities. Framework efficiency—87.4% variance captured by three dimensions from 12 indicators—supports measurement adequacy without redundancy.

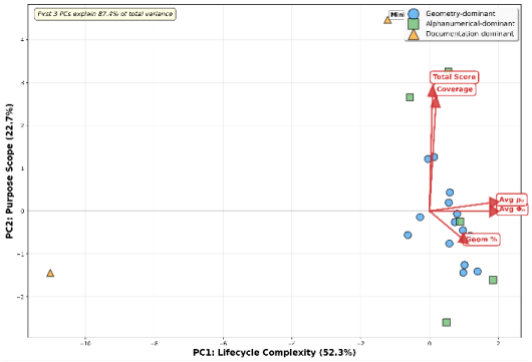

Figure 6. Principal component analysis biplot: purpose clustering and LOIN KPIs loadings.

Temporal Profile Analysis

Temporal profiling completes the validation of RQ1 by demonstrating archetype-specific lifecycle signatures. The temporal requirement profiling reveals that each archetype exhibits a distinct project lifecycle signature (see Figure 7). Geometrical-dominant purposes concentrate in Phase 3 (mean: 32.4%) and decline sharply in Phase 5 (mean: 12.6%). This reflects the spatial coordination emphasis during detailed design that diminishes after the construction stage. In contrast, alphanumerical-dominant purposes distribute more uniformly across phases (concentration coefficient: 0.33) and sustain strong operational presence (Phase 5: 22.5%). This reflects performance monitoring needs throughout the building lifecycle. Documentation-dominant purposes show gradual accumulation without dramatic peaks. Figure 7 left panel compares mean archetype profiles (solid lines) against the overall average (dotted lines). As seen, geometrical purposes peak earlier than average while alphanumerical purposes sustain beyond average into operation. Its right panel shows normalized stacked bars for all 21 individual purposes, revealing systematic clustering by archetype despite variation within groups. Purposes with similar component compositions exhibit similar temporal patterns, independent of their total burden. This temporal differentiation validates archetype classification through an independent dimension beyond component percentages, demonstrating that geometrical-dominant, alphanumerical-dominant, and documentation-dominant purposes differ fundamentally by which project phase requirements concentrate, not merely in what components dominate.

Discussion

The three-archetype classification, validated through PCA and temporal profiling, reveals fundamental differences in how information purposes operate across

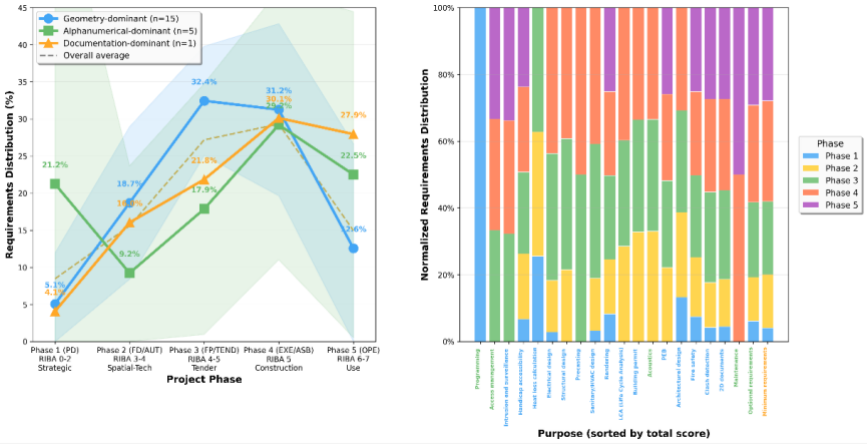

Figure 7. Temporal profiling analysis. Left: average temporal profile of the requirements distribution by project phase. Right: phase distribution per purpose.

building lifecycles. Geometrical-dominant purposes peak during detailed design coordination then declines post-construction, whereas alphanumerical-dominant purposes sustain operational relevance, reflecting performance monitoring needs. This suggests purpose selection should align with project delivery emphasis, consistent with established procurement patterns: design-build contracts typically emphasise early geometry coordination for clash detection, while long-term arrangements demonstrate value in lifecycle information exchange and operational performance monitoring (Ozcan-Deniz & Lokhandwala, 2023), indicating differential emphasis rather than exclusive requirements across procurement routes.

The identification of universal objects supporting 16-17 purposes confirms theoretical expectations from ISO 7817-1 about multi-purpose convergence on core architectural elements. However, the cumulative burden (e.g., door: 172 requirements) raises practical concerns about specification overload and duplicities. High uniqueness scores indicate however limited consolidation potential; available purposes genuinely require distinct information despite object overlap. This validates ISO 7817-1's purpose-driven approach but challenges assumptions about baseline specifications serving multiple purposes efficiently.

The interactive dashboard operationalises findings by quantifying marginal contribution and uniqueness for purpose combinations, letting practitioners identify high-value additions versus redundant purposes. For example, adding 'Maintenance' to geometrical-dominant baselines provides substantial alphanumerical information (57.8%) with moderate uniqueness, whereas adding 'Clash detection' to existing coordination purposes yields diminishing returns.

To illustrate, consider a practitioner preparing an EIR for a design-build project. They select 'Clash detection' and 'Energy analysis' as initial purposes, covering 58 and 41 objects respectively with predominantly geometrical requirements, giving cumulative coverage of 63 unique objects and 684 total requirements. The marginal contribution panel then ranks remaining purposes: 'Maintenance' contributes 552 new requirements (57.8% alphanumerical) with approximately 65% uniqueness, indicating substantial non-overlapping content. In contrast, 'Quantity take-off' contributes only 38% new requirements, largely duplicating geometrical specifications already covered by 'Clash detection'. The practitioner can therefore justify including 'Maintenance' as a high-value addition while deprioritising 'Quantity take-off', reducing overhead without sacrificing coverage.

The 12-KPI framework enables evidence-based EIR optimization, moving beyond institutional practice toward data-driven specification. Purpose-level indicators identify comprehensive versus specialized approaches; object-level metrics highlight multi-purpose integration points requiring quality management; combination-level metrics quantify consolidation feasibility. This hierarchical structure supports decisions at strategic (which purposes?), tactical (which objects?), and operational (which requirements?) levels.

The weighting assumption in Total Information Score treats geometrical and alphanumerical equally ($w_G = w_A = 1$) while assigning reduced weight to documentation ($w_D = 0.5$), potentially oversimplifying data acquisition and management differences between embedded model data and external file references. Preliminary sensitivity analysis varying the weighting ratio w_G:w_A:w_D across three alternative schemes, be that (2:1:0.5), (1:2:0.5), and (1:1:1), indicates that archetype classification remains stable: all 22 purposes retain their original archetype assignment, and the top-10 purpose ranking by Total Information Score changes by at most two positions. This suggests moderate robustness to weighting assumptions for the primary analytical findings. Nevertheless, further weighting scenarios (e.g., $w_D = 2$, reflecting high document management overhead in regulated projects) could alter downstream interpretations, and systematic sensitivity analysis across a wider parameter space, including weighting based on project role or stakeholder positioning, remains warranted.

The empirical findings reflect BIMids specification patterns and may not generalise directly to bespoke employer specifications, non-European regulatory contexts, or different infrastructure typologies (bridges, tunnels, process plants). Nevertheless, BIMids represents

the largest publicly available multi-purpose LOIN specification dataset with expert-consensus development, providing the strongest available empirical basis for cross-purpose analysis. The 12-KPI framework itself is source-agnostic: its formulations depend only on object-purpose-phase triplets with geometrical, alphanumerical, and documentation components, and can be applied to any dataset structured according to ISO 7817-1. Future research should validate archetype classification and universal object patterns through comparative crosswalks against national LOIN implementations (e.g., Dutch, Finnish, or Austrian frameworks) and extend analysis to the remaining LOIN aspects in ISO 7817-1 (detail, dimensionality, parametric behaviour) not covered here.

Conclusions

This study systematically quantified information requirement patterns across object-purpose-phase dimensions using 5,048 specifications from 22 standardized BIM purposes. The hierarchical 12-KPI framework operating at purpose, object, and combination levels revealed three distinct archetypes validated through multivariate analysis: geometrical-dominant purposes (68%) concentrating in design coordination, alphanumerical-dominant purposes (23%) sustaining through operations, and documentation-dominant purposes (5%) establishing baseline deliverables. Universal objects accumulate heaviest specification burden across 16-17 purposes, identifying critical multi-purpose integration points.

Principal component analysis confirmed framework dimensionality (87.4% variance in three components) and archetype clustering, demonstrating natural rather than arbitrary categorization. Temporal profiling validated archetypes through independent lifecycle signatures, transcending component composition differences. Correlation analysis revealed complementary indicator structure (median cross-level r=0.22), supporting measurement adequacy without redundancy.

The interactive dashboard operationalizes findings for practitioners, enabling evidence-based EIR optimization through marginal contribution and uniqueness quantification. High uniqueness scores across purposes challenge consolidation assumptions, validating ISO 7817-1's purpose-specific approach while highlighting ISO 19650 specification overhead implications.

This granular analysis advances BIM research from aggregate requirement studies to object-level multi-dimensional characterization, providing empirical foundation for standardization efforts and practical decision support for project information management. Future research should validate findings across construction typologies, test alternative KPI weighting schemes, and extend temporal analysis beyond RIBA phase structures to international delivery models.

FROM ANALYSIS TO DESIGN: TEACHING ALGORITHM-AIDED DESIGN IN STRUCTURAL ENGINEERING

Marcin Luczkowski[1], Anders Rønnquist[2]
[1]NTNU, Norwegian University of Science and Technology, Trondheim, Norway

Abstract

The increasing integration of computational tools and automated workflows in structural engineering practice calls for corresponding developments in engineering education. This paper presents TKT4198, a Master's-level course designed to introduce algorithm-aided design through a project-based, design-oriented format. Drawing partial inspiration from architectural design studios, the course enables structural engineering students to design structural systems from scratch while progressively integrating parametric modelling, finite element reasoning, and basic algorithmic methods. The paper describes the course structure, key assignments, and pedagogical rationale, and reflects on survey-based observations regarding student perceptions.

Introduction

The Architecture, Engineering, and Construction (AEC) sector is undergoing a rapid transformation driven by the increasing use of computational tools, data-rich models, and automated design workflows. Parametric modelling, algorithm-aided design (AAD), and digital optimisation techniques are now routinely employed in practice to support early-stage design exploration, performance assessment, and interdisciplinary collaboration. Structural engineers are therefore increasingly expected not only to analyse predefined systems, but also to actively engage with design logic, digital models, and evolving computational methods.

Despite these developments, structural engineering education remains largely centred on deterministic analysis methods and established calculation procedures. While these foundations are essential, they often provide limited exposure to computational thinking, parametric reasoning, and exploratory design workflows. As a result, students may graduate with strong analytical skills but limited experience working on design problems where geometry, structural behaviour, and digital tools are tightly coupled and continuously evolving.

In parallel, computational design education has historically been more strongly embedded within architectural curricula, where parametric modelling and visual programming have been used to explore form, spatial organisation, and fabrication logic. Only more recently have civil and structural engineering programmes begun to incorporate algorithmic design approaches, often in the form of advanced electives or software-oriented courses. There remains a need for accessible educational formats that introduce algorithm-aided design as a conceptual engineering skill, rather than as a specialised or tool-dependent competence.

This paper presents TKT4198, a Master's-level course developed at the Norwegian University of Science and Technology that addresses this gap through a project-based, design-oriented approach. Drawing partial inspiration from architectural design studios, the course is structured to allow structural engineering students to design structural systems from scratch while progressively integrating parametric modelling, finite element reasoning, and basic algorithmic methods. Rather than separating design and analysis, the course treats computation as an integral part of structural reasoning and decision-making.

The course emphasises gradual skill development through weekly assignments, live problem solving, and open-ended design tasks. Computational tools are introduced not as isolated software environments, but as instruments for exploring structural behaviour, testing design assumptions, and developing methodological understanding. By doing so, the course aims to prepare students for real-world engineering problems characterised by increasing automation, digital integration, and uncertainty.

The objective of this paper is to describe the pedagogical structure, content, and educational rationale of TKT4198, and to situate it within the broader context of computational design education for structural engineers. By presenting the course as a transferable educational framework rather than a software-driven solution, the paper contributes to ongoing discussions on how algorithm-aided design can be meaningfully integrated into contemporary structural engineering curricula.

In addition, the paper seeks to examine how the integration of parametric modelling, finite element reasoning, and introductory algorithm implementation within a single course framework influences students' perceived understanding of computational design concepts and their ability to engage with design-oriented structural problems. To support this, the study reflects on longitudinal survey data and course observations, addressing the following questions: (1) how students' awareness of parametric and algorithm-aided design

evolves during the course, and (2) to what extent the proposed teaching framework supports the integration of design and analysis in structural engineering education.

Background

Development of FEM Software and Its Integration with CAD and BIM Environments

The development of finite element method (FEM) software has evolved from standalone numerical analysis tools toward increasingly integrated components of digital design workflows. Early FEM applications were primarily verification-oriented, relying on simplified geometric input and manual data transfer, which reinforced a linear separation between design and analysis. Within the broader discourse on computational design, this separation has been critically examined, with authors arguing that designers and engineers should actively construct and adapt their own computational tools and workflows rather than rely solely on predefined software environments (Aish, 2014). This perspective has become increasingly relevant as structural design processes move toward automation, parametric control, and algorithm-aided workflows.

With the widespread adoption of computer-aided design (CAD) systems, FEM software began to accept direct geometric input, reducing the need for model reconstruction and enabling closer alignment between design intent and analytical representation. This shift was further accelerated by the introduction of Building Information Modelling (BIM), which promoted data-rich models combining geometry, material properties, and structural information. BIM platforms such as Autodesk Revit allow the creation of analytical models directly from geometric descriptions, supporting early structural reasoning within the design environment, although such models often require refinement for detailed analysis.

Interoperability between design and analysis tools has been further supported through standardised data exchange formats, most notably IFC. Structural analysis software such as FEM-Design can use IFC-based input, enabling FEM models to be derived from BIM environments while maintaining consistency in geometry and material definitions. In parallel, several FEM platforms have developed stronger links to parametric modelling environments, reflecting the growing importance of algorithm-aided workflows.

Over the last decade, parametric and algorithmic modelling tools have played a key role in automating and integrating structural design processes. Plugins and interfaces connecting FEM software with Grasshopper, such as those developed for FEM-Design and SOFiSTiK, allow procedural generation of analysis models and support iterative design exploration. At the same time, tools such as Karamba3D embed FEM functionality directly within the parametric modelling environment, enabling geometry generation, analysis, and feedback to occur within a single computational framework.

These developments mark a significant shift toward automated and iterative design processes, where FEM is no longer treated solely as a final verification step. Instead, analysis increasingly becomes an active component of design exploration, highlighting the importance of computational workflows that integrate modelling, analysis, and algorithmic control—both in professional practice and in engineering education.

Availability of Parametric Modelling and Algorithm-Aided Design Courses in Higher Education

For many years, parametric modelling and algorithm-aided design (AAD) were taught predominantly within the domain of architectural education. Early courses focused on geometric exploration, form generation, and visual programming, often prioritising conceptual and aesthetic outcomes over structural performance or numerical analysis. Visual programming environments enabled designers to explore complex geometries without extensive programming knowledge, reinforcing the adoption of parametric workflows primarily within architecture and design disciplines.

Over the past decade, this situation has begun to change. The increasing integration of computational tools into engineering practice has motivated civil and structural engineering programmes to introduce parametric modelling and algorithmic workflows into their curricula. These courses often aim to bridge design generation with structural reasoning, though the depth of integration between geometry, analysis, and computation varies significantly across institutions.

Several architecture-led courses incorporate structural performance as part of computational design education. For example, ARCH9110 Code to Production at The University of Sydney integrates parametric modelling with performance-driven design and fabrication workflows, including references to structural behaviour, while remaining primarily rooted in architectural education (The University of Sydney, 2024). Similarly, teaching and research activities at ETH Zurich have long addressed computational structural design through graphic statics and form-finding methods, typically embedded within architectural design studios rather than formal civil engineering courses (ETH Zurich, 2021).

In parallel, several engineering-oriented courses have emerged that explicitly connect parametric modelling with structural analysis. The course Computational Structural Design at the Technical University of Munich combines parametric geometry generation with structural evaluation methods, introducing students to form-finding techniques and finite element analysis within an integrated workflow (Technical University of Munich, 2024). At TU Darmstadt, courses on spatial structures introduce parametric design tools for generating and analysing structural systems, though they tend to focus on tool-based workflows rather than on student-implemented numerical methods (TU Darmstadt, 2024).

At the graduate level, some hybrid courses explicitly address computational optimisation and numerical reasoning. At the Massachusetts Institute of Technology, Computational Structural Design and Optimization integrates finite element methods with computational

design and optimisation strategies, but it assumes strong prior knowledge in structural mechanics and numerical methods and does not focus on introductory programming pedagogy (Massachusetts Institute of Technology, 2024). A comparable approach is found at Carnegie Mellon University, where advanced elective courses explore computational structural design and form-finding, typically targeting students with existing coding and analysis experience (Carnegie Mellon University, 2024).

Other offerings, such as CEE 220C Parametric Design and Optimization at Stanford University, introduce parametric and optimisation-based approaches within civil engineering, with a stronger emphasis on optimisation concepts than on early-stage geometric design or explicit finite element modelling (Stanford University, 2024). Similarly, modelling-oriented courses at Tampere University introduce algorithm-aided workflows within structural engineering contexts, though coding and optimisation are often addressed through predefined software environments rather than through student-implemented algorithms (Tampere University, 2022).

Overall, these examples illustrate a clear expansion of parametric modelling and AAD beyond architectural education into civil and structural engineering programmes. However, most existing courses focus either on parametric geometry generation without deep structural integration, or on advanced computational analysis and optimisation without addressing algorithmic transparency. Few courses systematically combine parametric modelling, finite element reasoning, and introductory algorithm implementation within a single, accessible course framework. This gap highlights the need for pedagogical approaches that treat algorithm-aided design as a conceptual engineering skill rather than as a specialised or software-dependent technique.

Course Context and Objectives

TKT4198 is a 7.5 ECTS course offered at the fifth-year (Master's) level at the Norwegian University of Science and Technology (NTNU, 2025). The course is primarily targeted at structural engineering students but is also open to students from other engineering disciplines, supporting interdisciplinary participation. It introduces algorithm-aided design and computational workflows as a complement to traditional analysis-oriented courses, with focusing on digital modelling, conceptual structural design, and the integration of geometry and analysis within contemporary engineering practice. The course is grounded in a project-based learning approach, where open-ended tasks are used to support the development of engineering judgement in computational design contexts.

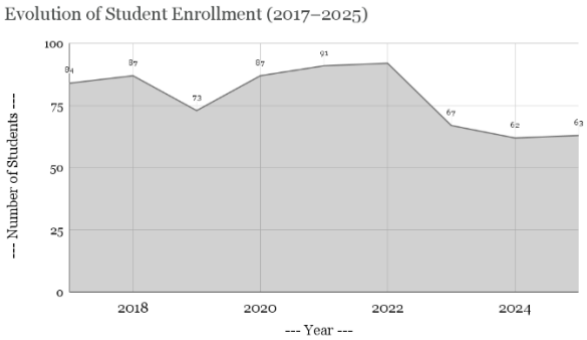

Figure 1: Number of students in the following years

As illustrated in Figure 1, the course has shown consistently high enrolment in recent years. The number of actively participating students in the course has stabilised at around 60 students per iteration, where "active" participation refers to students who regularly submit weekly assignments. In addition, the course typically attracts an additional 10–20 passive participants, who attend lectures and follow the course material without submitting all assignments. Approximately 20% of enrolled students are exchange students, contributing to a diverse cohort with varied academic and cultural backgrounds. This sustained level of participation indicates that computational and algorithm-aided design topics address a clear demand within the student body.

The course assumes prior knowledge consistent with a Master's-level engineering curriculum, including structural mechanics, basic structural analysis, and material behaviour. No prior experience with parametric modelling, visual programming, or programming languages is required. This allows computational methods to be introduced as conceptual design and reasoning tools rather than as advanced software or programming specialisations.

The primary objective of the course is to make students comfortable operating within digital environments commonly used in structural engineering. This includes the creation and interpretation of geometric and finite element (FE) models, as well as the critical assessment of modelling assumptions and analysis results. The course is organised into two main phases: an initial phase focusing on geometric modelling and finite element analysis, followed by a phase addressing conceptual structural design through algorithmic methods, including visual programming and introductory Python scripting. Throughout the course, structural analysis is treated as an integrated part of the design process rather than a post-design verification step, encouraging reflective and critical use of computational tools.

Course Assignments and Learning Progression

The course is organised as a 14-week sequence of weekly assignments, supported by five hours of scheduled teaching per week. In contrast to conventional course formats that separate lecturing and exercises (typically

two hours of lectures and three hours of supervised work), TKT4198 deliberately avoids a strict distinction between lectures and exercises. Each teaching session combines theoretical explanation with live problem solving, where the instructor develops models, analyses, and algorithms in real time while explaining the underlying concepts and design rationale.

This blended format allows students to engage with both theory and application simultaneously. Some students actively follow and reproduce the steps during class, while others observe and revisit the material later. To support different learning paces and backgrounds, all sessions are recorded, and recordings of both teaching and selected assignment solutions are made available through an online video platform. This ensures that students can revisit complex topics and reinforces continuity between weekly assignments and in-class activities.

Assignments constitute the core teaching mechanism of the course and are used to progressively introduce parametric modelling, finite element analysis, and algorithmic thinking. Students must successfully complete at least 80% of the weekly assignments to be eligible for the final examination. Rather than providing introductory software tutorials, the course adopts a learning-by-doing approach, where software proficiency emerges through increasingly complex modelling tasks.

Early assignments focus on fundamental structural modelling concepts, such as beam-based finite element models for investigating different truss topologies. Students are required to compare alternatives and justify structural choices through concise reports. As the semester progresses, assignments introduce parametric modelling, scripting, form-finding, buckling analysis, and optimisation tasks, with increasing freedom for students to propose their own solutions.

The course concludes with a four-hour, on-campus digital examination at NTNU facilities. All students work on identical computer setups with the same software environment. The exam consists of four open-ended design and analysis tasks, closely aligned with the assignments, and serves as a final assessment of the students' ability to integrate modelling, analysis, and algorithmic reasoning within a limited timeframe.

In the following sections, two representative assignments from the course are presented in more detail, as they illustrate the central pedagogical principles and methodological approach of TKT4198.

Parametric Auditorium Assignment

The parametric auditorium assignment is introduced after the third week of the semester, at a point when students have been exposed to basic parametric modelling concepts but have not yet engaged with finite element analysis or structural calculations. The aim of the assignment is to introduce algorithm-aided design through structural reasoning rather than numerical verification, reflecting early-stage design conditions where decisions are often made before detailed analysis is available.

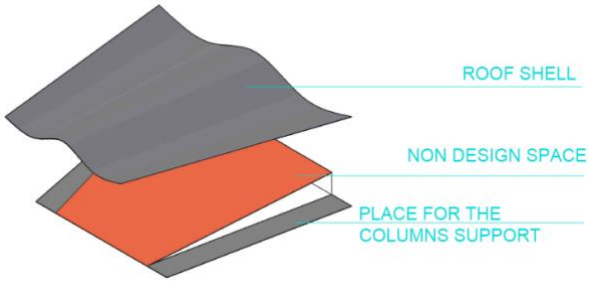

Figure 2: Graphical explanation of assignment task

The task requires students to propose a supporting structural system for an outdoor auditorium roof under clearly defined architectural constraints. As illustrated in Figure 2, the roof geometry is provided as a reference surface that must not be intersected by the structure. A non-design space is defined above the audience area, restricting the placement of structural elements in the central functional zone. Column supports are allowed only in designated areas along the sides of the auditorium. These constraints force students to explicitly plan the load-bearing system, considering issues such as spatial clearance, functional requirements, and constructability, without relying on structural calculations.

Students are required to generate the supporting structure using a fully parametric model, typically exploring systems such as grid shells, frames, or truss-based solutions. Key parameters—including grid spacing, geometric subdivision, and overall dimensions—must be controllable within the model. To demonstrate that the model is genuinely parametric, students are required to present at least three distinct design variants derived from the same algorithmic definition, rather than three separately modelled solutions.

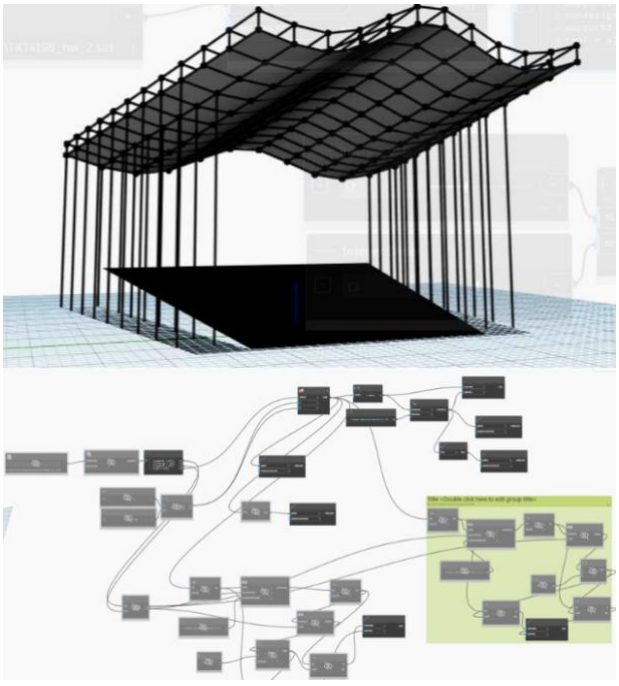

Figure 3: One of the possible solutions sent by student

An example of a student-developed solution is shown in Figure 3, where a grid-based roof structure is generated algorithmically and supported by columns placed outside the non-design space. The figure also illustrates the underlying parametric definition, highlighting how geometric logic, rather than manual modelling commands, governs the structural layout. At this stage, students are not asked to verify structural performance through FEM; instead, the focus is on structural discussion, including the plausibility of the load paths, the efficiency of the support strategy, and the adaptability of the system to changing design requirements.

The assignment is intentionally formulated to discourage the use of ad-hoc or purely geometric modelling commands. Instead, students are encouraged to approach parametric modelling from a methodological perspective, moving from general rules to detailed geometry. By observing how changes in parameters propagate through the model, students experience the practical value of parametric modelling as a design and analysis tool. This approach aims to motivate experimentation with algorithm-aided methods and to establish parametric thinking as a meaningful component of structural design reasoning, rather than as a purely formal or software-driven exercise.

Truss Optimisation with Genetic Algorithms

The truss optimisation assignment is introduced at the end of the semester, after approximately twelve weeks of continuous work with parametric modelling, finite element analysis, and scripting. At this stage, students have already performed FEM analyses of buildings, spatial structures, and bridge-like systems, and have implemented Python code within parametric environments to generate and manipulate structural components. The assignment is scheduled immediately after a dedicated lecture introducing the principles of simple genetic algorithms, including population-based search, mutation, selection, and convergence.

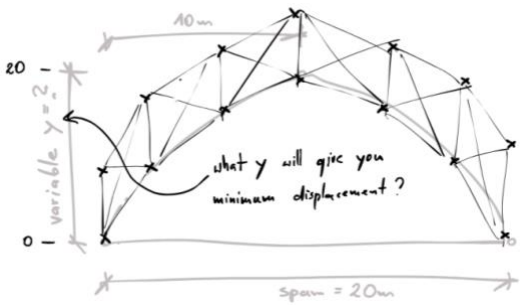

Figure 4: Graphical explanation of the assignment task

The task requires students to integrate parametric geometry generation, finite element modelling, and algorithmic optimisation within a self-written computational workflow. As illustrated in Figure 4, the optimisation problem is formulated using a simple, arc-like truss structure spanning a fixed distance. Selected geometric parameters—most notably the vertical position of nodes—serve as design variables. The objective is defined as a single-objective optimisation, typically minimising structural displacement under a prescribed load case.

Students are explicitly required to implement the genetic algorithm from scratch in Python, without relying on optimisation plugins or external libraries. The optimisation loop integrates three components: parametric geometry creation, linear elastic FEM analysis of a two-dimensional truss system, and fitness evaluation based on structural response. This requirement is intentional and reflects the course's emphasis on algorithmic transparency rather than software proficiency. Students are encouraged to implement and test their code in different computational environments, reinforcing the portability of algorithmic thinking beyond a single platform.

An example student solution is shown in Figure 5, including the resulting optimised geometry and the corresponding structural deformation. Quantitative results, such as convergence of displacement values across generations, are reported alongside visual feedback, allowing students to relate numerical outcomes to geometric changes. At this stage, the goal is not to obtain an optimal engineering solution, but to understand how design decisions propagate through a coupled geometry–analysis–optimisation pipeline.

The simplicity of the optimisation problem is a deliberate pedagogical choice. Based on several years of teaching experience, it has been observed that introducing highly complex numerical models or large variable sets often leads students to reproduce template solutions rather than actively engage with the algorithm. By limiting the number of variables and focusing on a transparent optimisation structure, the assignment encourages experimentation, modification, and critical reflection. In this way, students are exposed to optimisation not as a black-box tool, but as a design method that can be adapted, questioned, and extended—an approach that aligns with the broader aim of positioning algorithm-aided design as an active component of structural engineering practice.

Generation	$y\ [m]$	Displacement $[mm]$
1	7,38	3,03
10	9,40	2,93
20	9,40	2,93

I.e. the overall best arch height is $y = 9{,}4\ m$, yielding a maximum displacement of 2,93 mm.

In Figure 3 below, the green truss arch represents the deformed geometry, scaled with a factor of 200.

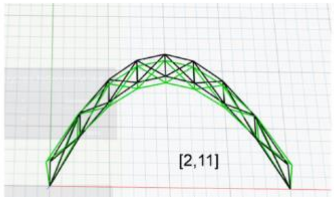

Figure 5: One of the possible solutions send by student

Pedagogical Reflections

This study is based on a longitudinal observation of the course since its introduction in 2017, combining iterative

course development with repeated survey-based data collection. Beginning in 2019, voluntary surveys have been conducted before and after each semester to capture students' perceptions, expectations, and self-assessed competencies related to algorithm-aided design and parametric modelling. Participation in the surveys has consistently exceeded 60% of enrolled students, and all responses are collected anonymously. The surveys include a consistent set of questions repeated annually, combining general course feedback with targeted items addressing parametric modelling awareness, prior exposure to algorithm-aided design, and intended future use of computational tools. Most responses are recorded using a five-point self-assessment scale, complemented by selected categorical questions (e.g. yes/no or multiple choice). The survey instrument consisted of a limited set of recurring items administered before and after the course, focusing on students' background, initial digital literacy, and expectations, as well as their perceived progression in parametric modelling, design skills, and awareness of computational tools. The key survey items used in the analysis are summarised in Table 1.

Table 1. Summary of key pre- and post-course survey items used in the analysis

Stage	Core item	Purpose
Pre	Self-assessed parametric modelling level	Establish baseline
Pre	Self-assessed FEM modelling level	Establish baseline
Pre	BIM/IFC awareness	Assess digital ecosystem familiarity
Pre	Motivation for taking the course	Identify expectations
Post	Self-assessed parametric modelling level	Measure perceived progression
Post	Awareness of new digital technologies	Measure broader learning effect
Post	Perceived improvement in design skills	Measure design-oriented impact
Post	Expected future use of AAD tools	Assess professional relevance
Post	Perceived importance of parametric modelling	Assess value recognition

The motivation for introducing these surveys was twofold. First, the course aims to position itself between academic education and engineering practice, responding to a frequently observed gap between theoretical training and professional workflows. Second, input from industry partners and consulting companies—collected through departmental meetings—has increasingly emphasised the need for greater automation and computational design competence in structural engineering practice. While the surveys are not intended as formal educational assessment instruments, their repeated application over time provides insight into longitudinal trends in student perceptions.

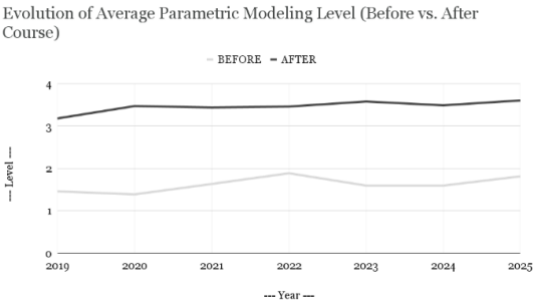

Figure 6: Self-assessed parametric modelling awareness

One consistent observation concerns students' self-assessed understanding of parametric modelling. As shown in Figure 6, students entering the course report a very low level of familiarity with parametric modelling concepts. Across multiple years, the average self-assessed level before the course remains close to 1.5 on a five-point scale, where 0 represents no prior knowledge and 5 represents a high level of understanding. This reflects the limited exposure to parametric and algorithmic design methods within traditional structural engineering curricula. After completing the course, the reported level increases substantially, reaching values close to 4.5, indicating a strong perceived improvement in conceptual understanding.

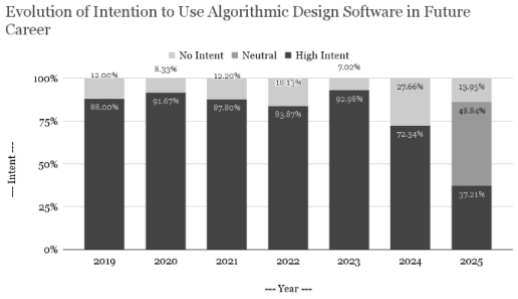

Figure 7: Intended use of AAD software in future careers

In addition to perceived competence, the surveys also address students' attitudes toward the use of algorithmic design tools in future professional practice. As illustrated in Figure 7, the majority of students express a positive intention to use parametric and algorithm-aided design methods in their careers. Until 2024, responses were limited to binary choices (yes/no). In the most recent iteration, a third option ("probably yes") was introduced, allowing for a more nuanced interpretation of student intentions. While a slight downward trend can be observed in recent years, the overall response remains strongly positive. At this stage, it is difficult to attribute this trend to specific factors, and further qualitative investigation would be required to interpret these changes.

Overall, the survey results suggest that the course format supports both increased awareness of parametric modelling concepts and a generally positive attitude toward algorithm-aided workflows. These observations reinforce the pedagogical choice to emphasise gradual skill development through practical assignments and

integrated computational workflows, while acknowledging the limitations of self-reported data.

Implications for Structural Engineering Education

An important implication emerging from the course experience concerns students' awareness of contemporary digital technologies relevant to the AEC sector. As shown in Figure 8, surveys conducted before and after the course indicate that a substantial proportion of students initially report limited or no understanding of concepts such as BIM, IFC, and the potential use of virtual reality (VR), augmented reality (AR), or artificial intelligence (AI) in design processes. While this level of awareness improves after the course, the consistently low baseline observed before the semester can be interpreted as a warning sign regarding how structural engineering students are prepared for current and emerging professional contexts.

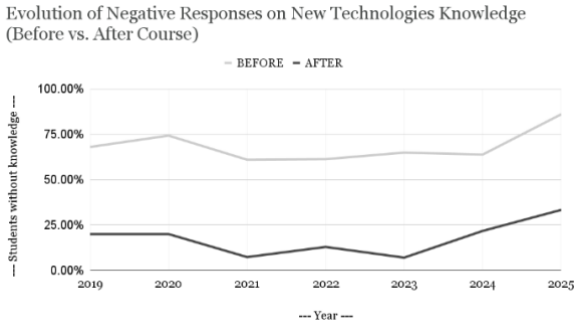

Figure 8: Awareness of new technologies in AEC

It is important to note that many of these technologies do not constitute the core of structural engineering education, where a solid understanding of mechanics, materials, and finite element analysis remains essential. However, limited awareness of digital ecosystems and emerging tools may restrict engineers' ability to participate in innovation-driven design processes. From this perspective, the issue is not the depth of technical mastery of specific technologies, but rather awareness and contextual understanding. If engineers are unfamiliar with the challenges and opportunities associated with new technologies, they are less likely to identify relevant problems or contribute to their solution.

The survey results also raise questions about the assumption that exposure to such technologies can be postponed until professional practice. While industry training plays an important role, relying exclusively on companies to introduce innovation-oriented workflows may be problematic. Early-career engineers often face limited freedom to experiment, while younger students typically show a higher willingness to explore new methods, accept uncertainty, and engage in risk-taking. From an educational standpoint, this suggests that universities play a critical role in creating safe environments for experimentation with emerging design methodologies.

At NTNU, efforts have already been made to strengthen programming competence, for example through the introduction of mandatory Python courses at the undergraduate level and the inclusion of scripting tasks in multiple courses. However, the survey responses suggest that learning programming languages in isolation, without a clear connection to design and engineering workflows, may limit students' ability to perceive their broader relevance. This highlights the importance of project-based courses that situate programming, parametric modelling, and algorithmic reasoning within meaningful engineering contexts.

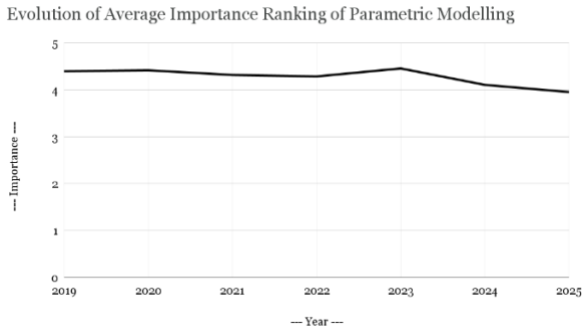

Figure 9: Perceived importance of parametric modelling

Finally, student responses regarding the perceived importance of parametric modelling provide a more optimistic perspective. As shown in Figure 9, students consistently rank the importance of parametric modelling at a high level, with average values exceeding 4 on a five-point scale in recent years. This suggests that, despite initial gaps in awareness, students increasingly recognise the relevance of computational and algorithm-aided approaches. Taken together, these observations support the integration of project-based, computational design courses as a means to bridge foundational engineering knowledge with emerging digital practices in structural engineering education.

Conclusions

This paper presents a Master's-level course that introduces algorithm-aided design into structural engineering education through a project-based, design-oriented format. Drawing inspiration from the practice of conceptual structural design in engineering, the course was developed to enable students to design structural systems from first principles, using computational tools as an integral component of the design process rather than as isolated analysis instruments.

By combining parametric modelling, finite element reasoning, and introductory algorithmic methods, the course positions computational design as a means of supporting structural understanding rather than replacing analytical thinking. The pedagogical approach is based on iterative, open-ended problem-solving tasks, where students are required to construct their own design strategies and explore the relationship between geometry, structural behaviour, and computational logic.

In contrast to traditional structural engineering education, which often focuses on well-defined problems with a single correct solution, the course adopts an open-ended assignment structure. Students are provided with design tasks and computational tools, but without prescribing specific analytical procedures or required verification methods. This shifts the emphasis from reproducing correct solutions toward developing reasoning, evaluation, and decision-making skills within a computational design context.

While the evaluation presented in this study is primarily based on self-reported data, learning effectiveness can also be assessed through observation of student outcomes. A consistent observation is that, both in assignments and in the final examination, students produce a wide range of structurally valid solutions to the same design problem. Within limited time constraints, students are required not only to generate designs, but also to assess their feasibility, including considerations of structural behaviour, constructability, and system logic.

This indicates the development of engineering judgement as a central learning outcome. In a context where computational tools enable the rapid generation of multiple design alternatives, the ability to critically evaluate, rationalise, and select appropriate solutions becomes a key competence. The course therefore aims to support not only technical skill acquisition, but also the ability to engage with computational processes in a reflective and methodologically informed manner.

Furthermore, the diversity and validity of student solutions can be interpreted as an indication of achieved learning outcomes related to design reasoning and structural understanding. Rather than applying predefined workflows, students demonstrate the ability to prototype and evaluate structural systems independently, suggesting a deeper integration of computational skills and engineering knowledge.

Overall, the course represents an initial step toward integrating computational and algorithmic methods into structural engineering education in alignment with contemporary design practice. Future work will focus on developing more systematic methods for assessing learning outcomes, particularly in relation to design reasoning, computational competence, and engineering judgement.

Acknowledgments

The authors would like to thank the students of TKT4198 for their engagement and feedback, which contributed to the continuous development of the course.

Abstract

This study presents the first comprehensive mapping of construction computing education in Europe, analysing 187 validated institutions across 35 countries. Using a three-tier verification methodology, we examine geographic distribution, program characteristics, and curriculum content. A sensitivity analysis estimates that current programs (~13,900 annual graduates) meet 6-49% of workforce demand depending on digitalization assumptions. Key findings include geographic concentration in Western Europe (40% in DACH and British Isles), predominance of master's programs (58.3%), and low ISO 19650 coverage (8.6%). These findings inform educational policy and workforce planning for EU construction digitalization.

Introduction

The construction sector is undergoing rapid digital transformation, driven by Building Information Modelling (BIM) mandates, sustainability requirements, and emerging technologies including digital twins, artificial intelligence, and robotics that showcase an internal transformation to tackle sector challenges. With increased external pressures, such as The European Union's Renovation Wave strategy targeting the renovation of 35 million buildings by 2030, or the revised Energy Performance of Buildings Directive (EPBD) which establishes increasingly stringent digitalization requirements, the sector is due a rather extensive upskilling of their workforce in digital competencies. These policy drivers create substantial demand for construction professionals equipped with advanced digital competencies. The European Construction Industry Federation estimates that more than two million additional workers will be needed in the sector by 2030, with digital skills identified as a critical gap (EFBWW, 2023).

BIM policies have been progressively introduced across European countries, beginning with the United Kingdom's in 2016, followed by Germany in 2021, Ireland in 2024, and additional countries including Spain, France, and Italy have implemented or are developing similar requirements as we speak. The adoption of ISO 19650 as the international standard for BIM information management further standardizes expectations for digital competency across the sector. Skills gaps and the inability to attract appropriately trained talent remain among the leading barriers to technology adoption in construction (Kjellmark & Hjelseth, 2025).

These policy mandates and industry demands translate directly into pressure on higher education institutions to produce graduates with appropriate digital competencies. Universities and technical schools across Europe have responded by developing specialized programs in BIM, digital construction, and construction informatics of various natures (Abdirad & Dossick, 2016). However, this response has been uncoordinated, with institutions independently designing curricula based on local industry needs, available expertise, and national accreditation frameworks. Several systematic reviews have highlighted the lack of common academic guidelines across institutions, noting that effective BIM implementation requires coordinated curriculum modifications and teaching strategies (Besné et al., 2021; Witt & Kähkönen, 2019). This fragmentation is compounded by the absence of a shared competency reference: while the European Digital Competence Framework (DigComp 2.2) and the ESCO classification define digital skills at a generic level, neither provides construction-specific occupational profiles for digitally skilled roles (Vuorikari et al., 2022). Moreover, European workforce intelligence reports have consistently identified construction among the sectors with the widest digital skills gaps, yet without granular data on how educational supply maps to these shortfalls (Cedefop, 2023). It is not surprising that the resulting educational landscape is fragmented: some regions have developed extensive program portfolios while others remain underserved; curriculum content varies significantly in scope and depth; and alignment with international standards such as ISO 19650 is inconsistent. To date, no comprehensive mapping of this provision exists, limiting the ability of policymakers, institutions, and industry to assess whether current educational capacity matches workforce requirements.

This paper addresses three research questions: (1) What is the current landscape of construction computing education across Europe in terms of geographic distribution, program characteristics, and curriculum content? (2) What is the estimated annual graduate output from specialized construction computing programs? (3) How does current educational capacity compare to workforce demand under different digitalization scenarios?

Methodology

To secure a comprehensive provision of the current academic offer across Europe, a sequential process is followed to gather the quantitative evidence. The research methodology comprised four stages: (1) data collection using structured searches and large language model (LLM) assisted extraction, (2) multi-tier verification against primary sources and an interactive dashboard, (3) classification and coding of programs and topics, and (4) sensitivity analysis to estimate capacity gaps.

Data Collection

Data collection followed a systematic multi-stage approach combining manual searches with LLM assisted extraction. Programs are initially identified through mass structured web searches using keywords in English and local languages (BIM, digital construction, construction informatics, computational design combined with country names and institution types). The LLM outputs provide a base dataset that is posteriorly reviewed through the institutions websites to confirm existence and relevance, as well as a review of professional body listings (buildingSMART national chapters, national BIM councils).

For each identified institution, the following data points were extracted: institution name, country, city, geographic coordinates, program names and URLs, language of instruction, delivery mode, duration, annual tuition cost (EUR), estimated graduates per year, and curriculum topics. LLM-assisted extraction was employed to accelerate initial data capture from institution websites and program documentation, with all extracted data subsequently verified against primary sources in the verification stage.

The LLM-assisted extraction used Claude Sonnet 4.5 via structured prompts requesting, for each institutional webpage, the extraction of institution name, programme title, URL, language of instruction, delivery mode, duration, tuition fees, and listed module topics. For non-English webpages, the LLM processed content in the source language with extraction fields specified in English, leveraging its multilingual capabilities; no separate machine translation step was applied. During L2 verification, approximately 60% of LLM-extracted records required correction, with errors concentrated in tuition fee fields (inconsistent currency formatting and missing fees) and graduate estimates (confused with total enrolment figures). The LLM therefore served as a productivity accelerator for initial data capture rather than a definitive extraction tool, with all final dataset values confirmed through manual verification.

Verification Framework

A three-tier verification framework was developed to assess data reliability, supported by an interactive dashboard that enabled systematic review and validation of institution records. Level 1 (L1) confirms program existence through accessible URLs and institution website confirmation. Level 2 (L2) validates core data including curriculum content verified against program documentation/specification, costs confirmed from official sources, and topics coded from syllabus or module descriptors. Level 3 (L3) additionally confirms all previous data, as well as graduate numbers, through direct institutional contact, accreditation reports, or official statistics.

The interactive dashboard served as the primary verification tool, displaying institution records with all associated data fields and enabling reviewers to flag inconsistencies, update verification levels, and track validation progress across the dataset. This systematic approach ensured consistent application of verification criteria across all institutions.

This analysis includes only institutions meeting L2 or L3 verification (n=187), of which 16 achieved L3 verification including confirmed graduate numbers. Eight L1-only institutions were excluded due to insufficient data reliability – this is due to the geopolitical situation in Eastern Europe (Russia, Ukraine, and Belarus institutions are therefore not included in this analysis for now).

Classification

Programs were classified according to ISCED levels: Bachelor studies (ISCED 6, including BEng, BA, and Foundation degrees), Master studies (ISCED 7, including MSc, MEng, MA, Mastère Spécialisé), Doctoral studies (ISCED 8), and Continuing Professional Development (CPD). Integrated programs such as the French Diplôme d'Ingénieur, which span both undergraduate and graduate levels across five years, were counted in both Bachelor's and Master's categories to accurately reflect their educational scope.

Curriculum topics were coded using a controlled vocabulary of 39 terms developed through iterative coding, consolidation of synonymous terms, and validation against ISO 19650 and buildingSMART terminology. The list of terms can be seen in Table 1.

Table 1: List of computational topics used as curriculum drivers.

Topics	
3D Modelling & Scanning	AI & Machine Learning
Architecture	BIM
BIM Software	CAD/CAM
Collaborative Workflows	Construction Engineering
Construction Informatics	Construction Management
Data Management	Digital Construction
Digital Design	Digital Fabrication
Digital Twins	Energy Performance
Facility & Asset Management	GIS & BIM Integration
Heritage BIM	ISO 19650

Infrastructure BIM	Infrastructure Engineering
Innovation & Entrepreneurship	IoT
Lean & Integrated Delivery	Parametric & Generative Design
Prefabrication & Modular Construction	Procurement & Contracts
Programming	Project Management
Risk & Safety Management	Robotics & Automation
Smart Cities & Buildings	Structural Engineering
Sustainability	Timber Construction
Virtual or Augmented Reality	nD BIM
openBIM & IFC	

During the posterior analysis, for specific geographical features, countries were grouped into ten regions based on geographic proximity and construction market characteristics: DACH, British Isles, Iberia, France, Nordic, Italy, Central Europe, Balkans, Benelux, and Baltic. The countries represented on each region and the number of institutions per region are listed in Table 2. A total of 187 institutions from 35 countries are represented in this study.

Table 2: List of regions represented in this study with its associated countries and number of institutions per region.

Region	Countries	Institutions
DACH	Germany, Austria, Switzerland	46
British Isles	UK, Ireland	29
Iberia	Spain, Portugal	25
France	France	23
Nordic	Sweden, Norway, Denmark, Finland, Iceland	12
Italy	Italy	10
Central Europe	Poland, Czech Republic, Slovakia, Hungary, Slovenia	11
Balkans	Greece, Turkey, Serbia, Croatia, Cyprus, Bulgaria, Romania, Bosnia & Herzegovina, North Macedonia, Albania	19
Benelux	Netherlands, Belgium, Luxembourg	8
Baltics	Lithuania, Estonia, Lithuania	4

Sensibility Analysis

The capacity gap analysis employs a parametric model adapted from workforce demand estimation approaches used in labour economics (Willems & De Grip, 1993; BLS, 2024). Annual demand for digitally skilled construction professionals is estimated as:

$$D = W \times P \times (r + g)$$

Where (W) represents total construction workforce, (P) is the digital skills penetration rate (proportion of workforce requiring specialized digital competencies), (r) is the replacement rate (proportion leaving annually due to retirement, career change, or attrition), and (g) is the growth rate (annual increase in digital roles).

The model structure reflects standard workforce planning practice, where total demand comprises both replacement of existing workers and expansion to meet growing requirements. Four scenarios were constructed by varying P across plausible ranges (0.03 to 0.12) and g (0.02 to 0.10), while holding r constant at 0.05 based on typical construction sector turnover rates. The lower bound for P (0.03) reflects the current proportion of explicitly BIM-designated roles in European construction job markets as reported by Cedefop (2024), while the upper bound (0.12) aligns with the EU Pact for Skills construction blueprint target and digital specialist penetration rates observed in more digitised sectors such as manufacturing (Eurostat DESI, 2024). Growth rate bounds (g = 0.02–0.10) span observed annual increases in digital construction job postings across major European markets between 2020 and 2024. Workforce data were drawn from the European Construction Observatory 2024 Skills Report, using the combined construction sector definition (NACE F + M.71) totalling approximately 18 million workers across analysed countries.

To account for institutions not captured in this mapping exercise, an institutional coverage factor (C) of 0.75-0.80 was applied to estimate total European graduate output: $S_{total} = S_{map}/C$. This estimate is a conservative number derived from observed search saturation: during the final two search iterations, fewer than 6% of queries yielded previously unidentified institutions, suggesting diminishing returns approaching dataset completeness. Unmapped institutions in smaller countries, newer programs, and non-English language offerings may contribute additional graduate output. Under this adjustment, estimated total European supply ranges from 16,062 $(C = 0.8)$ to 17,133 $(C = 0.75)$ graduates annually.

Results

Geographic Distribution

The dataset comprises 187 institutions across 35 countries. Germany leads with 32 institutions, followed by the United Kingdom (26), France (23), Spain (20), and Italy (10). Regional aggregation reveals concentration in Western Europe, with DACH countries (Germany, Austria, Switzerland) accounting for 46 institutions (24.6%) and British Isles (UK, Ireland) contributing 29

institutions (15.5%). Eastern and Southern European regions show lower provision density, with the Baltic states contributing to with only 4 institutions (2.1%).

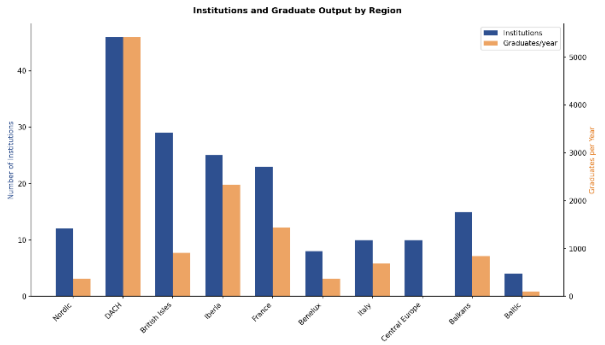

Figure 1: Bar chart of the geographic distribution of institutions and graduates (per year) per region.

Program Characteristics

A total of 372 programs were identified across 187 institutions. Master's-level programs dominate at 232 (58.3%), followed by bachelor's programs at 97 (22.6%), Doctoral programs at 55 (14.8%), and CPD offerings at 16 (4.3%). Twenty-six integrated programs (primarily French Diplôme d'Ingénieur and Double Degrees) are counted in both Bachelor's and Master's categories. Figure 2 represents the distribution of the current offer of programs that integrate construction informatics. Note that CPD offer is the lowest and may be due to bias in the data collection process or an undervalued approach to construction informatics education.

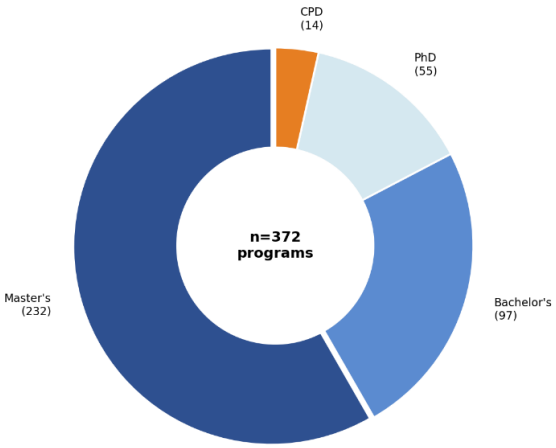

Figure 2: Pie chart of the program type distribution.

English is the most common language of instruction (96 programs), reflecting internationalization strategies particularly at master's level. German (44), French (26), and Spanish (19) serve primarily domestic markets. The predominance of Master's-level programs positions construction computing as a specialization layer atop foundational engineering or architecture education.

The overwhelming majority of construction computing programs in Europe are delivered through traditional presential (on campus) instruction, with 158 institutions (84.5%) operating exclusively in this mode. A further 11 institutions (5.9%) offer hybrid presential/online options, providing some flexibility while maintaining campus-based teaching as the primary delivery mechanism. Fully online provision remains limited, with only 5 institutions (2.7%) offering all programs entirely online, and an additional 5 operating in blended formats that combine synchronous and asynchronous elements. This distribution reflects the hands-on nature of construction computing education, where access to specialist software, hardware laboratories, and collaborative project work traditionally necessitates physical presence. However, the limited online provision may also represent a missed opportunity to reach working professionals seeking to upskill without career interruption, particularly in regions underserved by presential programs.

Full-time study dominates the European construction computing education landscape, with 114 institutions (61.0%) offering only full-time programs. A further 32 institutions (17.1%) provide both full-time and part-time pathways, while 13 (7.0%) cater exclusively to part-time students. Notably, apprenticeship models feature prominently in certain national contexts, with 12 institutions (6.4%) offering apprenticeship-only routes and 8 (4.3%) combining full-time study with apprenticeship options—these are concentrated primarily in France and Germany where dual education systems are well established. The predominance of full-time provision presents a potential barrier to workforce reskilling, as construction professionals seeking digital competencies must often choose between continued employment and formal education. The relatively limited part-time and flexible study options suggest that CPD pathways and micro-credentials may need to play a larger role in addressing the digital skills gap among the existing construction workforces.

Curriculum Content

BIM appears in 87.7% of institutions, confirming its status as the foundational topic. Digital Construction (43.9%), Construction Management (42.8%), and Sustainability (37.4%) follow. Emerging technologies show moderate coverage across programs: Digital Twins (21.4%), Parametric and Generative Design (20.3%), and AI/Machine Learning (14.4%).

Notably, explicit coverage of ISO 19650 standards appears in only 8.6% of institutions, despite its status as the international standard for BIM information management. Similarly, openBIM and IFC coverage stands at 8.6%. This suggests curriculum development has not kept pace with standardization efforts.

Regional specializations are evident. Nordic institutions emphasize Sustainability (67% versus 37% overall) and Digital Twins (58% versus 21%). DACH institutions show strength in Digital Fabrication (17%) and Robotics (11%). British institutions lead in Lean and Integrated Delivery (31%) and ISO 19650 coverage (17%). Iberian institutions focus on Infrastructure BIM (56%) and BIM Software tools (48%). Italian institutions specialize in Heritage BIM (40%) and Parametric Design (60%). This regionalisation can be evidenced in the heatmap provided in Figure 3.

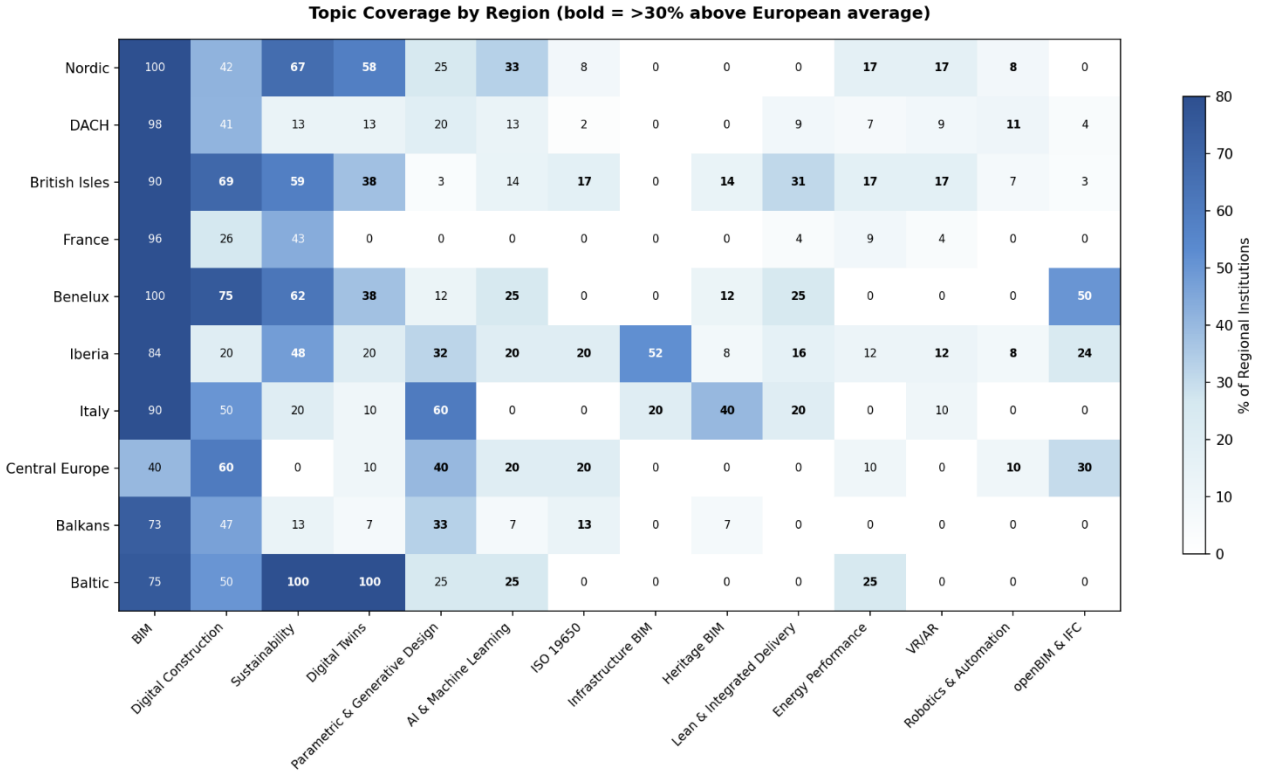

Figure 3: Heatmap of the topic coverage in academic programs across European regions.

Cost Analysis

Tuition costs for construction computing programs vary substantially across European regions, reflecting different national approaches to higher education funding (see Figure 4).

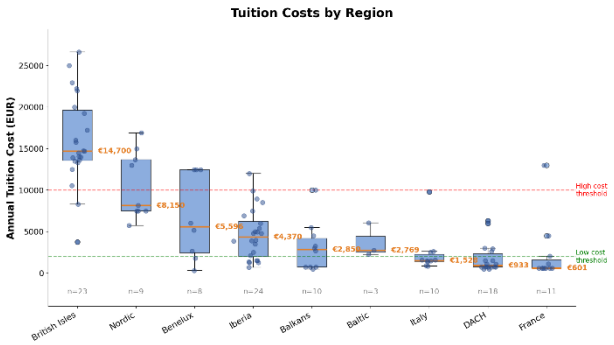

Figure 4: Box plot of the distribution of yearly cost of construction computing education per region.

The British Isles exhibit the highest median costs at €14,700 annually, with considerable variation ranging from approximately €7,000 to over €30,000 depending on institution and residency status. Nordic countries follow at €8,150 median, though this figure is skewed by high fees for non-EU/EEA students; domestic students in Norway, Sweden, and Denmark typically pay no tuition at public institutions. In contrast, DACH countries (Germany, Austria, Switzerland) demonstrate the lowest median costs at €933, benefiting from predominantly public university systems with nominal administrative fees and a predominance of part-time studies for active workers. France shows a bimodal distribution with low-cost public university programs alongside higher-fee Grandes Écoles. Southern European regions—Iberia (€4,370 median) and Italy (€1,528 median)—offer relatively affordable pathways to construction computing qualifications. This cost variation has implications for workforce development: while high-cost regions may produce fewer but potentially better-resourced graduates, low-cost regions could theoretically scale provision more rapidly to meet digital skills demands, though this would require corresponding investment in teaching capacity and infrastructure.

Graduate Capacity and Demand Gap

Graduate estimates from all 187 institutions show a total annual output from mapped institutions at approximately 13,900 graduates. Germany produces the largest volume (4,000), followed by Spain (2,048), France (1,435), Switzerland (975), and the United Kingdom (970).

When normalized against construction workforce size, smaller countries with strong programs show high output ratios: Switzerland produces 21.7 graduates per 10,000 construction workers, Greece 20.6, and Luxembourg 20.0. Larger markets show lower ratios despite higher absolute output: United Kingdom (3.9), France (6.0), and Italy (3.6).

The sensitivity analysis reveals substantial variation in estimated capacity gaps. Table 3 presents coverage percentages across scenarios and coverage assumptions. Under conservative assumptions (P=0.03, only dedicated BIM specialists), mapped programs meet 37% of

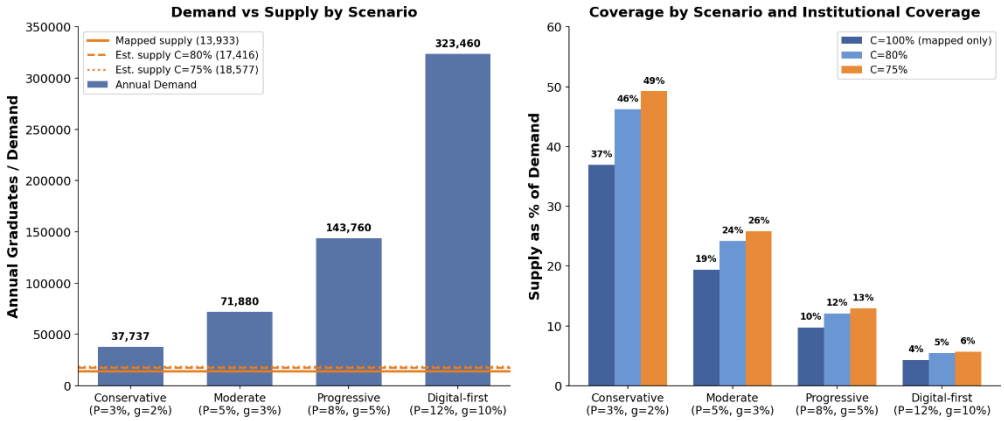

Figure 5: Sensitivity analysis showing demand versus supply by scenario and coverage percentages by institutional coverage assumption.

estimated annual demand; adjusting for institutional coverage (C=0.75-0.80) improves this to 46-49%. Under moderate assumptions (P=0.05, specialists plus power users), coverage drops to 19-26%. Progressive assumptions aligned with EU Renovation Wave ambitions (P=0.08) yield 10-13% coverage, while digital-first scenarios (P=0.12) suggest only 4-6% coverage even with optimistic supply adjustments.

Table 3: Capacity coverage by scenario and institutional coverage assumption.

Scenario	P	g	Annual Demand	C		
				100%	80%	75%
Conservative	0.03	0.02	37,737	36.9%	46.2%	49.2%
Moderate	0.05	0.03	71,880	19.4%	24.2%	25.8%
Progressive	0.08	0.05	143,760	9.7%	12.1%	12.9%
Digital-first	0.12	0.10	323,460	4.3%	5.4%	5.7%

Notes: P = digital skills penetration rate; g = growth rate; r = 0.05 (replacement rate); W = 17.97M workers. C = institutional coverage factor representing proportion of European programs captured in dataset.

Figure 5 illustrates these findings, showing annual demand under each scenario against mapped and estimated supply levels (left panel), and the resulting coverage percentages across coverage assumptions (right panel).

Discussion

Parameter Sensibility

To validate the results obtained, a parameter sensibility is performed by introducing variability and quantifying the impact on the demand. The details of the parameter sensitivity are summarized in Table 4.

Table 4: List of the parameter sensitivity ranked by impact.

Parameter	Range Tested	Impact on Demand	Total Swing
P	3% → 12%	-28,752 to +100,632	129,384
g	2% → 10%	-8,985 to +62,895	71,880
r	3% → 7%	-17,970 to +17,970	35,940
W	15M → 20M	-11,880 to +8,120	20,000

The tornado chart in Figure 6 shows how varying each model parameter individually affects annual demand, starting from a base case (moderate scenario) of 71,880 graduates of annual demand. Parameters are ranked by their impact on demand, with the most influential at the bottom.

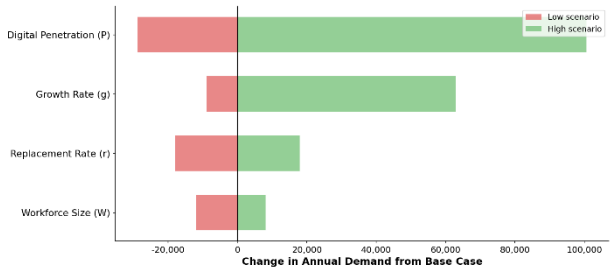

Figure 6: Sensitivity analysis on the impact of parameter variation on graduate demand.

The assumed proportion of the workforce requiring specialized digital skills has by far the largest impact. Varying P from 3% to 12% creates a swing of nearly 130,000 in annual demand, dwarfing all other parameters combined. Growth rate comes in second in impact. Assumptions about how quickly digital roles are expanding (2-10% annually) create a swing of ~72,000. Replacement and workforce size have limited impact. These parameters are relatively well-established from labour statistics and have narrower plausible ranges, limiting their influence on uncertainty. The critical unknown is not demographic (workforce size, turnover) but definitional: what proportion of construction workers

actually need specialized digital competencies? This question requires industry consensus to enable meaningful workforce planning.

Contributions to Academic Understanding

This study makes several contributions to the academic literature on construction computing education. First, it provides the first comprehensive, pan-European dataset of specialized construction computing programs, addressing a gap noted by previous systematic reviews which have highlighted the fragmented nature of curriculum documentation (Abdirad & Dossick, 2016; Besné et al., 2021). The dataset, comprising 187 verified institutions across 35 countries with standardized metadata on programs, topics, costs, and graduate capacity, offers researchers a foundation for comparative studies that was previously unavailable.

Second, the regional classification and topic coding framework enables systematic analysis of curriculum patterns. The identification of distinct regional specializations—Nordic emphasis on sustainability and digital twins, British focus on ISO 19650 and lean delivery, Iberian concentration on infrastructure BIM, Italian strength in heritage applications—provides empirical grounding for discussions of how local industry characteristics shape educational provision. Future research can build on this framework to examine whether regional specializations represent strategic differentiation or path-dependent responses to local market demands.

Third, the sensitivity analysis framework demonstrates a replicable methodology for estimating capacity gaps under uncertainty. Rather than presenting single-point estimates that imply false precision, the parametric approach makes explicit the assumptions underlying workforce demand calculations and allows stakeholders to assess implications under their preferred scenarios. The finding that definitional questions (what proportion of workers need digital skills?) matter far more than demographic parameters (workforce size, turnover rates) redirects attention toward the policy discussions that actually determine perceived shortages.

Fourth, the verification methodology offers a practical approach for maintaining data quality in large-scale educational mapping exercises. The three-tier framework (L1: existence confirmed; L2: curriculum verified; L3: graduate numbers confirmed) provides transparency about data reliability and can be adapted for similar studies in other regions or disciplines.

Implications for Curriculum Development

The findings suggest several directions for curriculum development. The near-universal coverage of BIM (87.7%) indicates that foundational digital modelling skills are well-embedded in European construction education. However, the low coverage of ISO 19650 (8.6%) and openBIM/IFC standards (8.6%) points to a gap between technical tool proficiency and information management competency. As BIM mandates increasingly reference ISO 19650 compliance, institutions may need to strengthen coverage of standardised processes, common data environments, and information delivery planning. Several non-exclusive explanations for this gap warrant investigation: ISO 19650 content may be embedded within general BIM modules without explicit labelling in programme descriptors, leading to systematic underreporting in web-sourced data; curriculum development cycles typically lag behind standardisation timelines, and ISO 19650's relatively recent transposition into many national frameworks may not yet be reflected in programme specifications; and institutions may perceive information management standards as practitioner-level knowledge better addressed through CPD than degree-level teaching. Distinguishing between these explanations would require qualitative curriculum document analysis or structured educator interviews, representing a priority for future research.

The predominance of Master's-level programs (58.3%) positions construction computing as a specialization layer atop foundational engineering or architecture education. While this model produces graduates with deep expertise, it may constrain the scaling of digital competencies across the broader workforce. The relatively limited CPD provision (4.3% of programs) represents a missed opportunity to upskill existing practitioners who cannot undertake full degree programs. Institutions and professional bodies might consider expanding short-course offerings, micro-credentials, and stackable qualifications that allow working professionals to acquire specific competencies incrementally.

Limitations

Several limitations should be noted. The dataset excludes vendor certifications (Autodesk, Bentley, Trimble), non-affiliated training programs or online programs (i.e., buildingSMART certificate), other informal training, and general IT/CS graduates who enter construction, representing significant but unmeasured supply channels. Graduate numbers are estimates for many institutions, with actual output potentially varying by ±30%. The institutional coverage factor (C=0.75–0.80), while supported by search saturation patterns and partial national cross-referencing, could not be empirically calibrated for all 35 countries and may understate or overstate unmapped provision. There is additional bias in the data collection process as the authors do not represent nor know the whole picture of the educational offer in this topic, therefore adding uncertainty and regional bias to the data collection process. The parametric demand model abstracts complex labour market dynamics and should be interpreted as indicative rather than predictive. Finally, the dataset represents a snapshot; given the rapid evolution of construction technology, regular updates would be needed to maintain currency.

Future Research Directions

This study opens several avenues for future research. Longitudinal tracking of program evolution would reveal how curricula respond to changing industry demands and policy requirements. Graduate outcome studies could assess whether regional curriculum specializations translate into differentiated career pathways. Comparative

analysis with vendor certification data would illuminate the relative contributions of academic and industry-based training to workforce development. Finally, extension of the methodology to other regions—North America, Asia-Pacific, Middle East—would enable global comparisons of construction computing education provision and potential strategic best practice.

Conclusions

This study presents the first comprehensive mapping of construction computing education across Europe, identifying 187 validated institutions across 35 countries producing approximately 13,900 graduates annually (estimated 17,400-18,600 total when accounting for search uncertainty). Key findings include: (1) geographic concentration in Western Europe with 40% of institutions in DACH and British Isles regions; (2) predominance of Master's-level programs (58.3%) positioning construction computing as specialization; (3) near-universal BIM coverage (87.7%) but limited ISO 19650 standards coverage (8.6%); (4) strong regional curriculum specializations aligned with local industry characteristics; and (5) current programs meeting between 6% and 49% of estimated demand depending on digitalization and coverage assumptions.

Meeting EU construction digitalization ambitions will likely require both scaling of specialized programs and development of complementary pathways including CPD offerings, vendor certification recognition, and integration of digital competencies at bachelor's level. Policy clarity on role definitions and competency requirements is essential for evidence-based workforce planning.

The authors also hope that the map dashboard developed is of useful to future students to take informed decisions regarding their instruction in the digital construction domain. While we do not aim to transform the created platform into a marketplace, we hope that it serves as an easier method for students to understand the European educational offer in this field, enabling them to succeed in their desired professional ambitions.

Acknowledgments

The authors would like to acknowledge the support of the EC3 Educational Committee members and the other colleagues that have validated the dataset for their own institutions.

TOWARDS A STREAMLINED DIGITAL PERMITTING PROCESS: A SWEDISH CASE STUDY

Nischal Bhattarai, Annika Moscati , Ulf Seigerroth , Alexandros Tzanetos , Erik Bergström
Jönköping University, Jönköping, Sweden

Abstract

Environmental permitting is a key instrument for enabling sustainable development, but it is often characterized by long processing times, administrative burdens, and uncertainty about outcomes. Although prior research and government inquiries highlight weaknesses in the Swedish permitting process, empirical evidence on how these challenges manifest themselves in practice remains limited. This study investigates the permitting process by triangulating a scoping review, government reports, and an exploratory case study. The findings identify challenges that constrain information flow, coordination, and decision-making, underscoring the need for a digitally enabled process architecture to support a more coordinated, streamlined permitting process.

Introduction

Environmental permitting ensures that infrastructure developments comply with environmental standards. European initiatives, such as the European Green Deal and REPowerEU, emphasize accelerating sustainable projects to achieve decarbonization by 2050 (European Commission, 2019). Achieving these objectives requires accelerating the deployment of clean energy while ensuring environmental protection and addressing regulatory constraints (IEA, 2023).

Sweden is recognized for demonstrating high ambition in environmental policy and climate governance, supported by advanced regulatory structures and strong eco-innovation performance (OECD, 2025). However, challenges remain in translating these ambitions into effective implementation across environmental domains and in coordinating the environmental permitting process (European Commission, 2022). Increasing pressure to accelerate permitting for electrification and infrastructure central to the green transition also exposes the limitations related to regulatory complexity and the lengthy approval process (Phan et al., 2025; Clean Energy for EU Islands Secretariat, 2023).

Although the permitting process aims to balance environmental protection and industrial growth, it remains complex and time-consuming, increasing procedural burdens and uncertainty (Marin et al., 2024). The processes involve multiple interdependent stages, stakeholder interactions, and decision points, affecting coordination within the permitting process (Fauth et al., 2025). In the Swedish environmental permitting process, key stages, such as examining environmental impact assessments, assessing the completeness of the application, consultation, supplementation, and written exchanges, are handled through sequential administrative routines that increase manual coordination and iterative exchanges (Miljötillståndsutredningen, 2024a; Swedish Environmental Protection Agency, 2025). Furthermore, handling and disclosing personal and sensitive data during stakeholder coordination and collaboration also requires a higher level of protection and poses challenges to facilitate such exchanges (Malmaeus et al., 2021).

Digital technologies have been proposed to improve environmental assessments, including GIS-based decision support systems, data-driven analytics, and platforms for real-time information sharing and monitoring (Fothergill and Murphy, 2021). While the implementation of such digital technologies in environmental governance could facilitate green transformation (Zhao et al., 2025), their effectiveness depends on how they are designed, implemented, and integrated into existing institutional and governance contexts (Kloppenburg et al., 2022).

In Sweden, the government inquiry report (SOU 2024:98) highlighted the need for a more coordinated and streamlined digital permitting process, noting that current systems are fragmented, lack coordination, and are insufficient to ensure transparency and predictability (Miljötillståndsutredningen, 2024a). The growing demand for procedural efficiency positions the Swedish permitting system as a valuable case for analyzing both structural challenges and potential reform pathways. Thus, the paper aims to contribute to the understanding of the underlying problems and challenges as a prerequisite to the conceptual design of a streamlined digital permitting process through triangulation of international scientific literature, a case study, and a Swedish government inquiry report addressing the following research question:

RQ: What are the challenges related to the Swedish permitting process that hinder the development of a streamlined digital permitting process?

Background

The Environmental Permitting Process in Sweden is governed by the Swedish Environmental Code, its associated ordinances, along with complementary administrative

and legal regulations (Miljötillståndsutredningen, 2024b). The Environmental Code provides a framework for environmental protection, including requirements for environmental assessments and permits for activities that may have environmental impacts (Cinthio, 2019). Such activities, defined as environmentally hazardous activities due to emissions, discharges, or other disturbances, are subject to a permit or notification obligation.

The environmental permitting process begins with an early investigation and screening consultation with the County Administration Board to determine whether the activity has a significant impact or not (SEI). If SEI is expected, a full environmental impact assessment (EIA) is required; otherwise, a simplified EIA is prepared (Malmaeus et al., 2021). In the next step, the application is formally submitted, together with the EIA and supporting documents, to the competent authority: Land and Environmental Court (activity type "A"), County Administrative Board (activity type "B"), and Municipality (activity type "C") (Swedish Environmental Protection Agency, 2025). After the application is received by the competent authority, it reviews the application completeness, publishes it for public comments, and exchanges. Once the comments are received from stakeholders, the operator addresses them through clarification and, if necessary, supplementation. Finally, the authority decides on the application after receiving clarifications from the operator (Cinthio, 2019). The operator may appeal the decision of the competent authority to higher instances, depending on the authority involved. The highlighted process is a brief overview; however, the actual process often involves sub-activities within each step, multiple supplementation rounds, iterations, and exchanges.

Digitization has been considered a strategic priority for improving decision-making in public governance in Sweden (Regeringskansliet, 2025). Studies have emphasized the role of digital systems in enabling coordination among stakeholders and supporting decision-making (Axelsson et al., 2025; Larsson, 2023). Although digital infrastructure for environmental data and biodiversity monitoring exists in Sweden, these systems are implemented across various authorities, leading to fragmented responsibilities and coordination challenges. The absence of a centralized data platform and the diversity of data formats and standards across systems reduce interoperability and limit the integration of digital systems into unified workflows (Biodiversa+, 2024). Consequently, while digitization in Sweden is relatively mature in terms of data infrastructure and information availability, it remains less developed in supporting integrated, end-to-end process architectures required to coordinate complex regulatory procedures, such as environmental permitting.

Research Method

This study triangulates the scientific literature, an exploratory case study, and SOU 2024:98 to investigate challenges in the permitting process in practice. A scoping review was used to gather information on the normative permitting process in Sweden, while an exploratory case study investigated how complex interactions influence the permitting process in a real project context, where normative process descriptions alone may not fully capture real-world complexity.

Scoping literature review

The PRISMA method for scoping literature reviews was applied (Tricco et al., 2018). The scientific literature was systematically selected and reviewed to analyze the state of the art in environmental permitting and identify the complexity of the process. To obtain a broad overview, relevant literature was searched in Scopus, Web of Science, and Google Scholar. An initial generic search was conducted to identify key terms. The keywords *Permitting process, Environmental impact assessment (EIA), Environmental regulations, Regulatory frameworks, Governance and policies, and Sector/context*, along with their synonyms, were combined using various Boolean operators to achieve the widest possible coverage of relevant studies published between 2020 and 2025. A total of 559 records were identified, exported in .ris format, and imported into the web-based software Rayyan for further screening. Automatic duplicate detection was run, and consequently, 212 records were removed. The remaining 318 articles were screened based on title and abstract, of which 27 were deemed relevant. Following the full-text assessment, 12 articles were selected for a detailed analysis, as illustrated in Table 1. The findings from the selected articles were extracted and organized in a structured format. The data were then categorized into thematic codes following an open coding approach to identify the recurring themes that support the analysis of the study (Strauss and Corbin, 2015).

Table 1: Summary of literature search and screening process

Stage	Records
Initial database search (Scopus, Google Scholar, and Web of Science)	**559**
Duplicates removed	212
Records after duplicates removed	**318**
Title and abstract screening excluded	291
Marked as "possibly relevant" (title/abstract)	27
Full-text studies included in thematic synthesis	**12**

Grey literature review analysis

Understanding of the Swedish permitting process was developed through grey literature, which enabled analysis of official reports, permitting process guidelines, and government inquiries (SOU 2024:98). Some of the grey literature was originally written in Swedish and was accurately translated using Microsoft Word's built-in translation features. The selection of such literature followed the CRAAP test, which evaluated these selections based on five criteria: Currency, Relevance, Authority, Accuracy, and Purpose (Meriam Library, 2010). The inquiry report (SOU 2024:98, part 2) was analyzed as secondary data using a document analysis approach to examine challenges in the Swedish permitting process. The themes thus identified in the investigation report were categorized into codes and reported in this study.

Case Study and focus group

A case study design was adopted to investigate the Swedish permitting process in a real-world context, where such factors are critical for identifying persistent challenges. The study provides analytical generalization by examining a project that followed the full permitting trajectory, including the application and judicial review (Yin, 2018). Thus, this case study provides empirical evidence of the underlying challenges that hinder the digitization of the permitting process. The case serves as the primary data source and is thematically analyzed to identify barriers to process efficiency and digitization. However, analysis is limited to the permitting phase and excludes post-permitting stages.

The case study analyzes the permitting process of one of the established industrial and infrastructure development companies in the Nordic region. The company is involved in the handling of aggregates and quarrying operations, which are classified as environmentally hazardous activities under Swedish Environmental legislation. Depending on the environmental impact and the scale of the project, such activities undergo a permitting process and are subject to environmental permit requirements. Thus, the case company is highly relevant, as it directly interacts with Swedish environmental regulatory frameworks and the permitting process, and serves as the basis for selection.

Furthermore, a focus group discussion was conducted using a purposive sampling of participants directly involved in the permitting process, including administrative practitioners, EIA specialists, an engineer, and a project manager (Creswell, 2009; Patton, 2015). The strategy followed a key informant approach, given their relevance and expertise in the process, and a homogeneous sampling approach due to their participation in the common permitting process (Patton, 2015). The discussion was guided and anchored by a simplified process model developed in accordance with the Swedish Environmental Protection Agency, and practitioners were allowed to express their opinions and reflect on the permitting process. Subsequently, notes were taken and categorized into the themes related to the permitting process in practice. The notes were verified through the member-checking approach and thus served as a tool for contextualizing the case study and interpreting the findings. Even though the purposeful sampling approach can introduce selection bias, several strategies, such as data triangulation, member checking, diverse participants, and focused discussion, helped ensure its credibility and reliability (Creswell, 2009).

Case Study

The case study analyzes a permitting process for the extension of an existing quarry operation, including rock blasting, sorting, asphalt production, landfill operations, and water activities, under the Swedish Environmental Code. The operation, active since 2007, required a new permit application in 2021 as the existing one was set to expire in 2022. Due to the scale and nature of the project, it was classified as Activity type "A" and examined by the District Land and Environment Court (Mark- och miljödomstolen, MMD). It was assessed to have a significant environmental impact, requiring consultation and submission of a full EIA.

During the review, the authorities requested that the application be supplemented and clarified regarding water management and landfill design, and the application was made public by the authority upon completion. Stakeholders raised several concerns about groundwater impacts, blasting noise, and trust in the evaluation of the process. The court proceeded after receiving clarification of the stakeholders' concerns and granted a permit with multiple operating and monitoring conditions.

The applicant appealed parts of the judgment (8, 9, and D3) to the Land and Environmental Court of Appeal (Mark- och miljööverdomstolen, MÖD), requesting clarification and amendments to specific permit provisions: Conditions 8, 9, and D3. The appeal focused on the ambiguous formulations of requirements related to sampling and classification, the restriction on the use of inert waste within the landfill without clarification, and the absence of explicit delegation that allows the supervisory authority to adapt inspection methods. The applicant did not challenge the environmental assessment of the reviewing authority, but argued that rigid and ambiguous conditions could create legal uncertainty. The court reviewed the appeal and, in 2023, amended these provisions while keeping the rest unchanged and legally binding.

The process involved document-based exchanges, including the submission of an application, raising stakeholders' concerns via a contact form, and the examination and interpretation of textual descriptions, permit conditions, and compliance criteria by both the applicant and the reviewing authority. The case study analysis presents an empirical investigation of the permitting process in practice and offers insights into the challenges identified in the literature, serving as a prerequisite for designing an efficient, streamlined, and coordinated digital permitting process.

Discussion and result analysis

Based on the literature review, the case study, and SOU 2024:98, several challenges in the Swedish permitting process are identified and summarized in Table 2. Each of these challenges identified in the study indicates underlying requirements for the conceptual design of a streamlined digital system to enable a transparent, coordinated, and efficient permitting process. The following sections present the challenges observed, the underlying requirements that these challenges produce, and analytical solutions that could potentially address such issues in the permitting process: *Regulatory Ambiguity and Interpretive Inconsistency, Institutional and governance constraints, Procedural sequencing failure, Stakeholder participation and legitimacy Issues, Confidentiality and Competition, Data Fragmentation and Usage Limitation.* The following subsections present the challenges observed in the Swedish permitting process.

Regulatory Ambiguity and Interpretive Inconsistency

One of the challenges identified in this study is the regulatory ambiguity and interpretive inconsistency in the permitting process. The case study demonstrates how ambiguous and unclear permit conditions triggered appeals due to difficulties in interpreting requirements.

Studies show that flexible, loosely harmonized regulatory criteria can lead to diverse interpretations and ambiguous decisions across regulatory authorities, prolonging the permitting process due to uncertainty (Wilson and Allard, 2023; Söderholm et al., 2022). A study by Wretling et al. (2022) highlights that spatial wind power plans in Sweden are applied and interpreted inconsistently across municipalities, leading to variation in their use as a decision-support tool.

Similarly, the SOU inquiry reports that the reviewing authorities are often perceived as not providing a clear position on requirements, such as what supplementary information is needed when assessing the completeness of the application. It highlights that the variation persists in permitting assessment across different authorities, leading to differences in requirements across regulating bodies, and illustrates the interpretative inconsistency of regulatory authorities (Miljötillståndsutredningen, 2024a).

This challenge of diverse regulatory interpretations indicates the need to represent legal requirements, provisions, and permit conditions in a clearer, standardized, and traceable manner. A potential solution could be to translate such regulatory requirements and provisions into machine-readable representations, such as ”rule as code”. This approach may not completely eliminate ambiguity; however, it can make underlying assumptions, thresholds, and relationships between regulatory provisions explicit, transparent, and traceable (Huggins et al., 2024). In addition, a decision support repository for storing prior applications, permit conditions, interpretations, and decision standards could complement it by linking rule representations with case-based evidence through structured metadata. This enables systematic comparison and alignment of interpretations across cases and regulatory bodies, therefore, improving consistency and predictability in the permitting process (Boess et al., 2021).

Institutional and governance constraints

Institutional and governance constraints are also identified as permitting challenges. Environmental assessments often require intergovernmental coordination due to overlapping jurisdictions, resulting in a fragmented, uncoordinated process (Wilson and Allard, 2023). In Sweden, the decentralized, multi-authority structure lacks horizontal coherence, while limited administrative capacity and expertise reduce efficiency (Streit et al., 2025). The increasing regulatory requirements for a broader scope of assessments, project characteristics, and institutional capacity make the permitting process time-consuming and pose a systemic challenge (Johnson et al., 2023; Söderholm et al., 2022).

Similarly, the SOU inquiry highlights unclear investigation requirements and reliance on referral authorities, and the absence of a clear threshold for application completeness. Limited guidance, staff turnover, and resource constraints at the regional and local level further affect consistency and timeliness, while increasing regulatory demands linked to the green transition intensify this pressure (Miljötillståndsutredningen, 2024a).

The case study also highlights decentralized institutional responsibilities and fragmentation in the current permitting process. The reviewing authority’s request for opinions from other regulatory bodies, such as the Building and Environment Administration, the County administration board, and the Geological Survey of Sweden, during application assessment indicates how the reviewing authority’s decisions could be influenced by such referral authorities.

The findings suggest the need for a coordinated, transparent system with common infrastructure, interoperable information exchanges, and clear role designations across authorities. A potential solution could be the design of a coordinated, centralized permitting platform that integrates data, actors, and procedural steps into a unified process architecture. This reduces fragmentation and improves information flow between stakeholders (Miljötillståndsutredningen, 2024a).

Procedural sequencing failure

Unclear procedural sequences and insufficient cross-referencing between regulations create additional challenges in the permitting process. The effectiveness of stakeholder participation is influenced by the sequencing and timing of procedural steps, as unresolved issues deferred to later stages can amplify risks and conflicts (Samec Berghaus et al., 2025; Fauth et al., 2025; Bernauer et al., 2023). Similarly, unclear scope definitions during consultation and redundant information flows across multiple authorities contribute to inefficiencies and delays (Freeman et al., 2022).

Table 2: Summary of the identified challenges in the permitting process and potential analytical solutions

Challenges Identified	SOU 2024:98	Case study/focus group	Literatures	Analytical Solution
Regulatory Ambiguity and Interpretive Inconsistency	X	X	X	Rule-as-code representations, decision-support repository and structured metadata to improve consistency, traceability, and predictability
Institutional and governance constraints	X	X	X	Coordinated centralized permitting platform with common infrastructure, interoperable information exchange, clear role designation across authorities
Procedural sequencing failure	X		X	Workflow orchestration model, rule-based validation, early application-completeness checks, clearly defined stages and information requirements
Stakeholder participation and legitimacy Issues	X	X	X	Digital stakeholder participation with access to project information, traceable feedback and monitoring, transparent review process
Data Fragmentation and Usage Limitation	X	X	X	Interoperable data infrastructure, harmonized metadata, API-based integration
Confidentiality and Competition	X	X		Data-sharing governance model, access control for sensitive information, selective sharing of commercially non-sensitive data

The SOU inquiry also highlights that procedural sequencing and timing, such as assessing completeness of the application and handling of supplementation, are recurring challenges in the Swedish permitting process. It notes the absence of a clear starting point of the deadline that the authority can confirm for the completeness of the application, and when statutory processing times begin. Workflow sequencing varies across authorities: some complete substantial work before formal processing begins, while others proceed only after formal public announcements. Thus, insufficient coordination and sequencing of procedural activities are also identified as contributing to delays in the permitting process (Miljötillståndsutredningen, 2024a).

The identified challenge, as presented above, points to the need for systems with a clear process flow, controlled sequencing of data and activities, and an early validation mechanism to ensure application completeness. A solution to the identified challenge could be implementing a workflow orchestration model in combination with a rule-based validation mechanism. This may reduce the need for iterative supplementation by structuring the process into clearly defined stages and information requirements.

Stakeholder participation and legitimacy Issues

Stakeholder participation and legitimacy are also identified as key challenges affecting the permitting process. While stakeholders play a critical role in shaping permitting outcomes, ineffective participation can undermine the EIA process and increase distrust (Bernauer et al., 2023). Although participation of affected groups, including indigenous communities, has improved, meaningful engagement remains constrained by resource limitations and procedural designs that marginalize concerns (Bernauer et al., 2023; Johnson et al., 2023). Delayed or insufficient early consultation, along with an unclear division of responsibilities, further contribute to conflicts during the review phase (Fauth et al., 2025). Wretling et al. (2022) argues that infrastructure development cannot realistically be achieved without harming the environment, so influencing the local opposition through a narrative of creating local jobs may not be sufficient

The inquiry indicates that the role of authorities in the Swedish permitting process is often perceived as unclear and unpredictable. Supervision and self-monitoring are perceived as person-dependent, raising concerns about consistency and competence. Inconsistent assessments of

similar activities across counties further reflect unclear roles and definitions, sometimes prompting applicants to adjust permit pathways to avoid uncertainty. This lack of procedural clarity leads to repeated supplementation and can prolong the permitting process. The inquiry notes that in some cases, authorities act simultaneously as advisors and supervisors, creating ambiguous roles that influence applicants' strategic choices regarding permit pathways (Miljötillståndsutredningen, 2024a).

The case study also illustrates that local stakeholders lack trust in the process, as they highlighted insufficient consultation and transparency requirements during the written exchange phase of the permitting process. Consequently, the demand for increased monitoring and for addressing perceived risks posed by activities in the vicinity was evident.

The issue of stakeholder participation and legitimacy indicates that transparent, traceable feedback and monitoring, and an inclusive participation mechanism are needed. A solution to address this challenge could be to enable digital stakeholder participation by providing access to project information, facilitating stakeholder engagement, tracking submitted concerns, and ensuring a transparent review process (Boess et al., 2021). Participation is most effective when it combines representation, communication, and delegation of power, and the mechanism ensures meaningful and traceable stakeholder influence in the decision-making process (Newig et al., 2023; Fothergill and Murphy, 2021).

Confidentiality and Competition

Confidentiality and competition are also identified as challenges that could lengthen permitting timelines. Although transparency is required, access to relevant data is constrained by legal considerations, institutional practices, and differences in digital information sharing across stakeholders (Miljötillståndsutredningen, 2024a). This limits the effectiveness of using the data and makes managing it more difficult.

The focus group also revealed that the information disclosure in the permitting process depends upon the sensitivity of the projects. For instance, projects that require handling and use of explosives, a rock quality assessment, and detailed exploration plans may be considered commercially confidential and therefore not shared publicly. This creates conflict between the transparency and the protection of commercial interests. It was emphasized that while early investigations allow applicants to assess and identify strategically viable locations, the public nature of the permitting process increases the risk of exposing competitive information.

It highlights the need for a secure data-sharing mechanism with controlled access to sensitive information, while balancing transparency and confidentiality. A solution to mitigate this issue could be implementing a governance model for data sharing and access control within the permitting process, thereby balancing transparency and competition. In addition, evidence from practice highlights the importance of structured metadata, interoperability standards, and the selective sharing of commercially non-sensitive data to enhance transparency while avoiding disclosure of sensitive information (Boess et al., 2021).

Data Fragmentation and Usage Limitation

Studies suggest that limited data accessibility and use also pose challenges for permitting, especially when evidence-based assessment depends on extensive environmental monitoring data (Streit et al., 2025). For example, in water discharge permitting, a lack of appropriate tools, monitoring technology, and structured emission can hinder evidence-based decision-making (Jensen et al., 2020). The presence of datasets from prior projects could help address stakeholders' recurring concerns and improve consultation efficiency (Freeman et al., 2022). Studies have indicated that the lack of accessible data for environmental permitting investigations can add a burden on applicants to conduct additional studies, which, otherwise, could help address recurring stakeholder concerns and enable evidence-based decision-making (Jensen et al., 2020; Streit et al., 2025; Freeman et al., 2022).

The inquiry report notes that, although County Administrative Boards and the Swedish Environmental Protection Agency initiated the collaboration to publish metadata for environmental assessment cases in digital form, the service may not have covered all relevant aspects and does not meet EU requirements. It emphasizes that the availability of data for measurement and monitoring enables reuse across different cases and can also facilitate automation (Miljötillståndsutredningen, 2024a).

The discussion from the focus group also highlights the challenges posed by the lack of accessibility of detailed data in the permitting process and indicates that, even though initial screening is performed using available information, the existing data lacks sufficient detail for assessment, requiring further studies. Furthermore, it notes that regions vary in digital adoption maturity, and the challenges lie in moving beyond the digital formats.

This challenge indicates that the data are fragmented and distributed across authorities, requiring improved integration, standardization, and interoperability. Due to the institutional independence of regulatory agencies in Sweden, the collection of such data into a centralized system might be difficult; therefore, enabling interoperability and integration between data infrastructures such as the Swedish Biodiversity Data Infrastructure, Species Observation Systems, agencies using shared, harmonized metadata, and application programming interface could be a potential solution (Biodiversa+, 2024).

Conclusions

This study investigated the challenges in the Swedish permitting process through a scoping review of available literature and conducted an exploratory case study. The findings reveal that the existing permitting challenges do not stem primarily from a single factor but rather from several

factors associated with the permitting process, distributed across different stages. Furthermore, it highlights that the permitting process extends beyond a regulatory procedure and involves complex socio-technical aspects, heavily influenced by interactions among legal requirements, stakeholders, procedural complexities, and dependencies. These challenges are not merely procedural but reflect underlying socio-technical constraints related to information flow, coordination, and decision-making across distributed actors. As such, they indicate the need for digitally enabled process architectures that can support structured workflows, interoperable data exchange, and transparent decision-making within the permitting system. Therefore, digitization efforts must go beyond standalone solutions and focus on integrated systems that could facilitate an improved, transparent, and efficient process.

This study also acknowledges several limitations. The analysis is based on a single case study and adds analytically to the understanding of issues within the permitting process; however, it limits generalization to the broader population. Moreover, though the approval process includes application, decision, and appeal, excluding the post-permitting stage limits the study's ability to capture challenges that may arise during implementation and monitoring. In addition, selecting focus group participants through a purposive sampling approach within a single organization may still introduce bias and limit the diversity of perspectives. Lastly, the study identifies digitization requirements at the conceptual level but does not provide empirical testing of the specific technologies to address these challenges. Future research will examine the conditions and requirements for conceptualizing and implementing the digital environmental permitting platform.

IFC5 FOR COLLABORATIVE AND TRACEABLE CIRCULARITY IN CONSTRUCTION

Tong Wang[1] and Thomas Krijnen[2]
[1]Delft University of Technology, Delft, The Netherlands
[2]AECgeeks, Eindhoven, The Netherlands

Abstract

Contemporary practices like evidence-based circularity and material tracking and tracing, are characterized by collaborative processes to layer, recombine, and update information non-destructively. This paper explores how the emerging IFC5, with USD-inspired, layer-based composition, enables such needs. The data model consists of layers, representing geometry, material characteristics, and lifecycle evidence. We explain how the principles help in a social housing circular window reuse scenario using a python-based web application on top of a Postgres database. By structuring information as composable layers, the introduced data model supports evidence-based circularity tracking, allows material and component matchmaking and information management.

Introduction

The transition to circularity in the built environment increasingly depends on the sector's ability to treat existing buildings as future supply systems, i.e. the repositories of products and components that can be recovered, verified, and redeployed. This shifts the feasibility of reuse and remanufacturing away from questions like "can we dismantle this?" toward information questions: what elements exist, where are they, what are their specifications and conditions, and can this evidence travel across project boundaries? This illustrates a critical premise for circular transition: without structured, component-level knowledge of the current stock, reused components remain difficult to specify, price, insure and certify.

The current information management practices in construction are typically fragmented across project phases, proprietary tools, and organizational boundaries, which makes multi-actor updating and validation difficult and leads to "static" records that quickly diverge from reality. This fragmentation is a well-recognized barrier in the circular construction literature, a persistent "information gap" between the data needed to scale reuse and what is available in practice, spanning identification, condition assessment and traceability (Byers et al., 2024).

To overcome circular transition challenges, in practice the use of digital technologies for tracking element reuse is increasing as exemplified in cases such as Durmiseciv (2018) and Hemubo (2026).

However, to scale up this way of managing information for circular transitions, system level stakeholder participation needs to be enabled. This increases the importance of governance, versioning, and responsibility for updates, which are features that are rarely robust in conventional document-based handovers (Çetin et al., 2023). Consequently, advancing circularity requires modular data models and lifecycle information infrastructures that enable multiple stakeholders to contribute, update, and reuse information consistently with traceable information records. This paper aims to answer:

RQ1 What are limitations in contemporary IFC technology in encoding buildings as future supply systems for circular construction?

RQ2 How can IFC5 and its JSON-based serialization format (IFCx) alleviate some of these pain points?

Methods

To answer the research questions, this study follows the following steps.

First, the current IFC technology limitations have been studied in literature as well as the IFC5 core principles to overcome such limitations.

Second, literature review has been conducted to understand the circular transition context in more detail, including the emerging regulations and supporting standards which make circular transition not wishful thinking, but a must take with mandatory data requirements, as illustrated in the emerging regulations and standards section below.

In parallel, we build upon ongoing research projects that support the understanding of challenges in the lifecycle information management of built assets for modular, participatory and traceable circular practice. This enables a solid foundation to showcase the potential that the new development in IFC5 could bring.

To make evaluation more concrete, we design a simple scenario of circular window reuse with the same asset owner.

The last part presents the data model, and the demonstration of the IFC5 at various milestones along the scenario process.

Results

Findings from the literature review as well as prototypical development to assess the applicability of IFC5 in the context of circularity are shown in this section.

Limitations of current IFC

Buildings as future supply systems require a data-oriented information modelling approach and to that extent Building Information Modelling (BIM) and the predominant open standard Industry Foundation Classes (IFC) to encode such information has seen more consistent adoption in the construction industry over time. The latest official edition of IFC is IFC4.3, encoded in the EXPRESS schema language, hereafter referred to as IFC4. There are limitations in IFC4 when it comes to facilitating circular construction. Tomczak et al. (2024) concludes that availability of specific information such as component connections that are vital for understanding demountability, remains a challenge in IFC and BIM-based workflows. This relates to (i) downstream information flows with limited ability for information to travel upwards; detailed manufacturing information might only be present at the time of a construction, but due to export-centric workflows where information flows downstream, authoring tools have little ability to consume this information to maintain a comprehensive record of information; (ii) construction knowledge is distributed across multiple project partners. While there are ample research and initiatives to define and compare information requirements, these only stipulate information contents between given point to point exchanges of information. Within the industry there is little incentive outside of these exchanges to combine knowledge.

Limitations of the current IFC and EXPRESS/SPF (Step Physical File; the predominant text-based serialization format used for IFC) it is based on can be summarized as: (i)Limited support for developer tooling and mindshare of the EXPRESS language and related serialization technologies due to idiosyncrasies and datedness, which does not connect to modern web-based APIs that are quick to deliver value and test assumptions. (ii) Technical serialization-level limitations such as the inability to combine data sets, inability to establish links across information carriers and lack of modularity in the IFC schema. (iii) Lack of uniformity in data due to the extensive set of modelling mechanisms, valuing backwards compatibility over consistency. (iv) High degree of complexity that impedes mapping to other storage technologies such as relational databases. (v)Monolithic exchange structures that do not enable granular composition with other datasets or incremental updates over time (van Berlo et al. 2021). These limitations impede the use of IFC for lifecycle updates of asset data, with multistakeholder collaboration. Building richer retrieval mechanisms on top of IFC serialization and data models has been attempted in Krijnen and Beetz (2018) and Wolf et al. (2025) using SPARQL on top of an efficient binary serialization mechanism or a GraphQL mapping respectively. While that aids discovery of information, it is not a step into the direction of freely recombining information. The semantic web has also been used in disseminating construction information and allows for collaborative authoring due to the nature of linked data, however geometrical information is not always efficiently stored (Pauwel et al. 2017) and there is not a rich ecosystem for working with geometry in the semantic web. The semantic web is most powerful when fully embraced natively in applications to depend on things like inference, which is not the case to date.

These aspects are recognized in buildingSMART. And over time, starting with designing and defining future principles (BuildingSmart,2020), the technical roadmap (BuildingSmart, 2020) and first explorations into a IFC5 resulted in the publication of a standard called IFC5 alpha (BuildingSmart, 2026). It is heavily inspired by Universal Scene Description (USD) (USD, 2026) a standard used in the film industry, a sector with similar needs in collaborative authoring. From USD, IFC5 derives its layer-based composition, data inheritance mechanisms, central placement tree and focus on explicit data for robustness with additional layers of meta-data for semantic richness. With such principles, IFC5 is particularly well aligned with the need for modular, multi-stakeholder lifecycle information management because its development direction explicitly shifts IFC towards modular schemas and extensibility. Information that is important for circular construction, e.g., condition assessment, deconstruction attributes can be added and iteratively refined without forcing every stakeholder to implement the entire schema or exchange the full model.

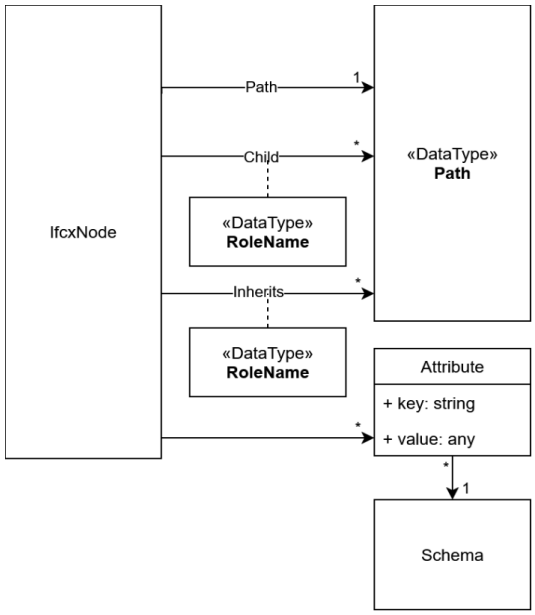

Figure 1: Schematic representation of the data model of nodes in IFCx. Children (for element decomposition and containment) and inheritance (for data reuse) are established as references to paths. The serialization remains flat without nesting. Multiple Paths do not uniquely identify a node. This realizes the collaborative distributed nature by allowing different sources to augment the shared understanding of an element

IFC5 alpha follows an exchange format in JSON with a minimal schema. The exchange structure is called IFCx

and consists of a header with provenance information, imports, schemas and a data array of primitives. Primitives are objects that have a path in the tree, inheritance relationships to other primitives, children relationships to other primitives and attributes as key-value pairs. The schemas in the header govern the validity of these key-value pairs. Imports from the header are essentially prepended to the dataset and can contain schemas and other primitives. Inheritance relationships broadcast all information, attributes and children, along the inheritance edge and are essential to realize re-use of information (see Figure 1).

Emerging regulations & supporting standards

The EU policy context for traceable, reusable construction components is increasingly shaped by a shift toward digitized, interoperable information flows. The Construction Products Regulation (CPR), Regulation (EU) 2024/3110, explicitly motivates the need for "well-functioning information flows" using electronic means and machine-readable formats, so that coherent product performance information is available along the supply chain and supports the digitalization of the construction sector (Eota, 2024). A central mechanism introduced by the CPR for product-level traceability is the Digital Product Passport (DPP). Article 76 requires that a DPP includes core compliance information (notably the declaration of performance and conformity), corresponds to the product type and its unique identification code, and allow designated actors to introduce or update information in the passport. Importantly for reuse workflows, Article 76(3) states that DPP requirements should improve traceability of products along the value chain. CPR also links unique identifiers, data carriers, and the DPP registry mechanisms to the horizontal DPP framework established under the Ecodesign for Sustainable Products Regulation Regulation (EU) 2024/1781, unless CPR delegated acts specify otherwise. For renovation, the Energy Performance of Buildings Directive (EPBD) introduces building-level information pathways via renovation passports and (where they exist) digital building logbooks (DBLs). In Article 12(7)(8) it requires renovation passport information to be uploadable to national energy performance databases, and that the "easiest approach" is to use a machine-readable, standard format that supports seamless integration and querying (European Commission, 2024). Open data schemas such as Industry Foundation Classes (IFC) are explicitly intended to provide vendor-neutral, machine-interpretable representations that enable information exchange across tools and use-cases, forming a backbone onto which circularity modules (e.g., material passports, audit results, condition states, reuse certifications) can be attached (BuildingSmart, 2026).

Lifecycle information management for circularity

Lifecycle information management has long been positioned as an enabler of collaboration in BIM-based delivery and operations, but circularity raises the bar by even requiring data continuity beyond a single project and into end-of-life recovery and second-life deployment. Standards-based guidance associated with ISO 19650 frames the core problem as ensuring the right information is created, shared, and maintained over the whole asset lifecycle through controlled processes and a common data environment (UK BIM Framework, 2021). In circular settings, this lifecycle requirement becomes sharper: component information must remain usable when the original design/construction team is gone and when new actors (deconstruction contractors, remanufacturers, reuse marketplaces, regulators, new designers) need to interpret and trust the data. Policy and practice guidance on pre-demolition or "waste" audits implicitly treat information as the first circular intervention: the European Commission's audit guidance emphasizes qualitative and quantitative assessment of what will arise from demolition/renovation in order to maximize recovery and reuse (European Commission, 2018). Yet, even where audits exist, their outputs are commonly delivered as isolated reports or spreadsheets that are difficult to integrate with design models, asset registers, maintenance systems, and marketplaces. This means that the information is generated but not maintained as an updatable asset. This is the specific information-management failure that circular pilots attempt to mitigate through traceability schemes (e.g., coded material databases in Kerkrade; component-level QR/NFC "DNA") because such mechanisms create a minimum viable link between physical components and persistent records that can be consulted by later stakeholders (Durmisevic, 2018). The same "information-first" premise appears in Amsterdam's circular window-frame practice: embedding an identifier on frames that links to a web page containing provenance, processing, finishing, and expected lifetime data which effectively treats the component as an information object that can be managed and verified across actors and over time (Hemubo, 2026). Together, these applied cases indicate that even though circularity is constrained by recovery logistics (Lu et al., 2023), emerging technologies are making assets into a next use traceable.

However, one key implication is that circularity is not well served by monolithic, one-size-fits-all datasets; instead, it requires modular data models that can (i) represent construction objects consistently, (ii) attach new lifecycle modules (condition monitoring, disassembly history, compliance evidence, ownership transfers), and (iii) support interoperability across heterogeneous systems. Research on digital product passports and material passports has increasingly converged on modular modelling as a response to the complexity and volume of lifecycle data. For example, a modular ontology modelling approach for digital product passports has been proposed specifically to address the challenge of representing, managing, and exchanging circularity-relevant information at scale, arguing that modularity improves extensibility and reuse of data structures as requirements evolve (Kebede et al., 2024). This direction is reinforced by the circular construction ecosystem (e.g., Buildings-as-Material-Banks initiatives), which frames material passports as structured datasets that describe the

characteristics giving materials value for recovery and reuse and positions them as "one-stop" information resources. This is an ambition that is only attainable if information can be structured, updated, and exchanged across actors (BAMB, 2020). The housing-sector evidence base further underlines why modularity matters: social-housing organisations need passport data that covers maintenance, renovation, and demolition use-cases simultaneously, implying that the underlying model must support different stakeholder views and responsibilities without losing semantic consistency (Çetin et al., 2023).

Implementation

To answer the second research question a protypical implementation is conceived to simulate a simplified scenario in a circular construction context. The scenario is developed and validated in the on-going research projects with multiple stakeholders in façade products to rethink future circular constructions (NGF, 2025); the phases and steps described have been discussed and validated as realistic potential to-be scenarios. This scenario is used to link various stakeholders with the modular design principle of IFC5. In this research the focus is not on a demonstration and validation of the entire workflow, but on the technical requirements involved. The scenario is explained as follows: a social housing organization (the client) demolishes a single residential building (Building A) and seeks to reuse selected windows in a new replacement building (Building B). The operational challenge is threefold: first, the demolisher must capture reliable "as-removed" window information during selective strip-out; second, the architect designing the new building must be able to perform matchmaking using data that is integrated into the building information model rather than dispersed across unstructured reports. And lastly the asset owners should be able to provide demolishers with demountable window sets and keep track of the reused windows in the new building.

Demolition phase: demonstrated in updating

Before demolition begins, windows in Building A are represented as identifiable component instances in the client's digital building model. During selective removal, the demolisher updates the model by appending statements to their layer of information, per window instance, the data required for downstream reuse decision-making. In addition, the demolisher records a condition snapshot and handling-related notes relevant to transport and onward processing, reflecting the practical reality that removal method, contamination, and damage significantly affect reuse feasibility. The demolisher's contribution is framed as a specialized dataset: it describes the state of each window at the point of removal and the conditions under which it can plausibly be reused, without requiring the demolisher to author design information for the new building. This separation of responsibilities is essential for scalability as demolishers can provide factual "as-removed" information, while architects can interpret that information within the constraints of the new project.

Design phase: demonstrated in matchmaking

The architect uses the updated window information (stored in a federated set of multiple layers) as a stock list for reuse. Matchmaking is performed by comparing recovered-window descriptors to the dimensional and performance requirements of the new building design. This produces a mapping between the new building's window openings and specific recovered window instances, which supports both procurement planning (reducing the number of new windows that must be purchased) and design development (ensuring that the design accommodates the constraints of the recovered stock, where reuse is intended).

Installation and maintenance phase: demonstrated partially in querying

Once installed in the new building, each reused window is recorded as an "as-installed" component instance, including its installed location, installation date, and any relevant references to associated product information. This paper only demonstrates the querying for windows without linking to the other digital repositories. Where a Digital Product Passport exists for a given window product (for example, if the window has been remanufactured and supplied under a product regime that provides a DPP), the installed component record includes a pointer to that passport. This creates product-level continuity: the same product information can be accessed later for maintenance, renovation, or audit, and updates can be managed by the responsible actors in the passport system rather than being embedded as static attachments. The building-level traceability layer is also established through a building repository approach consistent with the logbook pathway. The owner maintains a record of installed reused windows as part of the building's digital record, enabling future renovation planning. This links product-level traceability and building-level traceability so that reused windows remain discoverable across the building lifecycle, rather than becoming "lost".

Prototype development

Here we illustrate how IFC5 data models and serialization technologies relate to the circular construction context described above. Note that the demonstration is meant to show and validate features on a conceptual level. Due to the limited number of constructs, uniformity of structure and usage of JSON, for which most modern database management systems have native support, this structure is easily serialized to a relational database. For this experiment the following table layout (Figure 2) was chosen. Important to note are the indirections between Project – Layer – Primitive, so that a Project has multiple layers (this is the multi-disciplinary aspect). A primitive has a single attribute blob as a JSON field and inherits children edge pointing to UUIDs. Also note that Primitive UUIDs are not unique (in the IFCx structure they are called "path"), so that multiple definitions pointing to the same path can be retained. This also enables the multi-disciplinary nature so that objects are open to be extended with additional data.

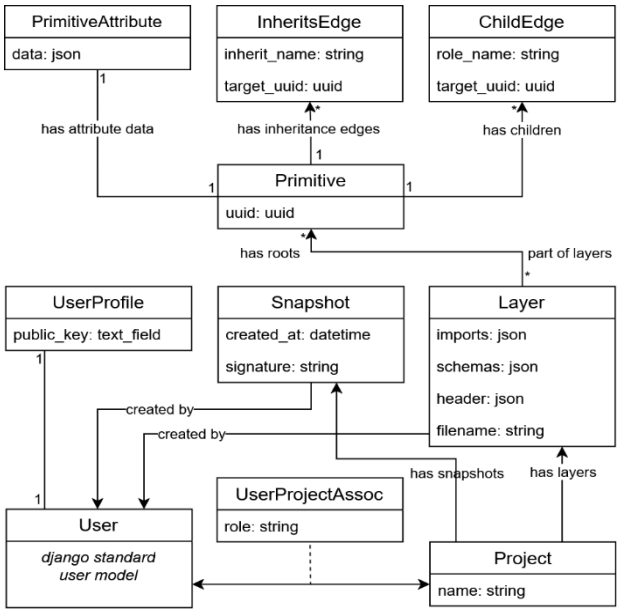

Figure 2: Data model used in the implementation.

Data ingestion follows an append-only nature, meaning that all data is immutable in the database, newer opinions (attributes at the same path) can override pre-existing ones and will come in with a higher strength, but it is possible to go back to a previous state because everything is time-stamped. Snapshot allows stakeholders to take a state of the project and create a digital signature. The database model is generated from python code and implemented in the Django web framework. The queries shown later are actual logged queries from the implemented prototype.

To investigate the implications of circularity tracing and reuse, we have experimented with only storing the layer_id in case of a root primitive (a primitive with no incoming child or inheritance edges). The root primitive is typically the IfcProject entity. Therefore, subsequent children can freely be associated with multiple layers (and therefore physical projects) to see how data can flow between projects in accordance with the physical products when one building is decommissioned and windows are moved to the next building. Listings below illustrate the different purposes enabled by this data model, i.e. querying, updating, and matchmaking.

Querying

As mentioned above, there have been initiatives of query languages on top of reserializations or conversions of IFC models but widely implemented IFC query languages to date are not in use. This section illustrates that by means of the simpler layout of IFC5 data, reliance on industry standard data representation techniques such as JSON and mappings to standard database management solutions, querying techniques are available on top of IFC5 content.

Listing 1 describes Postgres-specific query using JSON-object-subset search. As such we can locate all

PrimitiveAttribute instances of class IfcWindow. Note how the association of a class (or building element type) is like any other data attribute field an arbitrary (but schema-enforced) key-value pair. This is something already observed in van Berlo et al. (2021) where it was called “late bound” type definitions, since distinct building element classes do not relate to specific behavior in software, and mappings from native models to IFC classes need to be fully configurable by the end-user.

```
SELECT *
FROM primitive_attribute INNER JOIN primitive
ON (primitive_attribute.primitive_id = primitive.id)
WHERE primitive_attribute.data @> '{"bsi::ifc::class":
{"code": "IfcWindow"}}';
```

Listing 1. SQL query on top of the data model to demonstrate indexed JSON-object-subset search in contemporary database.

In addition, we want to find (recursively) all elements inheriting from the Primitive with this attribute (but not elements having it as a child) because the class association might be assigned at a re-used archetype (or a Family as sometimes called in BIM authoring tools). Everything that inherits from these primitives is also an IfcWindow (unless the attribute is locally overwritten there). The inheritance aspect can be solved transitively by applying a recursive Common Table Expression (CTE) in Postgres with the results from the previous query, following inwards edges (Listing 2).

```
WITH RECURSIVE edge AS (
  SELECT primitive_id, target_uuid FROM inherits_edge
),
walk AS (
  SELECT
    p.id, p.uuid,
    ARRAY[p.id]::bigint[] AS visited_ids,
    0::int AS depth
  FROM primitive p
  WHERE p.uuid = ANY(ARRAY['2c2d549f-f9fe-4e22-8590-
    562fda81a690'::uuid,'592504dc-469a-44d6-
    9ae8-c801b591679b'::uuid,'25503984-6605-
    43a1-8597-
    eae657ff5bea'::uuid]::uuid[])
  UNION ALL
  SELECT
    p2.id, p2.uuid,
    w.visited_ids || p2.id,
    w.depth + 1
  FROM walk w
  JOIN edge e ON e.target_uuid = w.uuid
  JOIN primitive p2 ON p2.id = e.primitive_id
  WHERE NOT (p2.id = ANY(w.visited_ids))
),
uniq AS (
  SELECT DISTINCT id FROM walk

)
SELECT p.*
FROM primitive p
JOIN uniq u ON u.id = p.id ORDER BY p.created_at, p.id;
```

Listing 2. SQL query using a recursive CTE to find inheriting primitives. This is a verbatim copy of the query. The array of uuids present in the query comes from the Object-Relational Mapping;program code to interact with the database schemas)

This also highlights how modern database solutions can be used to efficiently apply the inheritance and children relationships to the dataset. In the IFC5 project team it has been discussed whether data inheritance is necessary as it has negative implications on data locally and complexity. The experiment here shows that the complexity and performance concerns are not insurmountable.

The query above is for finding primitives that inherit from other primitives. Similarly, a query can be used to do a

forward traversal over inheritance and children edges. This query is used when returning the data to the user to return a full model subset. This query is equivalent, just the edges are formed as the union of inherits_edge and children_edge, and the direction is reversed (concerns the ON clauses in edge and primitive).

This full model subset is valid IFCx again that can be visualized in one of the supported tools (Figure 3).

Figure 3: Query demonstration. Note that the result presented is not a visual selection of relevant models: with the IFCx serialization structure, a query result is a complete and valid model subset that can be used and recombined, for the full set see (IFC5 Development, 2026).

This highlights an important distinction between IFC5 alpha and earlier editions of the spec, which had much more dense graphs requiring a lot of other contexts, such as IfcGeometricRepresentationContext and IfcProject with IfcUnitAssignment. These combinations made extracting and concatenating content much more complicated. In IFC5 because of the flat pre-composition data structure, the literal serialization of the primitives selected provides us with all the relevant contexts.

Updating

When the demolisher receives the window query model, they can go on-site to add inspection information. Using a modular ontology, they create a new layer with only this information. The usage of paths in IFCx, makes sure that information lines up with the pre-existing content. This is to illustrate the applicability of updating information by a specific stakeholder in the process (Listing 3).

```
{
  "path": "23ea7c34-6e5a-47ee-b292-ebedfd585438",
  "attributes": {
    "decommissioningStatus":"removed",
    "currentState": "stored",
    "conditionGrade": "B",
    "damage": "minor_scratch",
    "contamination": "none_detected",
    "disassemblyType": "reversible",
    "reusePotential": "direct_reuse",
    "recommendedAction":
      "clean_and_reinstall"
  }
}
```

Listing 3. IFC5 primitive that is ingested by the demolisher showing the modularity of IFC5 schemas and the collaborative data authoring by composition of data on paths

Matchmaking

At this stage, a new project is created. The architect uses this data model with the dimensions of the windows enriched with the inspection information to select suitable windows to be reused. We illustrate this with just a simple wall with the same void. To this experiment, a wall is created in the open-source BIM authoring tool Bonsai with an opening that matches the to-be-reused window, saved as IFC4 and converted to IFC5. The transfer of the window element from the old model to the new model is manifested by means of creating a new primitive in the old model that inherits from the window to be reused. In this case, a placement transformation is necessary because the demo model used does not have proper relative positioning (Listing 4).

```
{
  "path": "33ea7c34-6e5a-47ee-b292-ebedfd585438",
  "inherits": {
    "circularReuse":  "23ea7c34-6e5a-47ee-b292-
    ebedfd585438"
  },
  "attributes": { "usd::xformop": {
      "transform": [[0.0, -1.0, 0.0, 0.0],
            [1.0, 0.0, 0.0, 0.0],
            [0.0, 0.0, 1.0, 0.0],
            [4.98, 12.97, -0.71, 1.0]]
}}},
```

Listing 4. Primitive that is created in the new model that inherits from and repositions the reused window instance (The term "circularReuse" is a human-readable label to reference the inheritance edge; it has no computer-interpretable semantics.)

Now we place this removed window from another building on the newly created wall (Listing 5, Figure 4).

```
{
  "path": "46b17e20-783e-4bf5-ac74-714b859be0b3",
  "children": {
    "Body": "a03ebe4d-2e40-524e-9144-c03ebec7100e",
    "Window": "33ea7c34-6e5a-47ee-b292-ebedfd585438"
  },
  "inherits": {
    "material":  "8a187a90-3dcf-58cc-b3a6-51a9a407c55a"
  }
}
```

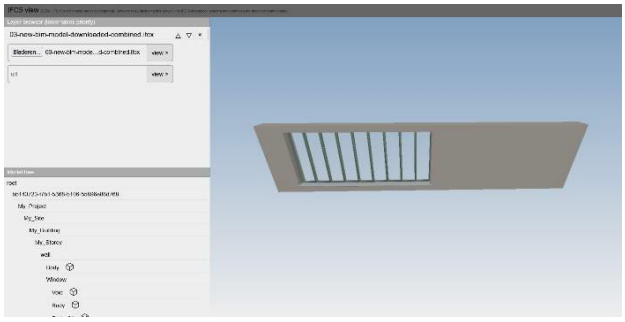

Figure 4: Result of reused window model when recursive query

traverses also into the reused window by means of path references

Discussion

The study can be further improved by testing other user requirements for circular construction, such as updating logistics constraints by transporting parties and warehouse facilities for storing the products and integrating other information sources like IoT for smart homes and linking with digital building logbooks or renovation passports.

It is worth noting that this research does not aim for a complete circular workflow but the technical possibilities of using IFC5 to enable modular, participatory and traceable data exchange. This is used to support circular use cases like querying by the clients for their assets, updating information from the perspective of the demolishers and the matchmaking by the architects using reclaimed windows for a new project. These are based on a simplified circular scenario. Future research should study from the user perspective to what extent this could be adopted and implemented in the inter and intra organizational settings, which will impose a greater need on transport and APIs as this research focused predominantly on the data-model.

In addition to that, the emphasis here has been mostly on the serialization-level aspects of the IFCx data encoding used by IFC5 and how industry-standard solutions such as the Postgres database management system with its support for JSON fields in tables, indexed JSON object subset search and recursive expressions enables a good amount of the core set of functionalities that are needed to deliver a platform to host such functionality. It is expected that other tooling around JSON is equally valid and useful, such as DuckDB or command line tools such as jq. In this implementation there is nothing special about Postgres and that is exactly the advantage of the IFCx JSON-based serialization mechanism.

In IFCx, provenance is tracked by means of the containing layer, but there is still ongoing debate on the balance between primary file-based workflows and more transient datasets created as query results and how this impacts the need for per-component identity or provenance records. The focus on data model in this research left aside most of the queries of transport: how do the various layers get into one (federated) data environment? In this research, the requirements for that have been simplified by simulating a case where the owner of the windows did not change. These are worthwhile, but also mostly orthogonal, questions for future research.

Conclusions

Emerging regulations for circular construction have raised requirements to exchange information among multiple actors in a modular and traceable approach. This paper has described pertinent IFC4 limitations in encoding information for the purpose of circularity and how IFC5 can help different actors in the value chain to deal with the emerging regulations for circular strategies like reuse of built assets using a simple context. The used dataset can be found in the following link: https://zenodo.org/records/18505849.

Currently, re-allocating the data representation of an IFC element to a new project in a fully immutable append-only and traceable data model would have been impossible to accomplish on IFC4 datasets due to the contextual references required to context and objectified relationships and the lack of data-level composition mechanisms.

With the new capability and data model of IFC5, the circular transition can be operationalized and upscaled by the supply chain partners participating in data querying, updating and matchmaking for reusing of assets.

Abstract

The Industry Foundation Classes (IFC) standard underpins BIM interoperability, but its STEP/EXPRESS stack is ill-suited to cloud-native, transactional workflows. Building on buildingSMART community-driven requirements and proposals, review of alternative solutions, and iterative prototyping, we propose the modernisation of IFC. The work includes a proposal for a data schema, JSON serialisation, and exchange mechanisms, while preserving IFC's role as a semantically rich neutral data model. Innovation includes a compositional, layered federation model allowing incremental updates, multi-author collaboration, versioning, and fine-grained, traceable ownership. We compare the proposal to existing standard and discuss the potential, trade-offs and implications.

Introduction

IFC originated in the mid-1990s as a vendor-neutral product model for exchanging building information, initiated by the International Alliance for Interoperability (IAI) and later stewarded by buildingSMART as an open standard for BIM (Building Information Modelling). Through iterative releases in the 1990s–2000s, IFC gravitated towards its current scope. The common IFC use cases span design and construction coordination, design data transfer, asset management, building permitting and documentation archiving. The IFC in its current form has matured into a widely adopted format, implemented in over 400 software tools (buildingSMART Int., 2026b), enabling structured exchange of building and infrastructure data worldwide.

The IFC specification has been extended with each subsequent release, with addition of more entities and properties to describe the broad landscape of architecture, engineering, construction and operations (AECO) concepts. For example, the latest release – the IFC 4.3.2 – introduced classes and properties to more accurately describe roads and rails (buildingSMART Int., 2024). Some updates unified properties, that before could differ in definition depending on the object described.

Aiming to support plurality of industry use cases, the IFC standard grew in complexity, allowing many alternative ways for modelling some aspects. For example, alphanumeric data can be attached to objects as attributes or properties; objects are classified using IFC entities, but also predefined types and classification references; there are forty ways to assign material to an object (Tomczak et al., 2024) and over 170 kinds of geometric primitives - subtypes of *IfcRepresentationItem* and *IfcProfileDef* (buildingSMART, 2024). Noardo et al. (2019) investigated geometric errors and implementation inconsistency. This kind of implementation inconsistency is incredibly detrimental to the necessary trust in a digital language of the construction sector. The combinatorial nature of the geometry definitions results in implementations supporting different subsets of the standard which further inhibits successful interoperability. Lastly, the complexity associated with the immense breadth of geometric paradigms can be seen as a barrier to adoption.

On a specification level, the IFC follows strict compatibility dogmas, so reductions in scope are rarely realised, which results in a gap between specification content and actual usage in practice. While cloud-based data exchange and incremental updates are not new in contemporary BIM tools, the IFC today is primarily used for file-based exchange, where a full dataset needs to be transferred, even for a simple update of one property value. Furthermore, the IFC preserves information about a single author and authoring application per file, limiting traceability.

Related works

An influential attempt at modernizing IFC has been captured by van Berlo et al. (2021). Core ideas there were a re-evaluation of the amount and lack of consistency between relationship types, and introduction of the concept of 'late binding' to IFC. Over time, the community has come to realise that the taxonomy of building elements does not need to map to distinct classes in computer programming languages, and are therefore better kept out of the main schema in a secondary "late bound" layer, more akin to the data format in which property sets are described in the specification. This same research also indicates the desire to move towards 'object-based incremental updates' but does not yet give concrete technical steps towards realizing this, but does list predictable, normalised tree structures in the graph as an enabler. The Technical Roadmap (buildingSMART, 2020) sets the direction and calls to reconsider the technological stack of openBIM standards.

The STEP Physical File (SPF) remains the primary and most widely used serialisation format for IFC, although it is not the only officially supported option. Alternative serialisations include ifcXML and the compressed ifcZIP

formats (buildingSMART, 2022). JSON-based representations, aligned with contemporary web data exchange practices, have been proposed as alternatives to the traditional IFC stack by Afsari et al. (2017) and Brouwer et al. (2020). Despite these efforts, SPF has retained dominance due to its tight coupling with EXPRESS schemas. It enforces strict schema rigidity and ordered, unnamed attribute sequences, allowing SPF to represent complex graph structures concisely. This effective SPF structure has no real equivalent in modern languages and thus limits the industrial adoption of alternative serialisation formats.

Several efforts have explored the application of semantic web technologies for BIM. As part of the IfcOWL project, the IFC has been mapped to OWL, enabling RDF-based representations that can be queried using SPARQL and linked with other web resources (Pauwels et al. 2017). IfcOWL also introduced alternative geometric encodings based on Well-Known Text (WKT) to reduce verbosity and support GeoSPARQL. However, the direct mapping of EXPRESS to OWL introduces many indirections, which negatively affect query performance and reasoning expressiveness. In response, lighter-weight ontologies such as BOT have been proposed to support higher-level building topology without replicating the full IFC schema (Bonduel et al., 2018).

Indirections are the intermediary constructs and steps that must be traversed in order to relate a value to an entity. IFC is known for its many indirections, for example to get from a material to a colour: "*IfcMaterial←IfcMaterialDefinitionRepresentation→IfcStyledRepresentation→IfcStyledItem→IfcStyleAssignmentSelect→IfcPresentationStyleAssignment→IfcPresentationStyleSelect→IfcSurfaceStyle→IfcSurfaceStyleElementSelect→IfcSurfaceStyleShading→IfcColourRgb".* These indirections come at a cost in terms of: (a) performance; data model size; query joins (b) cognitive overhead in understanding (c) lack of ownership clarity when reusing data. In RDF additional indirection occurs by representing ordered lists as binary trees of *<first, rest>*-pairs.

Property graph approaches have been explored in systems such as IFCWebServer (Ismail et al., 2017) and in multiple Neo4j-based mappings (Zhu et al., 2023). These approaches leverage graph traversal and analytics capabilities but typically require bespoke schema mappings and tooling.

Relational database storage of IFC data has also been extensively studied (Li et al., 2016; Solihin et al., 2017), with roots tracing back to early systems such as BLIS and Sable within the IMSrv platform (Beetz et al., 2010). However, mapping EXPRESS constructs - including deep inheritance hierarchies, complex aggregations, inverse attributes, and SELECT types - to relational schemas introduces significant complexity. This results either in large numbers of tables or substantial application-layer logic, a challenge commonly referred to as the object-relational impedance mismatch.

Key-value stores offer a more flexible alternative, as they impose minimal structural constraints and delegate serialisation entirely to the application. BIMserver.org is a prominent example of this approach (Beetz et al., 2010). While efficient and well-suited to complex object graphs, key-value storage is typically binary, non-portable, and not human-readable, limiting its suitability for archival or interoperable exchange scenarios.

Binary formats have also been explored for handling large explicit datasets, particularly meshes and point clouds, using HDF5 (Krijnen & Beetz, 2020). Although technically effective for specific high-volume data scenarios, these approaches address a narrow set of use cases and introduce dependencies on additional complex standards, despite the existence of an official EXPRESS-to-HDF5 mapping in ISO 10303-26. They also do not align well with requirements for incremental exchange or web-based workflows.

More recently, Universal Scene Description (USD), originally developed by Pixar, has gained attention due to its strong support for large-scale collaborative asset composition. Governed by the Alliance for OpenUSD and undergoing standardisation efforts, USD emphasises explicit data, layered composition, and conflict resolution through ordered 'opinions'. Its schema-agnostic composition mechanisms resemble certain IFC concepts, such as TypeObject–Occurrence relationships but operate at the serialisation level rather than within a formal schema. These characteristics make USD conceptually attractive for AEC collaboration, despite its origins outside the domain.

Finally, lightweight mesh-based formats such as glTF support many contemporary visualisation-centric use cases, including coordination and clash detection, while enabling integration with a broad ecosystem of off-the-shelf tools. However, they largely omit semantic richness.

Borkowski (2026) argues that mesh-based formats such as glTF and USD, combined with structured non-geometric data stored for example in JSON, CSV, or SQL, represent a plausible alternative to kernel-dependent IFC. He characterises traditional file-based BIM workflows as slower and more cumbersome to integrate than granular data systems, and suggests that BIM practice may need to shift from a software-centric toward more data-centric.

The breadth of explored serialisation and storage approaches highlights fundamental limitations of the EXPRESS-based ecosystem in supporting contemporary construction industry use cases. The expressive power of EXPRESS, while beneficial for formal schema definition, complicates mapping to modern, web-oriented data frameworks. The requirements driving these investigations are discussed in the following section.

Method

Requirements

The requirements documented here were shaped over years of involvement in the buildingSMART community, and have been refined through in-person meetings and presentations.

1. Distributed ownership and authorship traceability

The construction sector is a multi-disciplinary field with strict responsibility boundaries and liability. It should be possible to combine datasets while strictly retaining the provenance of where information comes from, without inhibiting establishing rich semantic links between concepts from distinct disciplines. To realise accountability, the provenance of information needs to be traceable. IFC to date has an *IfcOwnerHistory* entity, but that tracks only the meta-data of the latest rendition of the object. There is no way to retain deleted information, or a longer provenance trail.

2. Incremental updates

Building models can realistically amount up to gigabytes of data in contemporary engineering projects. It should be possible to provide only the changes to earlier exchanged model.

3. Moderate complexity

Many of the contemporary use cases in which IFC is employed are not that complex, such as visualisation and coordination. There is also an asymmetry in complexity: IFC is often seen as a compromise between many different options of representing elements. Therefore, for an authoring tool it is sufficient to only support one single option and write that out. Conversely, a downstream application, such as a viewer or manufacturing platform must harmonize all different options coming from different tools. This asymmetry needs to be reduced to open BIM data to a wide variety of neighbouring domains and facilitate reuse of information downstream. This could for example mean moving the responsibility of interpreting complex procedural geometry to the producing side, where it is already rendered to a triangle mesh for display anyway.

4. Plurality of representation

Each physical and spatial object can be represented with geometry, but the accuracy, complexity and kind of geometry might differ, depending on the needs. A building at an urban scale might be simplified to a bounding box cube, while at close-up could be highly detailed. An example wall can be modelled as an extruded set of layers with procedurally cut-through openings, or as a triangulated mesh resulted from computation, to speed-up rendering speed. Same wall could be simplified to a guide curve and thickness, or have a point-cloud representation to compare as-built model with reality.

5. Performant

In order to increase the number of iterative design and engineering cycles the import/export/analysis times need to be reduced compared to contemporary IFC workflows. This also means less indirection (intermediary steps) between data, that are problematic in current querying workflows and may obscure ownership semantics.

6. Cloud-friendly, web-native

Common Data Environments (CDE) have become more popular, but true distributed and collaborative workflows are impeded by the monolithic and idiosyncratic nature of SPF-based exchanges.

7. Granular data access

Ability to expose or load only a subset of information. This could be either for performance or confidentiality reasons. For example, an engineer might want to see architect's walls, but not their finishing.

8. Extensibility

To support rapid innovation and multi-disciplinary challenges, extensibility should be possible on a level beyond adding additional key-value pairs as user-defined property sets. Examples include efficient encoding of compressed point clouds (Krijnen & Beetz 2017) or the impediments in realizing modelling circularity related element connectivity (Tomczak et al. 2024). Currently, in EXPRESS-based schemas, there is no realistic way to provide this kind of extensibility as it would require publishing a novel schema version with a unique schema identifier which affects even the software that would ignore the extension because it is outside of their intended domain.

9. More predictable and atomic data patterns.

Currently unclear whether something is a primitive with an identity or an attribute with a value. For example, *IfcMaterial* does not have a Globally Unique Identifier (GUID), and is therefore only a transitive object. Relationships have GUIDs, but tools cannot typically maintain consistency between export cycles.

10. Bridge BIM with GIS, IoT, Digital Twins etc.

Building information is not limited to design data, but fits into larger geospatial context commonly represented with GIS, and can serve during asset operation phase. In case of continuously updated models, often fed with live sensor data, BIM can serve a role of a Digital Twin. Therefore the data exchange standard of the future should not limit to one, but rather allow multiple schemas and representations.

11. Independent and easy to update modules

Up until now, the IFC standard has functioned as a monolithic data model published as one large standard document with almost 500 pages (ISO 16739-1:2024). While this ensured a comprehensive coverage of the built environment, it also resulted in a massive specification that is difficult to maintain and cumbersome for software vendors to implement fully. As the scope of IFC expanded to include new domains such as Rail, Road, and Tunnel, the time required between release cycles increased, often taking years to ratify updates.

Proposed Solution

We propose a novel data exchange solution, that is aimed to resolve common IFC issues, and address the requirements (1-11). The first building-block module of the proposed modern IFC is the schema, enabling further definition of an API module, domain knowledge/semantics modules and technical extensions.

A dataset called the 'Hello Wall' will be used to demonstrate functionalities of the proposed modern IFC, and is available together with other examples, in the *IFC 5 Development* GitHub repository (buildingSMART, 2026a). The dataset is presented in figures 3 and 4.

Layers and independent data storage

We advocate a fundamental dissociation between the business logic data model and its physical storage. A dataset should not be required to be a single monolithic file; instead, it operates as a compositional, layered federation of data. The *layers* mechanism in our proposal addresses requirements for distributed ownership (1) and incremental updates (2) by dissociating the data from physical storage, allowing a single dataset (or 'stream') to be composed of one or multiple federated chunks resolved at runtime.

This architecture enables non-destructive collaboration, where stakeholders can overlay their own data attributes onto a base model without altering the original data, thereby strictly preserving authorship and liability boundaries. Furthermore, this same technical framework handles incremental updates by treating changes as lightweight *delta* streams containing only the proposed modifications, eliminating the need to re-transmit massive monolithic files when only specific data points have evolved.

Composition and paths

For software to make meaning out of disconnected layers or streams, the composition needs to take place. The composition relies on consistent path identifiers like GUIDs, e.g. *'e3035b71-bd9f-4cdc-86fd-b56e2f4605b6'*, or a tree path, e.g. *'project/site/ building/wall_id'*. Because every piece of data is tied to a specific path, information about a single object does not need to reside in the same physical location.

For example, the base geometry of a wall might exist in a *geometry.ifcx* file, while its material properties reside in *materials.ifcx*, and a fire engineer's specific requirements in a yet separate *fire_safety.ifcx* file. When a software tool loads the data by reading these files, it recognises that they all refer to the same object path. It then overlays or *composes* these attributes to form the complete object.

Attributes

The most trivial data to attach to a path is an attribute, which links some set of data to a specific path. Attributes have a name and value and follow a pre-specified schema. Attributes in the proposed IFC are JSON key-value pair objects. For every key a schema needs to be defined either locally in the file or imported. Attribute keys are also namespaced to provide context. Numeric attribute values derive their unit from the quantity kind associated with the schemas. There is no distinction alike IFC4's Attributes and Properties, both are exchanged and validated in the same fashion. Similar situation is presented in figure 1.

```
(…)"data":[
{"path": "c8b…c48",
"attributes": {"name": "Something"}},
{"path": "c8b…c48",
"attributes": {"my::prop": 3}},
```

```
c8b…c48:
- name = "Something"
- my::prop = 3
```

Figure 1: Raw data nodes (top) and resultant composed object with attributes (bottom)

Incremental updates and distributed ownership

The proposed architecture directly supports modern workflows that were difficult to manage with previous IFC versions. Instead of re-sending a massive file when a single property changes, a user can exchange a small *delta* set containing only the changed attributes for specific object paths.

Different disciplines can maintain their own data – their *opinions* – without altering the original author's data. As demonstrated on figure 2, one user can add a '*FireRating: R60*' property in their own layer. If this conflicts with an existing *'FireRating'* of value *'R30'*, the composition engine warns user about the conflict. All while ensuring that ownership and provenance of data are preserved at fine-grained level, allowing to see exactly who authored each information and when.

```
(…)"data":[
{"path":"c8b…c48",
   "attributes":{"FireRating": "R30"}},
{"path":"c8b…c48",
   "attributes":{"FireRating": "R60"}},
```

```
c8b…c48:
- FireRating = ~~"R30"~~ "R60"
```

Figure 2: Demonstration of conflict during composition – the nodes (top) and resultant compiled object (bottom)

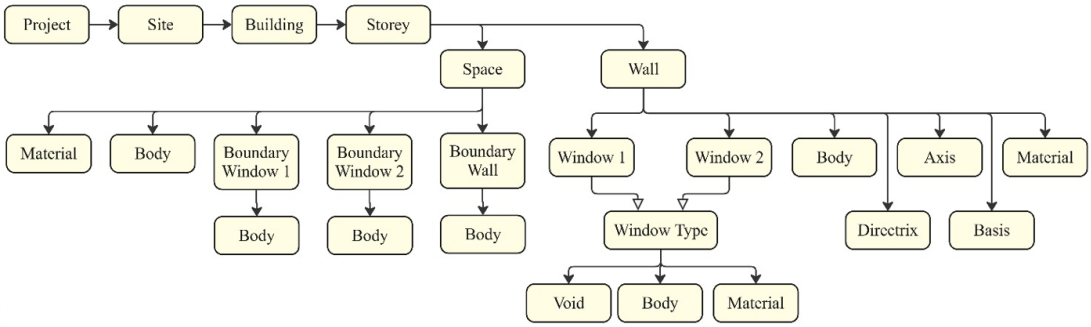

Figure 3: Diagram of the entities in the 'Hello Wall' file

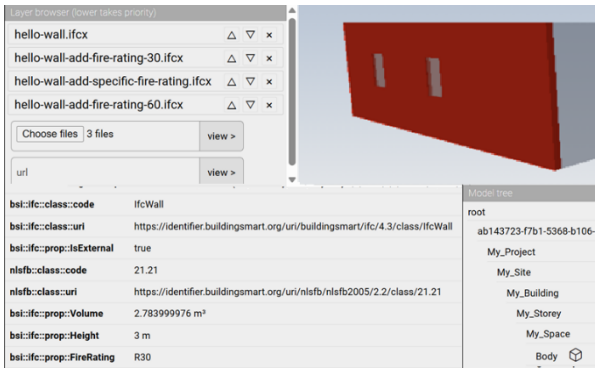

Figure 4: Layered 'Hello Wall' model composed and displayed in a demo IFCX viewer.

Children

Spatial decomposition relationships and local placement known from IFC 4.3.2 are represented in the proposal with *children*. Merging into one concept improves consistency. This, however, only applies to hierarchical IFC relationships like *Decomposes, Nests, AdheresTo, Voids, FillsVoids*. System-like graph relationships will be realised by means of attributes with path references.

Inheritance

We propose a generic, and multi-level information reuse mechanism to avoid complexity of mapped items and textual documentation on how to implement relationship between them. An example application is presented in figure 5, where two windows inherit from the same type defining frame and glazing.

```
(…)"data":[
{"path":"c8b…c48","children":
   {"window1":"e48…834",
   "window2":"caa…15d"}},
{"path":"e48…834","inherits":
   {"windowType":"189…5c3"}},
{"path":"caa…15d","inherits":
   {"windowType":"189…5c3"}},
{"path":"189…5c3","children":
   {"frame":"651…f2b",
   "glazing":"6ed…953"}}]
```

```
c8b…c48
   c8b…c48/window1
      c8b…c48/window1/frame
      c8b…c48/window1/glazing
   c8b…c48/window2
      c8b…c48/window2/frame
      c8b…c48/window2/glazing
```

Figure 5: Demonstration of the children and inheritance – the nodes (top) and compiled hierarchy tree (bottom)

Note that this is not the multiple inheritance that has gotten a negative connotation in certain programming languages with things like the 'diamond problems' but rather a formalised information reusage mechanism.

Modularisation of the schema

To address Requirement 11, our solution introduces a modular setup that streamlines ISO standardisation by decoupling a stable technical core from more dynamic, domain-specific semantics and extensions. Organised into distinct ISO Parts, this strategy replaces the previous monolithic structure to allow for independent versioning and faster industry adoption. This enables software to implement a reliable core quickly while allowing domain experts to expand semantic coverage without disrupting the underlying ecosystem.

Serialisation

The presented solution is serialised entirely in JSON, making it human-readable and compatible with modern web technologies. However, other serialisation forms are not off the table, JSON is just a readable and universally understood logical choice at this phase of the development and facilitates easy dissemination of the ideas around composition and file format mechanisms without being obfuscated by complex serialisation mechanisms. Binary format was discussed and can become a potential solution.

Schema definition

Our solution is defined using TypeSpec, a highly productive API description language that brings a concise, developer-friendly syntax (Microsoft, 2026). By leveraging TypeSpec, the schema benefits from improved readability and modularity, allowing for the automated generation of multi-protocol representations such as JSON Schema, OpenAPI, and GraphQL from a single source of truth. By utilising TypeSpec as the authoritative source for maintaining the standard, the architecture effectively decouples internal schema management from external distribution (JSON Schema, OpenAPI, etc.). This ensures rigor-

ous type safety across disparate data exchanges, ultimately fostering a more agile and interoperable ecosystem for the built environment.

Import flexibility

Our proposed architecture introduces a flexible import mechanism that allows the core schema to be extended with external vocabularies via URIs, preventing the standard from becoming a monolithic 'theory of everything'. This capability enables the composition of data models that mix and match distinct domain semantics while keeping the core lightweight.

In the 'Hello Wall' example, this is demonstrated through the direct import of OpenUSD for geometry, glTF PBR (Physically Based Rendering) for material definitions, and NlSfb and CCI for classification systems, and Open Geospatial Consortium (OGC) standards for geospatial data. By namespacing these attributes, we allow these diverse standards to coexist within a single dataset, facilitating richer interoperability and allowing the industry to leverage existing specialised standards rather than redefining them within IFC.

Similarly, the IFC does not need to reinvent the identifiers like *Global Trade Item Number* (GTIN) or *Global Location Number* (GLN), instead, those can be added to datasets with metadata acknowledging they are originating from GS1 organisation.

Geometry and Representation

Our proposal prioritises the use of explicit geometry to ensure consistent and efficient visualisation across software platforms. While the framework supports computational or procedural geometry definitions as semantic overlays or extensions, a objects should always be accompanied by an explicit geometric representation. This dual approach maximises interoperability by ensuring fast rendering and precise analysis without requiring consuming applications to interpret complex procedural logic. Currently, the alpha examples utilize the USD geometry schema (*usd::usdgeom*) as the rendering core to leverage its robust capabilities in visual composition and incremental updates. However, the architecture remains technology-agnostic regarding specific mesh formats; other explicit geometry definitions, such as those from the OGC and glTF, have also been evaluated to ensure broader compatibility with digital twin and GIS ecosystems.

Discussion and comparative analysis

Schema difference

Differences are visible when comparing equivalent IFC content captured in traditional STEP-based and proposed JSON-based form – see figure 6. The STEP sample has many more first-class objects like Direction, Point or Axis. While the STEP sample lists data in specific and defined entities, like the IfcSpace, the JSON sample defines data through components, inspired by the Entity Component System (ECS) architecture.

```
#1=IFCCARTESIANPOINT((0.,0.,0.));
#2=IFCDIRECTION((0.,0.,1.));
#3=IFCDIRECTION((1.,0.,0.));
#4=IFCAXIS2PLACEMENT3D(#1,#2,#3);
#5=IFCLOCALPLACEMENT($,#4);
#6=IFCCARTESIANPOINT((0.,0.,0.));
#7=IFCDIRECTION((0.,0.,1.));
#8=IFCDIRECTION((1.,0.,0.));
#9=IFCAXIS2PLACEMENT3D(#6,#7,#8);
#10=IFCLOCALPLACEMENT(#5,#9);
#11=IFCCARTESIANPOINT((0.,0.,0.));
#12=IFCDIRECTION((0.,0.,1.));
#13=IFCDIRECTION((1.,0.,0.));
#14=IFCAXIS2PLACEMENT3D(#11,#12,#13);
#15=IFCLOCALPLACEMENT(#10,#14);
#16=IFCCARTESIANPOINT((0.,0.123,0.));
#17=IFCDIRECTION((0.,0.,1.));
#18=IFCDIRECTION((1.,0.,0.));
#19=IFCAXIS2PLACEMENT3D(#16,#17,#18);
#20=IFCLOCALPLACEMENT(#15,#19);
#21=IFCSPACE('x…1',$,$,$,$,#20,#22,$,$,$,$);
```

```
(…)"data":[
{"path": "x...1",
  "attributes": {
    "usd::xformop": {
      "transform": [
        [1,0,0,0],[0,1,0,0],
        [0,0,1,0],[0,0.123,0,1]]}}},
{"path": "x...1",
  "attributes": {
       "bsi::ifc::class": {
         "code": "IfcSpace",
         "uri": "https://.../IfcSpace"}}}]
```

Figure 6: Comparison of a space definition in STEP-based IFC 4.3.2 (top) and proposed JSON syntax (bottom).

Inheritance depth and reification

The traditional IFC is full of reified objects, like a relation or a set of properties. For example, there are five intermediate entities between object and its property value: *"Object←RelDefinesByType→TypeObject→PropertySet→Property→IfcValue (select)→Simple value"*. In contrast, the proposal simplifies the assignment by allowing values to be added directly to objects: *"Object: {Property: Value}"*.

The IFC of today also employs rather deep inheritance of the entities. To read the attributes of an IfcWall shown in figure 7, one needs to traverse six levels up and six down the concept hierarchy. In proposed IFC, the inheritance depth can be three to four times shorter.

```
IfcRoot→…IfcObject→IfcProduct→IfcElement→…
IfcWall
→IfcRelDefinesByType
  →IfcWallType
    →IfcRelAssociatesMaterial
      →IfcMaterialLayerSetUsage
        →IfcMaterialLayerSet
          →IfcMaterialLayer: "mineral wool"
          →IfcMaterialLayer: "concrete"
```

```
Wall
(→WallType)
  →Insulation
```

```
    →Material: "mineral wool"
  →Core
    →Material: "concrete"
```

Figure 7: Comparison of inheritance depth in defining materials of a wall; IFC 4.3.2 (top) our solution (bottom).

On the other hand, the IFC 4.3.2 allows elements to only be typed by one element (type), while proposed IFC allows multiple typical levels to reuse data from. For example, a certain manufacturer's product could inherit from a typical kind of a product, that could also inherit from a more generic type.

Even though using IFC as product catalogues were possible with previous versions, our proposal introduces data ownership that allows to track origins of each property value, ensuring higher trust in the data. For example, a sustainability analyst could spot if Environmental Product Declaration (EPD) values were altered by architect before performing the Life Cycle Assessment (LCA).

Storage size

The mere storage is not a priority these days with fast internet and cheap storage. Still, the smaller files can be exchanged faster, so we performed a comparison of the simple building model represented as both STEP-based IFC and the proposed modernised IFC.

At first glance, the proposed IFC JSON syntax and serialisation does not bring advantages to storage size – the 'Simple scene' model recreated in .ifcx is over a quarter larger (see table 1). However, the JSON format is commonly condensed (minified), which gives our proposed solution a significant advantage over STEP representation – almost 60% reduced size. Additionally, it also compresses twice as efficiently as STEP, which is relevant for archiving.

Table 1: File size comparison on the sample dataset.

Version	Default (pretty-tified)	Minified	Compressed (zipped)
IFC 4.3.2	7.91 Mb	NA (same)	1.04 Mb
Proposed IFC (.ifcx)	10.10 Mb	3.39 Mb	0.52 Mb
Difference	+27.7 %	-57.1 %	- 50 %

The big difference can be observed when we look at a typical exchange process where files are being sent at regular intervals, despite insignificant changes being made. Table 3 shows that whereas in STEP-based IFC each transfer involves export of the full dataset, in the proposed solution only the deltas containing a change are being exchanged. This means significant storage saving throughout project duration.

Next steps

The comprehensive restructuring of the IFC data model into a modular, predictable ecosystem of parts serves as the necessary foundation for the true long-term objective: the creation of a standardised API. As articulated in the development roadmap, the finalisation of the Core data schema is the critical prerequisite that allows the industry to move beyond static file exchanges toward dynamic, cloud-native interactions where online agents or automated services, such as energy analysis tools or (manufacturing, simulation, etc.) bots, can interact directly with data. The current technical shifts toward JSON serialisation and ECS-like components are essentially the predecessor work required to standardize the openAPI interface itself – covering authentication, endpoints, and transactional calls. Binary data streaming is also not ruled out as part of the final solution. This will ultimately enable the real-time, granular data access that modern digital twins and connected ecosystems require.

Table 2: File size comparison on the sample dataset with two iterations of property value changes.

Version	Default (Mb)	1st change (Mb)	2nd change (Mb)	Total growth (%)
IFC 4.3.2	7.91	7.91	7.91	+200
Proposed IFC (.ifcx)	10.10	0.0004	0.0004	+0.008

Conclusions

The proposed modernisation of IFC represents a necessary shift for the construction industry, moving away from the monolithic legacy of previous standards toward a modular, high-performance data architecture. By adopting ECS-like components serialised in JSON, our proposal addresses the long-standing industry demand for files that are not only human-readable and web-friendly but also capable of supporting modern workflows such as incremental updates, version control, and multi-user collaboration. This technological leap is designed to drastically lower the barrier to entry for software vendors, prioritizing implementation speed and predictability to foster a more robust and reliable openBIM ecosystem.

The introduction of a modularisation strategy is central to this vision. By decoupling the stable technical Core from dynamic Domain Semantics and Industry Practices, the standard solves the historical challenge of painfully slow-release cycles. This separation of concerns allows the Core to serve as a reliable, domain-agnostic kernel for identifying, grouping, and positioning objects, while allowing specific disciplines, such as Rail, Tunnel, or Structural, to evolve their semantic definitions independently and rapidly.

While we introduce a breaking change regarding file formats, it ensures semantic continuity by leveraging existing IFC 4.x definitions and integrating with broader industry standards like USD, 3D Tiles, glTF, GS1, OGC or classification systems like ETIM, ECLASS, CCI or UNICLASS. Ultimately, the goal of IFC modernisation is to achieve fully reliable data usage. By reducing the complexity of the core schema and eliminating ambiguous exceptions, our work positions itself as a predictable and reliable foundation for the next generation of automation, digital twins, and connected built environment data.

Acknowledgments

The paper represents the result of the incubation phase of IFC 5 project at buildingSMART during 2021 to 2025. The final version will be further shaped by the buildingSMART and ISO processes. Authors would like to thank all the people involved in the initiative over the years, the members and community of buildingSMART, participants in recurring Implementers Assemblies and independent contributors.

Teaching BIM as a Computational, Queryable, and Analyzable Model: A Project-Based Framework Integrating APIs, Programming, and Early Performance Reasoning

Tobias Maile, Burcu Güldür Erkal
Technical University of Applied Sciences Augsburg, Germany

Abstract

Building Information Modeling (BIM) education in architecture, engineering, and construction (AEC) remains largely tool-centric, limiting students' understanding of data quality, automation, and performance reasoning. This paper presents a project-based educational framework that treats BIM models as computational, data-driven artifacts. Through programming, API-based model access, simplified performance analyses, and human-in-the-loop large language model (LLM) support, students develop computational BIM literacy through learning-by-doing. Student feedback indicates improved awareness of modeling consequences, data quality, and early performance assessment. The framework offers a transferable approach for computationally oriented AEC curricula and reframes BIM education as data quality education.

Introduction

Building Information Modeling (BIM) has become a central methodology in architecture, engineering, and construction (AEC), serving as a shared digital representation for design, analysis, construction, and operation. While BIM is gaining momentum in professional practice, its integration into higher education remains uneven. Many curricula still emphasize software operation and predefined workflows rather than conceptual understanding of BIM models as structured, queryable, data-driven representations (Succar, 2009; Eastman et al., 2018).

A recurring challenge in BIM education is the limited awareness of **data quality and data consistency**. Students frequently interact with BIM models as geometric artifacts, without fully understanding how model structure, parameter completeness, or semantic consistency influence downstream use. As a result, modeling errors or implicit assumptions often remain unnoticed until they manifest as problems in later project stages, such as performance analysis, quantity take-off, or interdisciplinary coordination. This delayed feedback makes it difficult for students to develop a causal understanding of how early modeling decisions propagate through digital workflows.

Automation and computational workflows represent another critical gap. Scripting and model-based automation are often introduced as advanced or optional topics, reinforcing the perception of computational methods as expert-only skills. This contributes to black-box tool usage and reliance on default software settings, limiting transparency and reproducibility of model-based reasoning (Borrmann et al., 2018).

Furthermore, BIM education is commonly dominated by **lecture-driven teaching formats**. While lectures convey conceptual knowledge, they are often insufficient for developing experiential understanding of how digital models behave under computational use. Multidisciplinary analyses, such as energy and structural assessment, are typically taught as isolated workflows, obscuring their shared reliance on a common underlying model.

Multidisciplinary performance analysis is frequently introduced as a set of isolated tools or domain-specific workflows. Structural, energy, and environmental analyses are often treated independently, each relying on separate model abstractions and software environments. This fragmentation obscures the fact that all analyses ultimately depend on the same underlying building model, albeit represented through different abstractions such as analytical models for structural reasoning or simplified thermal representations for energy assessment.

Summarizing the current challenges in education:

- Limited awareness of data quality and data consistency
- Insufficient understanding of how modeling decisions propagate errors
- Automation perceived as expert-only or tool-specific
- Predominance of front-loaded, lecture-based teaching
- Fragmentation of multidisciplinary performance analysis
- Lack of model transparency and explainability
- Over-reliance on software defaults and black-box workflows

Together, these challenges point to a fundamental educational gap: students are rarely taught to understand BIM models as **computational, data-driven artifacts** that can support automation, reasoning, and early performance exploration across multiple domains. Addressing this gap requires a shift from tool-oriented instruction toward **computational BIM literacy**, where modeling, data quality, automation, and performance reasoning are treated as interconnected aspects of a single workflow.

While prior BIM education research emphasizes collaboration, interoperability, and process integration, the ex-

plicit integration of programming, API-based data access, and performance reasoning into core BIM teaching remains largely unaddressed.

This paper investigates the following research question: How can BIM education be redesigned so that students develop computational BIM literacy - understanding BIM models as data-driven, queryable, and analyzable artifacts - rather than learning BIM primarily as a geometric authoring process?

To address this question, we designed, implemented, and evaluated a project-based educational framework that integrates programming, API-based model access, and simplified multidisciplinary performance reasoning within a single workflow.

The core pedagogical mechanism is that simplified performance models foster a learning-by-doing environment that exposes BIM data quality issues during computation.

In this work, the term *framework* refers to a transferable, tool-agnostic structure that integrates (1) BIM data access via APIs, (2) computational logic implemented in Python, and (3) simplified multidisciplinary performance models. The framework has been applied successfully with Revit, ArchiCAD, and Vectorworks, demonstrating that it is not dependent on any specific authoring tool. While the competencies addressed-data structuring, scripting, API querying, and performance reasoning-are most relevant for architecture and engineering students.

Recent developments in BIM education research highlight that these challenges are not only technical but pedagogical. Studies emphasize the importance of constructivist and project-based learning environments for developing digital competencies, particularly when students interact with computational models and simplified analyses Ao et al. (2025b); Nguyen and Adhikari (2025). Positioning BIM teaching within such learning theories reinforces the need for hands-on, exploratory workflows that connect model semantics, assumptions, and analytical consequences. This perspective motivates the project-based computational framework presented in this work.

This paper further positions the framework in recent educational research, describes the course's overall concept and learning objectives, before detailing the computational BIM workflow. It explains the project-based learning and describes the early performance reasoning for the energy and static topics. We refer to the LLM-supported learning, present evaluation results, and finally conclude the paper with a discussion and outlook.

Positioning within Existing BIM Education Research

Recent educational approaches further emphasize the need to move beyond tool-centric BIM teaching toward model-centric, computational, and interdisciplinary learning environments. The concept of "Next Generation BIM" frames BIM models as active carriers of data, logic, and assumptions that support automation, early performance reasoning, and life-cycle thinking across disciplines. This perspective explicitly calls for integrating programming, data access, and computational workflows into BIM education rather than treating them as advanced or optional skills (Wimmer et al., 2025).

Research on BIM education consistently highlights a gap between industry demands and academic training. Early BIM frameworks focused on maturity levels, collaboration, and process integration, while noting that education often lags behind professional practice (Succar, 2009). More recent studies confirm that BIM is frequently taught as software proficiency rather than as an integrated methodological paradigm (Eastman et al., 2018).

Recent global reviews highlight persistent gaps in BIM education, particularly in understanding student learning pathways, interdisciplinary curriculum design, and assessment practices Ao et al. (2025a). Moreover, contemporary studies show that computational thinking, programming, and automation remain underrepresented in most BIM programs despite their increasing relevance in industry. Evidence from AI-supported classroom environments demonstrates that students frequently struggle with debugging and data schema interpretation, underscoring the need for computational literacy as a core educational objective Sahraoui et al. (2025).

Large-scale empirical work further reveals a perception–practice gap: students appreciate the value of BIM for sustainability and analytical workflows but often lack the practical ability to apply these concepts independently Nguyen and Adhikari (2025). This finding aligns with our observations that students rarely develop a deep awareness of model structure, data consistency, and semantic assumptions when BIM is taught only through tool-oriented modeling.

Pedagogically, our approach aligns with constructivist and project-based learning principles. Recent BIM education research highlights the importance of learning motivation, behavioral intention, and authentic project engagement in developing digital competencies Ao et al. (2025b). Global curriculum reports also indicate a shift towards experiential learning models that integrate AI, automation, and computational reasoning Li (2025); Sofiane (2024).

Model-centric and openBIM-oriented teaching approaches have improved interdisciplinary collaboration and awareness of data exchange. However, computational literacy and automation remain underrepresented in many curricula. Prior work on life-cycle-oriented BIM education emphasizes interoperability and collaboration but often relies on predefined workflows and tool-specific processes (Maile et al., 2023). Conceptual frameworks for open BIM education similarly identify limited integration of programming and computational reasoning (Preidel et al., 2024).

The framework presented in this paper builds on this body of work by explicitly integrating programming and API-based model access into core BIM education. Rather than treating computation as an add-on, BIM models are framed as computational artifacts that can be queried,

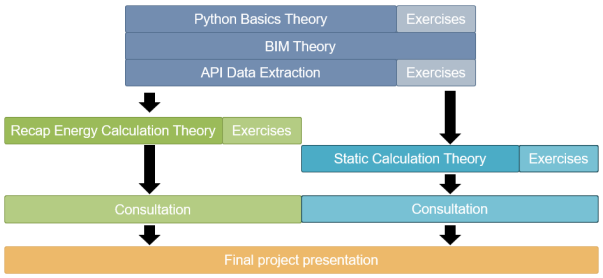

Figure 1: Phased course structure combining short theoretical inputs with exercises, consultations, and iterative project work. Programming, BIM theory, and performance reasoning are introduced incrementally and integrated into a single project-based workflow.

transformed, and evaluated across multiple performance domains.

Course Concept and Learning Objectives

The framework was implemented as a CAX module in the master program Energy Efficiency Design – E2D at the Technical University of Applied Sciences, Augsburg. Programming experience ranged from none to intermediate, and the course was explicitly designed to accommodate this diversity. Learning objectives focused on developing computational BIM literacy rather than tool proficiency. Students were expected to

1. understand BIM models as structured, data-centric representations,
2. access and query models via authoring APIs,
3. formulate explicit modeling and analysis assumptions,
4. implement transparent computational logic, and
5. interpret early-stage performance results critically.

Python serves as a lightweight orchestration layer, supporting analytical reasoning rather than being a primary goal of the work.

Course Structure. Teaching followed a phased progression, combining theoretical inputs with exercises and eventually project-based application as outlined in Figure 1. Programming fundamentals, BIM theory, and API-based data access for the first part of the course. Concepts of energy and structural performance reasoning were then introduced through accompanying exercises. The final part of the course was performing the project from modeling to code writing to result interpretation. In this phase, the students are supported through multiple consultation sessions to answer technical and scope questions and guide them towards a successful project. Consultation sessions provide targeted support and enable reflection on both modeling and computational decisions. Finally, the project was presented by each group in front of the class.

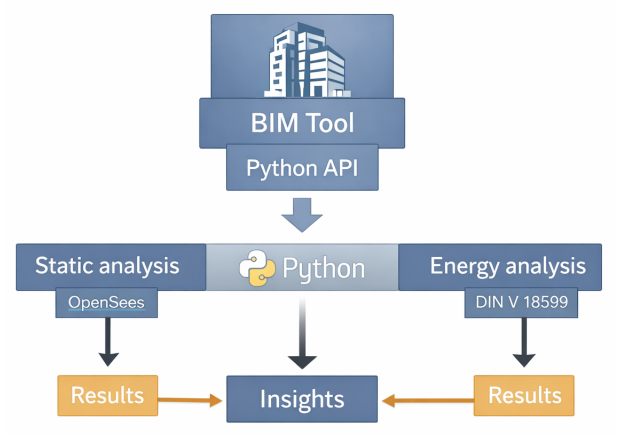

Figure 2: Computational BIM workflow used in the course. BIM models are accessed via authoring APIs and processed through Python-based computational logic to support parallel energy and structural reasoning and the generation of integrated insights.

Methods: Course Structure and Implementation

The course was conducted over 14 weeks (5 ECTS) and included students from the Energy Efficiency Design master program. The weekly structure consisted of typically 90-120 minutes of conceptual input (Python basics, BIM theory, energy and structural fundamentals) followed by guided hands-on sessions on API data access, code debugging, and computational workflow development.

Students were provided with Python templates, API documentation, example extraction routines, and simplified analytical formulations. Their final project required them to: (1) model a small building; (2) extract geometric and semantic data through the authoring tool's API; (3) compute simplified energy balances and generate structural models in OpenSees; and (4) present their assumptions, computational decisions, and debugging steps. Emphasis was placed on transparency, reproducibility, and reasoning rather than numerical accuracy.

Computational BIM Workflow

Students created BIM models using standard authoring tools. While most groups worked with Autodesk Revit, individual groups experimented with Vectorworks and ArchiCAD. The framework was intentionally designed to remain independent of specific authoring environments, focusing on API-based access to model data rather than tool-specific workflows.

Figure 2 summarizes the computational workflow used throughout the course. BIM geometry and metadata are accessed via authoring APIs and processed using Python scripts. Relevant information is mapped into simplified analytical representations for energy and structural reasoning, allowing students to explore performance implications of modeling decisions early in the design process.

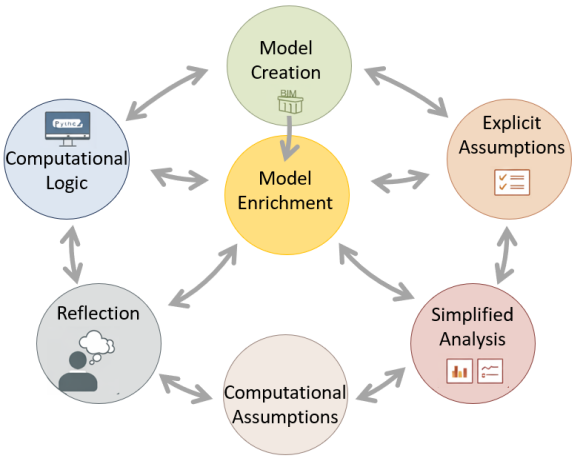

Figure 3: Learning-by-doing and reasoning loop adopted in the course. Students iteratively create BIM models, formulate explicit assumptions, implement computational logic, analyze simplified results, and reflect on outcomes to guide subsequent design iterations.

Object-Oriented Structuring as Didactic Principle

To support transparent and meaningful automation, students were encouraged to structure their scripts using basic object-oriented principles. Computational tasks were organized into domain-specific components, such as energy-related calculations, structural abstractions, and unit handling, rather than monolithic scripts.

This structuring was introduced as a didactic scaffold rather than formal software engineering training. Aligning code structure with domain concepts helped students clarify responsibilities, make assumptions explicit, improve the traceability of computational logic, and ease debugging and testing. In earlier course iterations, debugging within the Python API environment proved challenging for students and motivated the introduction of a more structured coding approach. This is why the object-oriented approach naturally emerged as a way to organize code and provide enough structure so that error checking and debugging were improved.

Human-in-the-loop computational assistance

Large language models were used as human-in-the-loop assistants to support syntax, debugging, and API exploration. Automated solution generation with LLMs was explicitly discouraged. Students remained responsible for validating logic and interpreting results. Recent work suggests that such assistive use of LLMs can effectively support exploratory reasoning in AEC contexts (Maile and Güldür Erkal, 2025).

Project-Based Learning Setup

The course followed an open-ended project-based learning approach without predefined solutions. Students were responsible for model creation, scripting, assumption definition, and interpretation of results.

Figure 3 illustrates the iterative learning process. Students repeatedly move between modeling, computation, and interpretation, enabling them to understand how design decisions, data quality, and assumptions influence analytical outcomes.

Early Performance Reasoning

The complementary expertise of the instructors enabled the integration of early performance reasoning in both energy and structural domains.

Energy Reasoning

Energy reasoning was introduced using a simplified monthly steady-state balance formulation that explicitly distinguishes between transmission losses, ventilation losses, internal gains, solar gains, and heating. This builds on prior coursework in construction physics in the related bachelor's program, where students were introduced to these principles.

This energy balance abstraction, used in the course, is based on the German Standard DIN V 18599 and is further simplified to omit storage effects and system efficiencies. Instead of aiming for regulatory compliance or high-fidelity simulation, the approach emphasizes transparency and causal understanding. Students explicitly define all assumptions and directly experience how changes in geometry, envelope properties, or usage profiles affect heating demand. For the various energy balance terms, the following information was needed from the BIM model:

- ventilation losses:
  - building volume
- transmission losses (for all building elements)
  - external surface area
  - u-value
- solar gains (for all windows)
  - g-value/solar heat gain coefficient (SHGC)
  - external surface area
  - orientation
- internal gains
  - usable area inside the building

Static Reasoning

Structural reasoning was introduced as a simplified approach to support early understanding of structural behavior within a CAX workflow. Rather than performing detailed structural design, the goal was to help students understand how structural layout and geometry influence global structural response.

The following key elements were obtained from the BIM model:

- nodal coordinates derived from element geometry,
- connectivity between structural elements,
- element types such as columns, beams, walls, and slabs,
- idealized material and cross-section properties,

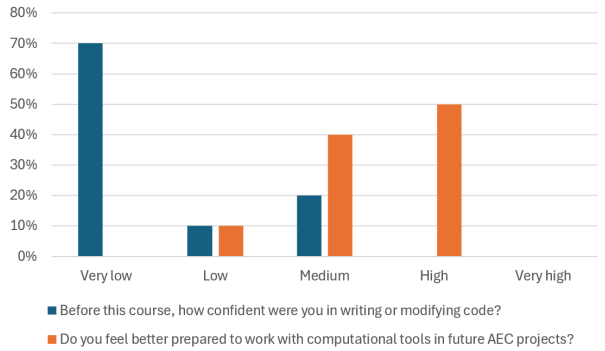

Figure 4: Self-assessed student confidence before and after the course. Responses indicate low initial confidence in writing or modifying code and a substantial increase in perceived preparedness to work with computational tools in future AEC projects.

- support conditions and boundary constraints.

Starting from the BIM model, students used authoring APIs to extract structural information and translate it into simplified analytical representations. Based on this extracted information, students automatically generated a code-based structural model in `Tcl` format for use in OpenSees (McKenna et al., 2010). Reduced assumptions appropriate for early design stages were applied to maintain transparency and ease of interpretation. This allowed students to directly observe how changes in BIM geometry or structural layout affected the generated OpenSees model and its global structural response.

The limitations of this simplified approach were explicitly addressed by emphasizing that the generated models represent idealized structural systems and provide insight into overall behavior rather than detailed effects.

Evaluation and Observed Learning Effects

Evaluation was based on qualitative and self-assessed feedback collected through an anonymous questionnaire at the end of the course, combined with evidence from student project presentations and submitted computational artifacts. In total, 23 students participated in the course, of which n=10 completed the questionnaire.

Questionnaire results. Students were asked to reflect on their prior experience with programming and their perceived preparedness to work with computational tools in future AEC projects. Figure 5 illustrates the distribution of responses. The results show that most students entered the course with low confidence in writing or modifying code, confirming the heterogeneous and largely non-programming-oriented background typical of AEC cohorts. Despite this, students reported a clear shift toward higher confidence in using computational tools after completing the course.

Students frequently emphasized that simplified models, explicit assumptions, and hands-on experimentation were more valuable for understanding performance relationships than black-box tools or lecture-only formats. Rather than focusing on numerical accuracy, students highlighted an improved ability to reason about cause–effect relationships and to explain why results changed.

Evidence from student work. Beyond self-assessment, student project outcomes provided concrete evidence of learning effects. Across all teams, students demonstrated mastery in three interconnected domains:

1. BIM modeling quality,
2. computational data extraction and analysis, and
3. integrated energy and structural reasoning.

Students developed a strong awareness that reliable downstream analyses depend on precise geometry, correct units, and well-structured parameter data. Several teams reported discovering unit inconsistencies (e.g. feet-to-meter conversions), missing thermal parameters, and incorrect element assignments only when attempting to compute energy balances or generate structural models from their BIM data. These experiences directly reinforced the importance of semantically consistent modeling practices. In multiple cases, students had to revise their BIM models because computational scripts exposed missing or inconsistent parameters.

All teams successfully implemented Python-based workflows that accessed BIM data via authoring APIs to compute simplified energy balances and generate analytical structural models for OpenSees. Students produced reproducible outputs such as CSV files, TCL scripts, and graphical plots derived directly from their BIM models. This demonstrates that students were not only able to model buildings but to compute with their models across multiple domains.

Several groups explicitly recognized interdependencies between energy performance and structural modeling. They observed how geometric decisions influenced both thermal behavior and structural response, for example how envelope area affects transmission losses while structural layout influences mass and connectivity. The use of a single parametric BIM model feeding both energy and structural analyses strengthened this integrated design understanding.

Typical outputs produced by the groups included CSV files listing extracted surface areas, thermal parameters, and orientations; Python-generated plots of monthly heating demand; and automatically generated Tcl files for simplified OpenSees models. Several teams performed gravity load analyses and modal evaluations, demonstrating how geometric changes in the BIM model directly influenced the analytical model.

Common errors included inconsistent units (e.g., feet-to-meters), missing or misassigned U-values, disconnected analytical nodes in slabs, incorrect window orientation extraction, and Python path issues in the Revit environment. These issues only became visible during computation, reinforcing the pedagogical principle that data quality awareness emerges most effectively when students compute with their own model data.

Table 1: Summary of lessons learned across all student teams.

Competency Area	Lessons Learned (Evidence)
BIM Model Quality	Students emphasized precise geometry, correct units, and complete thermal and structural parameters. Errors such as incorrect unit conversions reinforced the need for careful model structuring.
Data Extraction and API Usage	Students extracted areas, volumes, U-values, materials, and orientations using authoring APIs. They automated energy balance calculations and implemented robust parameter detection.
Energy Calculation Concepts	Teams implemented simplified energy balances including transmission and ventilation losses, internal and solar gains, and heating demand, recognizing how geometry and assumptions influence results.
Structural Modeling and Analysis	Students exported analytical models and executed OpenSees simulations. They learned the importance of node alignment, connectivity, and consistent element definitions.
Integrated Design Thinking	Students identified synergies and trade-offs between energy demand and structural utilization. A single BIM model fed both energy and structural workflows, enabling informed design decisions.
Workflow and Project Management	Students emphasized consistent naming, version control, file organization, and avoiding special-character issues in BIM workflows.
Debugging and Problem Solving	Students encountered and resolved API syntax errors, incorrect file paths, misassigned properties, and parameter inconsistencies, reinforcing reflective learning.

Students also reported meta-level workflow lessons, including the importance of consistent naming conventions, file organization, API error handling, and validation of modeling assumptions. These reflections indicate that the course fostered realistic digital engineering competencies beyond isolated tool usage.

Table 1 summarizes the lessons learned across all student teams.

Observed learning effects. Three dominant learning effects were observed across participants (as shown in Table 2):

- *Increased programming confidence.* Students reported improved understanding of basic programming concepts such as variables, loops, and functions, indicating a reduced computational entry barrier.
- *Shift in BIM understanding.* Several students described a conceptual shift from geometry-focused modeling toward working with structured, queryable data.
- *Improved performance reasoning.* Implementing simplified energy and structural calculations improved students' confidence in interpreting results rather than accepting outputs from black-box tools.

The role of large language models was also highlighted by many students. LLM tools were primarily used for syntax support, debugging, and API exploration, enabling students to focus on conceptual reasoning.

Overall, the triangulated evidence from questionnaires, student artifacts, and project presentations indicates that treating BIM models as computational artifacts - combined with learning-by-doing and transparent simplifications - can foster meaningful computational BIM literacy even among students with limited prior coding experience.

Implementation Challenges

Integrating programming into BIM education required a substantial time investment, particularly for students with limited coding experience. Approximately one-third of weekly contact time was dedicated to debugging assistance and API exploration. These observations mirror findings from recent studies showing that students in AI-assisted BIM classrooms struggle with syntax, rule formulation, and data-schema interpretation Sahraoui et al. (2025). Instructor expertise in both BIM semantics and computational methods was essential to ensure that the cognitive load remained manageable within a project-based learning environment.

Table 2: Summary of qualitative student feedback (self-reported).

Dimension	Dominant Observation
Prior programming experience	Predominantly low or very low
Perceived programming understanding after course	Improved or partially improved
BIM understanding shift	From geometry-focused to data-oriented (for most students)
Usefulness of LLM assistance	High for syntax, debugging, and API exploration
Performance reasoning confidence	Improved understanding and interpretability
Ability to extend scripts independently	Possible with guidance; limited full independence

Limitations

The evaluation is qualitative in nature and based on a single course iteration with a limited number of participants. No control group was used, and results reflect perceived learning outcomes rather than measured performance gains. Future work will include longitudinal and comparative studies.

Discussion and Outlook

The presented framework addresses several persistent shortcomings in BIM education, including tool-centric teaching, black-box workflows, and fragmented multidisciplinary analysis. By treating BIM models as computational artifacts rather than geometric authoring results, the course enabled students to directly experience how data quality, modeling assumptions, and semantic consistency influence analytical outcomes.

A key insight emerging from this framework is that simplified performance models act as a didactic mirror. When students attempt to compute energy demand or generate structural models from their BIM data, inconsistencies, missing parameters, unit errors, and modeling assumptions become immediately visible. Rather than discovering such issues in later project phases or external tools, students encounter them during the act of computation. This immediate feedback loop fosters a causal understanding of how modeling decisions propagate through digital workflows and strengthens awareness of data quality and consistency.

This approach differs fundamentally from conventional BIM teaching practices. Conventional teaching often follows a sequence of modeling, exporting, and processing models in domain-specific tools. In contrast, the presented framework establishes a direct connection between the BIM model and computational reasoning through API access and scripting. This shifts the educational focus, as shown in Table 3:

Table 3: Comparison between traditional BIM education and the presented computational framework.

Traditional BIM education	Presented framework
Geometry-focused modeling	Data- and structure-focused modeling
Tool proficiency	Computational BIM literacy
Predefined workflows	Querying and transforming model data
Black-box simulations	Transparent simplified reasoning
Fragmented domain analyses	Multiple analyses from the same model

The results indicate that even students with little or no programming experience can develop meaningful computational literacy when programming is framed as a reasoning tool rather than an end in itself. The use of Python as a lightweight orchestration language, combined with object-oriented structuring aligned to domain concepts, allowed students to organize computational logic in a way that was traceable and understandable.

The integration of large language models as human-in-the-loop assistants, enabling students to make and implement their own decisions, further supported this process. Students reported that LLM tools helped them overcome syntactic barriers and explore APIs, allowing them to focus on conceptual reasoning. Importantly, responsibility for validating logic and interpreting results remained with the students, reinforcing critical engagement rather than automated solution generation.

Although the evaluation is qualitative and limited to a single course iteration, observed learning effects and student feedback indicate a shift in how BIM is perceived - from a geometric modeling task to working with structured data that can be queried, transformed, and analyzed. Students reported improved confidence in programming, a changed understanding of BIM, and an increased ability to reason about performance outcomes rather than accept results from black-box tools.

A central strength of the framework lies in its transferability. The approach does not depend on specific authoring software but on the availability of an API and basic scripting capabilities. This makes the framework adaptable to

different BIM environments and educational contexts. Future investigations into open-source BIM platforms and API-rich environments may further enhance its accessibility.

Future work will extend the framework to additional performance domains such as embodied carbon assessment and cost analysis, enabling students to explore further dimensions of model-based reasoning. Longitudinal studies and comparative evaluations with traditional BIM courses are planned to assess learning effects quantitatively. The integration of agent-based and LLM-supported workflows also represents a promising direction for further research into computational BIM education. Future work will explore integrating the Model Context Protocol (MCP) to enable LLMs to access and query BIM models through standardized, auditable tool interfaces (MCP, 2026; Anthropic, 2024). First preliminary investigations of this approach promise more transparent, reproducible, and educationally effective natural-language interactions with BIM data by explicitly linking user intent to authoring-tool API operations.

Ultimately, this work suggests that BIM education can move beyond teaching how to model buildings toward teaching how to compute with building models. By embedding programming, API access, and simplified performance reasoning into core BIM teaching, students can develop the computational literacy necessary to understand, question, and extend digital workflows in contemporary AEC practice.

Beyond its immediate didactic benefits, the framework contributes to broader discussions in BIM education. Recent reviews call for integrated, interdisciplinary, and computationally grounded learning models Ao et al. (2025a); Li (2025). Our findings support these directions by demonstrating that constructivist, project-based environments, combined with transparent computational workflows, can reduce the perception–practice gap documented in current educational research Nguyen and Adhikari (2025). By embedding programming and performance reasoning directly into students' modeling workflows, the course advances emerging pedagogical aspirations for computational BIM literacy.

Acknowledgments

We want to thank the students of the CAX module for their participation in the course and for their feedback.

NARRATIVES OF DIGITAL TWINS: HOW FRAMINGS SCRIPT GOVERNANCE

Johan Ninan and Ranjith K. Soman
Delft University of Technology, the Netherlands

Abstract

Infrastructure digital twins are transformative tools for managing complex systems. This study examines how infrastructure digital twins are narratively constructed and how these narratives shape governance. Drawing on narrative theory, we analyze 75 academic publications and their framing of digital twins to identify recurring conceptual patterns. The findings indicate that digital twins are beyond mere technical artefacts, rather are embedded in narratives that implicitly script technological function, institutional roles, and governance alignments. There is a need to treat digital twin adoption as a technical innovation and also as an institutional design challenge shaping how infrastructure decisions will be made.

Introduction

Digital twins are increasingly promoted as transformative tools for the planning, operation, and governance of infrastructure systems (Keskin et al., 2022). Across transport networks, water management, and energy systems, digital twins are expected to improve performance monitoring, predictive maintenance, and long-term asset management (Pan & Zhang, 2021). In this sense, they are often presented as key enablers of data-driven infrastructure governance. Yet research on digitalization in the construction sector has consistently shown that the success of digital technologies depends not only on technical capability but also on their integration into organizational practices, professional roles, and institutional decision processes (Miraj et al., 2025). Studies of building information modelling and related technologies demonstrate that implementation outcomes are shaped by how tools are interpreted, embedded, and governed within organizational life, rather than by their technical sophistication alone (Datta et al., 2020). This suggests that the way emerging technologies are conceptualized may influence how they are specified, procured, and ultimately used (Broo & Schooling, 2023).

The rapid expansion of digital twin research has resulted in a focus on defining what a digital twin is, identifying technical architecture, or assessing potential performance benefits (Jiang et al., 2021). Much less attention has been paid to how digital twins are conceptually framed in practice. In particular, little empirical work examines how infrastructure digital twins are described in academic discourse and what these descriptions imply about users, responsibilities, and decision processes. This is a significant gap, because the language used to characterize new technologies often shapes how problems are understood and how solutions are designed (Ninan et al., 2022). The paper therefore asks: How are infrastructure digital twins conceptually framed in academic discourse, and what institutional assumptions do these frames imply for their governance?

The aim is to contribute to an understanding of digitalization in infrastructure sectors by highlighting the role of conceptual framing in shaping technological expectations and institutional integration. In the literature review section, we review literature on digital twins in infrastructure and the role of narratives in technologies. Following this, we detail the methodological choices relating to the use of academic literature, search criteria and highlight how data was collected and analyzed. In the findings section, the dataset is summarized and in the discussion section the conceptual categories are argued. The conclusion section summarizes the findings from this research and emphasizes the theoretical and practical contributions before highlighting the limitations and scope for future research.

Literature review

Digital twins in infrastructure projects

Digital twins have rapidly emerged as a central concept in the digital transformation of infrastructure projects and support predictive maintenance, optimization, and long-term planning (Ham & Kim, 2020). They have potential to improve operational efficiency, sustainability, and system reliability by linking physical assets with continuously updated digital representations (Kaewunruen & Lian, 2019). Digital twin research in the built environment spans multiple strands, including framework development, technical integration, and case-based applications (Broo & Schooling, 2023). Much of the literature categorizes studies into technical modelling approaches, implementation architectures, or application domains such as asset management and smart cities (Keskin et al., 2022). Similarly, work focusing specifically on civil infrastructure emphasizes issues such as interoperability, data integration, and lifecycle modelling, reflecting the strong engineering orientation of the field (Jiang et al., 2021). Across these studies, digital twins are typically treated as technical systems that integrate IoT data, analytics, and simulation capabilities.

Olde Scholtenhuis & Soman (2025) challenge this techno-centric framing, showing that many construction digital twins function effectively despite operating with varying latency, fidelity, and levels of automation, suggesting that usefulness depends more on contextual decision needs than on technological sophistication. While existing focus has produced valuable advances in system architecture and modelling techniques, however, the conceptual and institutional dimensions of digital twin adoption remain comparatively under-explored.

While early digital twin research emphasized technical architectures, more recent work acknowledges that digital twins operate within complex sociotechnical environments (Miraj et al., 2025). Scholars increasingly recognize that digital twins affect organizational coordination, professional roles, and governance arrangements, rather than simply providing new computational capabilities (Agrawal et al., 2023). Research in the AEC sector has long shown that digital technologies reshape work practices and decision processes (Ernstsen et al., 2021). Studies of BIM adoption demonstrate that implementation outcomes depend on how digital tools are interpreted, negotiated, and embedded in organizational routines (Papadonikolaki et al., 2019). Similar insights are now emerging in digital twin research, where scholars highlight organizational adaptation, data governance, and institutional coordination as key barriers to implementation (Broo & Schooling, 2023). Digital twin deployment often encounters conceptual ambiguity and difficulties in creating shared understanding among stakeholders (Tripathi et al., 2024). Practitioners and other stakeholders struggle not only with technical integration but also with defining what a digital twin actually is and how it should be used within organizational processes (Kober et al., 2024). Thus, digital twins should be understood as sociotechnical systems whose performance depends on institutional integration and shared interpretive frameworks (Nochta et al., 2021).

A related strand of research focuses on the role of digital twins in supporting decision-making, policy and governance processes (Solman et al., 2022). In smart city and infrastructure contexts, digital twins are increasingly presented as tools for scenario analysis, policy evaluation, and long-term system planning (Ham & Kim, 2020). Digital twins afford multiple possibilities to support public-sector decision-making by modelling complex urban dynamics and enabling scenario-based planning (O'Dwyer et al., 2020). There is a need to understand digital twins as human-technology interfaces rather than purely analytical systems; for instance, studies of construction control rooms show how digital twins can function as collaborative decision environments that enhance coordination and judgement rather than simply automate analysis (Soman et al., 2025). Similarly, research on digital twin ontologies and standards emphasizes the need to align digital twin development with principles such as trustworthiness, public value, and governance transparency (Lavikka et al., 2018; Deng et al., 2021). Thus, digital twins must support technical performance as well as accountability and institutional legitimacy.

Despite these emerging concerns, digital twins are primarily conceptualized as information systems or modelling platforms rather than as environments for structured institutional decision-making (Korenhof et al., 2021). Researchers and practitioners use the term to refer to a wide range of systems, from data visualization dashboards to high-fidelity simulation environments (Nochta et al., 2021). To resolve this ambiguity, typologies, architectures, or maturity models are proposed (Uhlenkamp et al., 2022). Yet few studies examine how digital twins are actually described in discourse or how conceptual metaphors shape expectations about their functions.

Narratives of technology

The role of narratives and framing in shaping technological trajectories are emphasized in construction innovation, particularly on how narratives shape innovation (Ninan et al., 2022). Technologies diffuse based on technical superiority as well as how they are interpreted, justified, and legitimized through narratives that make certain futures appear plausible and desirable (Williams, 2006). Within infrastructure sectors, narratives help manage tensions between innovation and risk, often shaping how stakeholders interpret responsibility, value, and uncertainty (Sergeeva and Ninan, 2023). Conceptual framings therefore influence how technologies are discussed and how they are designed, procured, and governed (Davidson, 2002).

From this perspective, analyzing how digital twins are described can reveal the institutional assumptions embedded in their conceptualization. Language such as "platform," "service," or "dashboard" invokes particular models of interaction and responsibility that originate in software ecosystems rather than infrastructure governance. Although existing research acknowledges the sociotechnical nature of digital twins and the importance of governance considerations, little empirical work examines how digital twins are conceptually framed in academic discourse. Most studies focus on technical architectures, implementation challenges, or application benefits. Few investigate how language constructs expectations about digital twins, what kinds of actors and decisions are implied, or how responsibility and uncertainty are represented. This gap is particularly important in infrastructure contexts, where digital twins must support long-lived systems involving multiple organizations, regulatory constraints, and public accountability. Conceptual framings that emphasize software metaphors may obscure these institutional realities and shape design priorities in ways that misalign with governance needs.

Research setting and method

The present study adopts a qualitative interpretive design to examine how infrastructure digital twins are conceptually framed (Gephart, 2004). Conceptual framing is understood here as a sociotechnical process

through which technologies are described, interpreted, and rendered meaningful. Such processes are not directly observable in technical artefacts themselves but are expressed through language, metaphors, and descriptive formulations (Goatly, 2004). A qualitative approach is therefore appropriate because it allows the study of how technologies are imagined, positioned, and justified through discourse rather than through measurable performance outcomes (Dyer & Wilkins, 1991).

Academic publications are treated in this study as a discursive arena in which technological expectations and norms are constructed and reproduced. They play an important role in shaping technological trajectories because they influence funding priorities, procurement practices, standards development, and professional education. The way technologies are described in the literature therefore contributes to how they are specified and implemented in practice. The empirical material consists of peer-reviewed publications indexed in Scopus. The dataset was constructed using the search query: TITLE-ABS-KEY ("digital twin as" AND infrastructure) till 31 December 2025. This query was chosen because "digital twin as …" constructions explicitly reveal conceptual framings rather than technical functions. Such phrases tend to appear in definitional passages where authors articulate what a digital twin is understood to be. The search returned 75 publications spanning infrastructure domains including transport, energy systems, water management, and urban infrastructure. The papers represent a heterogeneous set of disciplines including engineering, information systems, urban planning, and construction management. Together, they provide a cross-disciplinary corpus capturing how digital twins are framed in infrastructure research and constitute as a naturally occurring data (Ninan, 2020). The analysis therefore focuses not on the intentions or beliefs of the authors, but rather on how digital twins are represented and what institutional assumptions those representations imply.

The study employs qualitative content analysis with iterative coding (Miles & Huberman, 1994). The analysis proceeded in three stages. Stage 1 involves the identification of framing constructions. All publications were read to identify passages where digital twins were defined, described, or metaphorically framed. Particular attention was given to sentences using the structure "digital twin as …", and these passages were extracted and compiled into a corpus of framing statements. Stage 2 involved coding of conceptual framings. Framing statements were coded inductively to identify recurring conceptual categories. Through iterative comparison, seven dominant framings emerged such as digital twin as product, digital twin as platform, digital twin as service, digital twin as dashboard/interface, digital twin as predictive or optimization system, digital twin as organizational capability, digital twin as decision environment. Each framing category was treated as an interpretive lens through which authors implicitly define the system's purpose, users, and scope. Stage 3 involved coding of institutional implications. The themes were grounded in existing literature for validation.

Findings

The analysis of 75 infrastructure digital twin publications reveals three empirical patterns such as dominance of software metaphors, marginalization of decision processes, and absence of governance-centered framings. These are described below.

Dominance of software metaphors

Across the entire period from 2017 to 2025, digital twins are overwhelmingly framed using software- and computation-oriented metaphors. Early publications establish this pattern clearly, presenting digital twins as virtual replicas, models, or services that mirror physical systems. For example, Borodulin et al. (2017) describe manufacturing processes as being "accompanied by virtual models – Digital Twins," emphasizing that these models should be implemented as "independent computational service[s]." In this framing, the digital twin is conceptualized primarily as a software artefact that represents and simulates the physical world. This metaphorical emphasis persists in subsequent years. Kudriashov and Markov (2019) frame digital twins as analytical instruments designed to analyze the behavior of complex technical systems under various operating conditions, reinforcing the idea of the digital twin as a computational lens rather than an organizational or political construct. Even as application domains expand, the core metaphor remains rooted in modelling, simulation, and software execution.

From 2020 onwards, software metaphors become increasingly elaborate and infrastructural. Zibuschka and Ruff (2020) describe digital twins as systems that aggregate data from multiple sources, implicitly positioning them as data platforms. Deutschmann et al. (2021) similarly emphasize integration, noting that digital twins must combine technical, operational, and social components within what they describe as "industrial-social mobility hubs." Despite this broader scope, the language remains grounded in systems engineering and software integration.

Subsequently, software metaphors are further reinforced through references to real-time operation, automation, and scenario generation. Michalec (2025), while critical of prevailing framings, notes that digital twins are commonly promised as systems "able to automatically operate in real-time and generate countless scenarios to advise with planning of new infrastructures." Even here, where the article explicitly interrogates governance, the dominant discourse it critiques remains firmly anchored in computational imaginaries.

Marginalization of decision processes

A second major finding concerns how decision-making is treated in the publications. While many papers state that digital twins support decisions, the decision processes themselves are rarely described, theorized, or problematized. Instead, decision-making is presented as a

downstream activity that benefits automatically from improved models and data. In early industrial literature, this marginalization is particularly pronounced. Borodulin et al. (2017) focus extensively on simulation orchestration and scalability but make no reference to who uses these simulations or how decisions are made on their basis. Similarly, Kudriashov and Markov (2019) emphasize system analysis without specifying decision contexts, actors, or institutional settings. As digital twins are increasingly linked to complex systems, decision-making begins to appear more frequently, yet still in a limited form. Deutschmann et al. (2021) acknowledge the socio-technical complexity of airports but do not elaborate on how conflicting objectives or interests are negotiated through digital twin systems. Decision-making is implied rather than examined.

By 2022 and 2023, several publications explicitly reference uncertainty and coordination, which implicitly presuppose decision-making under conditions of risk. Barat and Kulkarni (2022) frame digital twins as responses to "environmental uncertainties and hyperconnectivity," suggesting that they play a role in navigating complex choices. However, the publications do not specify decision rules, accountability structures, or the distribution of authority.

More explicit references to decision-making appear in the most recent publications, yet even here the process remains under-specified. Fett and Wilking (2025) state that digital twins offer support of decision-making processes, but do not clarify whose decisions are supported, how conflicting values are addressed, or how responsibility is allocated. Decision-making is treated as a technical function rather than a social or political practice. The marginalization of decision processes is particularly notable given the increasing scope and influence attributed to digital twins. As these systems are positioned as tools for planning infrastructure, managing energy systems, or shaping urban environments, the lack of attention to how decisions are made, contested, and legitimized becomes a significant analytical gap.

Absence of governance-centered framings

The third and most striking finding is the persistent absence of governance-centered framings across the dataset. Although many papers deal with domains that are inherently governance-intensive, such as energy systems, urban infrastructure, and sustainability, governance is rarely named explicitly and even more rarely analyzed.

In early publications between 2017–2019, governance is entirely absent. Digital twins are framed as internal tools for firms or engineers, with no reference to regulation, public accountability, or collective decision-making. This absence reflects the technical orientation of early digital twin research communities. From 2020 onwards, governance-relevant issues begin to surface indirectly. Zibuschka et al. (2020) discuss data aggregation, while Deutschmann et al. (2021) describe industrial-social mobility hubs, implicitly raising questions about coordination and oversight. However, these issues are not framed in governance terms.

The clearest engagement with governance appears in a small subset of recent publications. Michalec (2025) explicitly critiques the dominant framing of digital twins-as-models, arguing that this framing conceals the politics of data sharing. The paper highlights that debate on ethics and politics remain limited to modelling concerns such as "bias, accuracy or explainability," while broader governance questions are sidelined. Michalec (2025) argues that energy governance should instead focus on "anticipating the reconfiguration of the political and economic relationships enabled by new data sharing infrastructures." Despite this exception, governance-centered framings remain rare. Even sustainability-oriented studies, such as López-Alfaro et al. (2025), frame digital twins as tools for "reducing light pollution and promoting sustainable lighting strategies" without addressing regulatory authority, public participation, or democratic accountability. Sustainability is treated as a technical outcome rather than a governance challenge.

Overall, the findings demonstrate that digital twin discourse has expanded in scope but not in governance awareness. While digital twins are increasingly positioned as central to infrastructure planning, sustainability transitions, and public decision-making, the papers largely avoid explicit engagement with governance concepts. These findings show a consistent pattern across time. Digital twins are predominantly framed through software metaphors, decision-making is treated as a secondary and largely unexamined activity, and governance-centered perspectives are largely absent. This combination suggests that digital twin discourse remains technically sophisticated but institutionally and politically underdeveloped. The persistence of these patterns across multiple publications indicates that they are not incidental but structural features of how digital twins are currently conceptualized.

Discussion

This study sets out to examine how infrastructure digital twins are narratively framed in academic discourse and what institutional assumptions these framings imply for governance. The findings indicate that digital twins are beyond mere technical artefacts, rather are embedded in narratives that implicitly script technological function, institutional roles, and governance alignments. Drawing on narrative theory, we interpret these framings as institutional scripts that shape how technologies are expected to function within socio-technical systems.

Narratives of technological function

Across the literature, infrastructure digital twins are predominantly narrated through metaphors of platforms, monitoring systems, optimization engines, and predictive tools. These framings define the technology primarily in terms of functional capability rather than institutional purpose. Narrative theory suggests that such descriptions do more than communicate features; they establish what counts as the legitimate problem-solving role of technology within organizational life.

By emphasizing simulation, optimization, and real-time monitoring, these narratives position digital twins as instruments for enhancing technical performance. In doing so, they foreground engineering rationality while backgrounding institutional negotiation. This aligns with broader observations in science and technology studies that technical narratives often stabilize innovation trajectories by narrowing attention to calculable functions rather than contested purposes (Bowker, 2008). Within infrastructure contexts, this functional scripting matters because it frames digital twins as solutions to operational inefficiencies rather than as tools embedded in political or governance processes. As a result, literature implicitly constructs digital twins as technologies of optimization rather than technologies of institutional coordination.

Narratives of institutional roles

A second narrative pattern concerns the institutional roles implied by digital twin framings. Actors are frequently described generically as "users," "operators," or "stakeholders," while decision processes remain largely implicit. From a narrative perspective, this abstraction is consequential: it removes the need to specify authority structures, decision rights, or accountability mechanisms. Narratives that present digital twin outputs as automatically actionable insights reinforce what can be termed a technocratic authority script, in which the legitimacy of decisions derives from data visibility rather than institutional deliberation. This pattern resonates with research on socio-technical imaginaries showing how technological visions can naturalize particular governance assumptions without explicitly debating them (Jasanoff, 2015).

In the context of infrastructure systems, this narrative shift is particularly important. Infrastructure decisions typically involve trade-offs between public value, cost, environmental impact, and political priorities (Foerster et al., 2015). Yet when digital twins are framed as providing objective, real-time knowledge, the decision process itself becomes narratively compressed. Responsibility appears to follow from information access rather than institutional authority. Thus, literature implicitly constructs governance as a downstream effect of data rather than as a structured process of collective judgement.

Narratives of governance alignment

The third narrative dimension concerns how digital twins are imagined aligning with institutional arrangements. Much of the literature situates digital twins within procurement cycles, lifecycle management frameworks, or operational integration processes. Governance is therefore narrated as an implementation issue rather than as a domain of institutional design.

Narrative theory suggests that such framings matter because they define the "setting" in which technologies are expected to operate (Coeckelbergh & Reijers, 2016). By embedding digital twins within performance management and efficiency narratives, literature positions them as tools that reinforce existing institutional logics rather than as technologies that might reconfigure them. These echoes work on technological narratives showing how innovations are often framed as extensions of current systems rather than as catalysts for institutional change (Bijker & Law, 1994). The absence of governance-centered farming is therefore not merely an omission but a narrative effect. When digital twins are described primarily through operational and performance lenses, alternative imaginaries, such as digital twins as platforms for public deliberation, regulatory coordination, or cross-sector negotiation, remain outside the discursive horizon.

Taken together, these narrative patterns show that academic discourse does more than describe digital twins; it constructs institutional expectations about them. Literature tends to script digital twins as technologies for optimization rather than coordination, sources of actionable insight rather than inputs to deliberation, and tools embedded in existing institutional structures rather than catalysts for institutional redesign. This interpretation contributes to narrative theory by demonstrating how technological discourse can function as a form of institutional scripting. It also extends infrastructure governance research by showing that governance assumptions are often embedded in technical descriptions long before systems are implemented. In this sense, digital twin narratives shape not only how technologies are understood but also how their governance becomes thinkable.

Conclusion

This study examined how infrastructure digital twins are narratively framed and what institutional assumptions these framings imply for governance. The analysis shows that infrastructure digital twins are predominantly framed using software-oriented concepts such as platforms, dashboards, and services. While these framings may be useful for describing technical components, they risk obscuring the role of digital twins as socio-technical decision environments embedded in organizational processes and governance structures.

Three key insights emerge. First, digital twins are predominantly framed through narratives of technological function that emphasize optimization, monitoring, and predictive capability. These narratives foreground engineering rationality while backgrounding institutional negotiation. Second, narratives of institutional roles tend to abstract decision-makers and compress governance processes, implying that actionable knowledge flows automatically from data visibility. Third, narratives of governance alignment position digital twins within existing procurement and performance structures, thereby reinforcing current institutional logic rather than questioning them. Together, these findings suggest that digital twin discourse performs an anticipatory governance function: it defines how the technology is expected to operate within institutions before those arrangements are explicitly designed. This insight contributes to narrative theory by showing how technological descriptions act as institutional scripts that shape future governance possibilities. It also contributes to infrastructure studies by highlighting that digital

transformation is not only a technical process but also a narrative one, in which assumptions about authority, responsibility, and coordination are constructed through narratives and discourses. Practically, the study suggests that policymakers and infrastructure organizations should treat digital twin adoption not only as a technical investment but as an institutional design challenge. If digital twins are to support strategic decision-making, cross-agency coordination, and public accountability, governance arrangements must be explicitly articulated rather than assumed to follow from technical capability.

The study has several limitations. It focuses on academic discourse rather than implementation contexts, meaning that it captures how digital twins are imagined rather than how they are enacted. Future research could compare these narratives with practitioner discourse, policy frameworks, or project case studies to examine how narrative assumptions translate into institutional practice. Comparative studies across infrastructure sectors or national contexts could also reveal whether governance assumptions differ depending on regulatory environments or political traditions.

BUILDING ENERGY SIMULATION MODULE: THE DESIGN, IMPLEMENTATION AND EVALUATION OF A DUAL-ASSESSMENT MASTERS MODULE

Divyanshu Sood[1], Donal Finn[1], James OḊonnell[2]
[1] School of Mechanical and Materials Engineering, University College Dublin, Ireland
[2] School of Engineering and Bernal Institute, University of Limerick, Limerick, Ireland

Abstract

Building energy simulation is a key competence in energy systems engineering education. Students are often challenged to appropriately apply core concepts in modelling workflows. This paper presents a novel curriculum design for masters level building energy module delivered through a combined lecture and project format. Cohort evidence includes pre and post comparison of project outcomes. Project outcomes show similar central tendency pre versus post periods, with reduced spread in the post period, consistent with more structured milestone-driven delivery. The paper provides a transferable module structure, workflow, and assessment rubric for building energy education using professional modelling toolchains.

Context and motivation

Energy use in buildings is central to the climate agenda and building professionals are increasingly expected to evaluate retrofit pathways using performance simulation modelling (Sood et al., 2025). Within tertiary education, a key challenge is that students need to need to acquire competence in building energy system concepts, yet they often struggle when these concepts need to be applied in a modelling workflow where outcomes depend on assumptions and controls. This topic directly aligns with five of the seventeen United Nations Sustainable Development Goals (SDGs): 7) Renewable Energy, 8) Good Jobs and Economic Growth, 11) Sustainable Cities and Communities, 12) Responsible Consumption and 13) Climate Action (Kartal et al., 2024). It is therefore of paramount importance that graduate students understand fundamental building physics, as well as building energy simulation know-how, so they are equipped with the required skills and experiences to make informed decisions during their professional careers.

A recurring concern, observed in project-based delivery, is that a subgroup of students engage late or inconsistently and therefore do not reach the workload threshold required for deeper analysis. This pattern aligns with reported observations in similar project-led modules. The curriculum design described here aims to reduce this failure mode through milestone-driven structure and explicit assessment criteria.

The module is delivered to masters level mechanical and energy systems engineering students in the final year of their programme. The module combines theory, worked examples, and a simulation retrofit project. The design intent is that students learn concepts in lectures and then use them in the project to build and defend a building retrofit recommendation. The summative weighting was 40% project and 60% examination prior to 2021, and was changed to 50% project and 50% examination from 2021 onward to strengthen sustained engagement with project-based learning. Module assessment comprises two components: an end of trimester exam (worth 50% of the the overall grade) and a project, an example of which is shown in Figure 1, for groups of two or three students (worth 50% of the overall grade). The same grade is awarded to all group members for the project component.

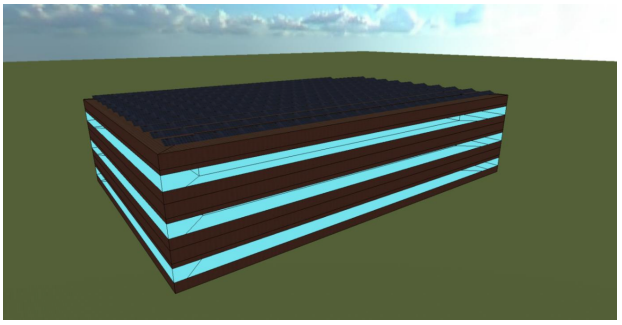

Figure 1: Example building project used for the group retrofit project.

Curriculum design approach

The curriculum design goal is to deliver deep pedagogical outcome through a balanced combination of lectures, problem sets, and project work (Gilchrist, 1999). The project is designed as a top-down building performance analysis and retrofit appraisal of an existing commercial building. The core threshold concept for the module is holistic building performance analysis through systems thinking, where building physics, HVAC systems operation, comfort, and economics are treated as linked rather than isolated topics.

The approach follows integrated course design principles, focusing on: learning goals, assessment and feedback, and aligned teaching activities. The design also draws on threshold concept theory (Timmermans and Meyer, 2019) and project based learning principles (Savery, 2006). A practical requirement is that the assessment

structure must encourage sustained engagement across the trimester rather than late engagement with the project component. This module has prerequisites and expects a considerable level of prior learning in the areas of thermodynamics and heat transfer. The key issue is that buildings can be viewed rather simplistically as static assets over which occupants have very little control but in reality buildings are dynamic and fulfil a range of functions that vary significantly over time. The lecture material, combined with related problem sets and exercises contribute to much of the formative learning within the module and in turn contribute to the group project that applies, analyses, evaluates and synthesises the course content. The end of trimester summative assessment also examines a deep understanding of course material but in a different way to the group project. Figure 2 is used to frame the design from both teacher and student perspectives.

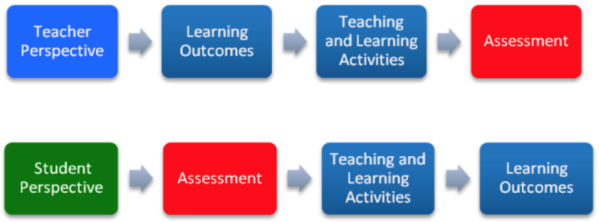

Figure 2: Curriculum design from teacher and student perspectives (adapted from (Biggs, 2003)).

Threshold concepts and learning objectives

The module is organised around a key number of threshold concepts that students must master to progress:

1. Key principles of building physics and heat transfer in buildings.
2. Psychrometrics and understanding of air-conditioning processes.
3. HVAC systems and control.
4. Building economic performance analysis.

The learning objectives and key concept map used to structure lecture content and project tasks are shown in Figure 3. The concept map is used as a reference throughout the trimester to reduce content fragmentation and to make linkages between topics explicit. The map is organised around a central question: how to ensure deep learning throughout the module. Learning objectives branch into four threshold concept areas: fundamental building physics, HVAC systems operation, building energy performance simulation, and the role and nature of occupancy in buildings. Prior learning in fluid mechanics, heat transfer, and thermodynamics is a stated prerequisite. Two summative assessment components emerge from the learning objectives: the end-of-year exam and the EBL group project. Both connect to programme outcomes and professional accreditation. The group project is designed for a variety of learning styles and is enabled by formative learning and in-class tutorials. It is assessed through presentations and links to potential industry and academic employers as external stakeholders. The exam ensures authenticity and transparency of individual learning. Assessment methods collectively facilitate skill development and transparency. The design is grounded in focused problem-based learning exercises and informed by relevant legislation, standards, and guides. Feedback continuously improves the design. Node colours identify type: green for the key question, orange for module-specific content, blue for programme-specific content, and yellow for external nodes.

Table 1 maps each intended learning outcome to the teaching activities through which it is developed and to the assessment component through which it is evaluated. The rubric criteria in Table 2 correspond directly to these outcomes: assumption traceability and plausibility checking map to outcomes 1 and 2; comfort interpretation maps to outcome 2; economic logic maps to outcome 4; and the oral defence maps to outcome 5.

Table 1: Constructive alignment: intended learning outcomes, teaching activities, and assessment methods.

Learning outcome	Teaching activity	Assessment
Building physics and heat transfer	Lectures wks 1–4; problem sets	Exam; baseline model
Psychrometrics and A/C processes	Lectures wks 5–7; chart exercises	Exam; comfort evaluation
HVAC systems and control	Lectures wks 8–10; tutorials 4–6	Exam; retrofit options
Economic performance (NPV)	Lectures wks 10–11; discounting exercise	Exam; economic analysis
Defend modelling decisions holistically	Mid-term gate; reasoning exercise	Oral defence (individual)

Lecture–project integration and milestone staging

The module is delivered through aligned lectures and project sessions over a 12 week teaching trimester. Lectures introduce concepts and methods. Project sessions require students to apply these concepts to the project case study through staged tasks. The staging is intentional. Without milestones, students tend to allocate effort toward software tasks and output generation rather than interpretation and diagnosis.

A student-centric overview of the module structure, including lecture content, project tutorials, and assessment milestones, is shown in Figure 8 in Appendix. The figure is intended to communicate what is expected, by when, and why each milestone exists. This covers 12 teaching weeks plus an exam period across six columns: week, topic, lecture topic, reading material, learning milestone, progress milestone, and assessment detail. Weeks 1 and 2 cover buildings and climate, the internal environment, and

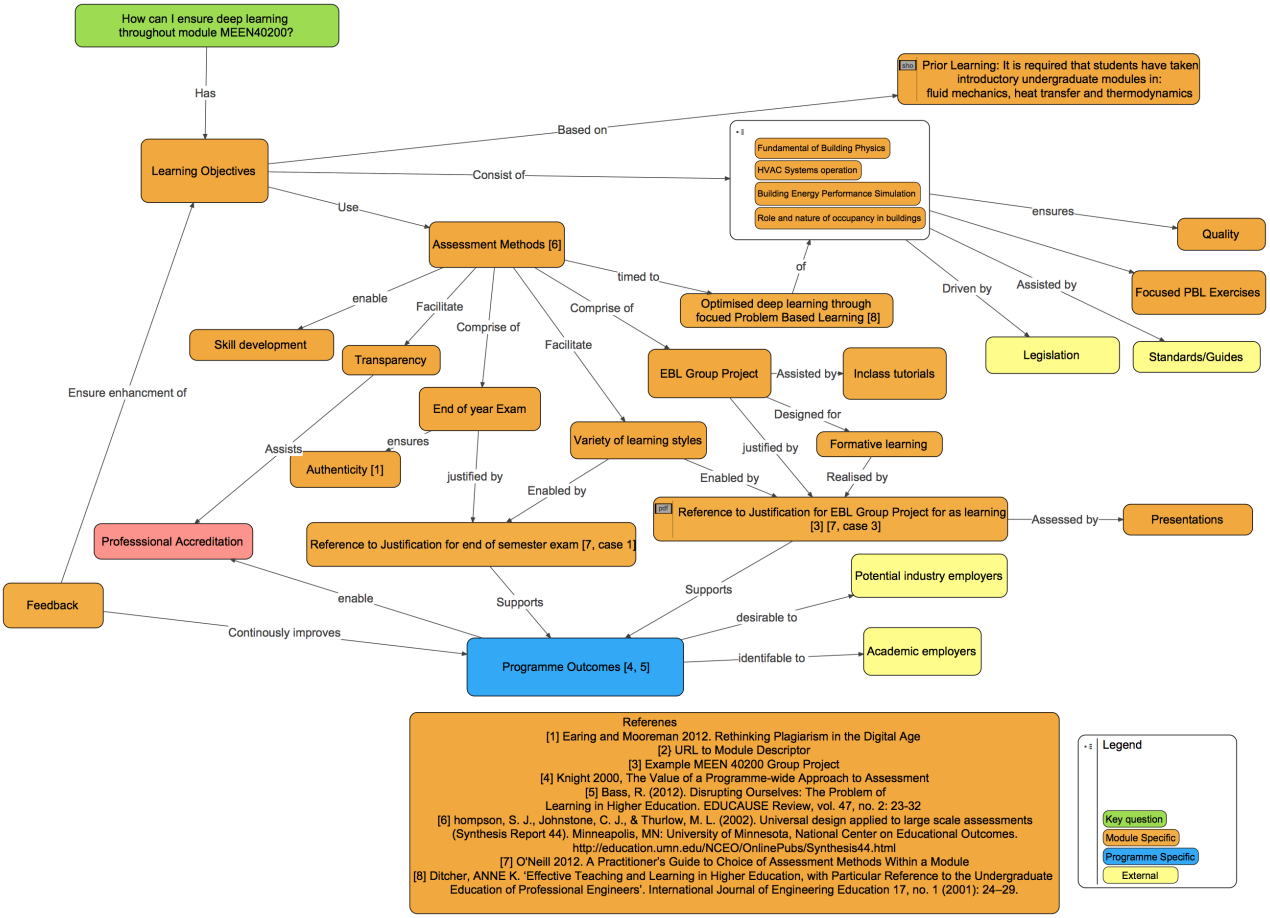

Figure 3: Learning objectives and key concepts used to structure the module.

building energy balance; the first project overview session establishes teams and the initial site. Week 3 introduces energy simulation and heat transfer; building fabric investigations are expected to be complete by its end. Week 4 covers internal gains, thermal mass, and thermal bridges; a formative self-assessment checkpoint occurs here, shown in orange. Week 5 covers daylighting and introduces psychrometrics; the key learning milestone is to understand the key principles of building physics. Week 6 covers natural ventilation and a formative problem set is released to students. Week 7 completes psychrometrics in practice; the base case model must be finished and the initial mid-term report submitted by the end of this week, which is the quality gate. After two study weeks, weeks 8–10 cover demand-side equipment, plant heating, heat pumps, and cooling; HVAC design alternatives are progressively completed during this period. Weeks 11 and 12 are reserved for make-up sessions and final project submission and presentation. The summative exam falls in the exam period. Row colours identify content type: white for lectures, blue for project tutorials, green for prerecorded lectures, light grey for reading material, yellow for key learning outcomes, purple for progress milestones, and orange for assessment components.

A week-by-week schedule is provided to students to support planning and to reduce drift in the project. An example is shown in Table **??** in Appendix.

Assessment design and feedback

Assessment components

The assessment model combines two summative components:

- An individual written examination to assess conceptual understanding and analytical competence under time constraints.
- A group retrofit project to assess applied modelling judgement and decision justification through a report and oral defence.

Formative feedback and quality gates

The project includes structured feedback loops. A mid-term formative deliverable requires groups to present baseline model behaviour, identify key drivers of performance, and propose retrofit pathways for the second half of the module. The deliverable is returned quickly to support iteration and project progression. This mid term checkpoint functions as a quality gate. It reduces late rework by identifying issues in schedules, internal gains,

controls, and zoning logic before option comparisons are finalised.

Oral defence

The final presentation includes technical assessment across individual group members. The questioning targets: assumption selection, plausibility checks, interpretation of comfort outputs, and the causal link between retrofit measures and changes in energy, comfort, and cost. Questioning is directed at each group member individually in turn. A student who has not engaged with the project in depth will most likely answer incomplete or vague to these questions at the required level, and the responses inform the overall project assessment alongside the written report. This is the primary mechanism through which individual competence is differentiated within the group grade.

Project workflow and evidence of operationalisation

Workflow overview

The project workflow follows five staged steps. In the first stage, baseline model establishment, the group configures and validates the building model against reference benchmarks to confirm that model behaviour is physically reasonable before any retrofit analysis begins. In the second stage, baseline diagnosis, energy drivers, comfort conditions, and operating patterns are identified and documented alongside the assumptions that underpin them. In the third stage, option definition, retrofit measures are selected and their technical feasibility assessed under the constraints of the building and its occupancy. In the fourth stage, option comparison, the selected measures are evaluated against the baseline on energy, comfort, and economic criteria using net present value analysis. In the fifth stage, final justification, the group defends the chosen retrofit pathway and explains the reasoning behind the assumptions, results, and conclusions. The workflow is designed so that lecture content is operationalised at each stage. For example, psychrometrics and HVAC concepts appear in control intent and comfort interpretation, and discounting appears in NPV-based comparison rather than as a stand-alone calculation.

The simulation software used for the project is IES Virtual Environment (IES VE) (IES, 2026). Prior to IES VE, Simergy was used. The module design is not dependent on either tool specifically. Any professional-grade building energy simulation environment that supports multi-zone thermal and HVAC modelling would support the same workflow.

The module structure is transferable to other institutional contexts. Three factors are relevant when adapting the design. The first is class size, which affects how group supervision and oral defence logistics are managed. Larger cohorts may require more structured oral defence scheduling and more explicit supervision records to support individual contribution monitoring. The second is software availability; the workflow does not depend on IES VE specifically. The third is curriculum prerequisites: the module assumes prior learning in thermodynamics and heat transfer.

Example of holistic building performance analysis

The module leverages the concept of Problem Based Learning (PBL) and this requires three key elements (Lloyd-Jones et al., 1998): the students must be presented with a problem or initiating trigger at the start of the process, learning takes place through the research of issues identified in the initial tutorial, and knowledge is used to further the understanding of the trigger situation. This approach is used within individual concepts but overarching threshold concept of holistic building performance analysis through systems of systems thinking is achieved through a **project** based learning approach for the group project.

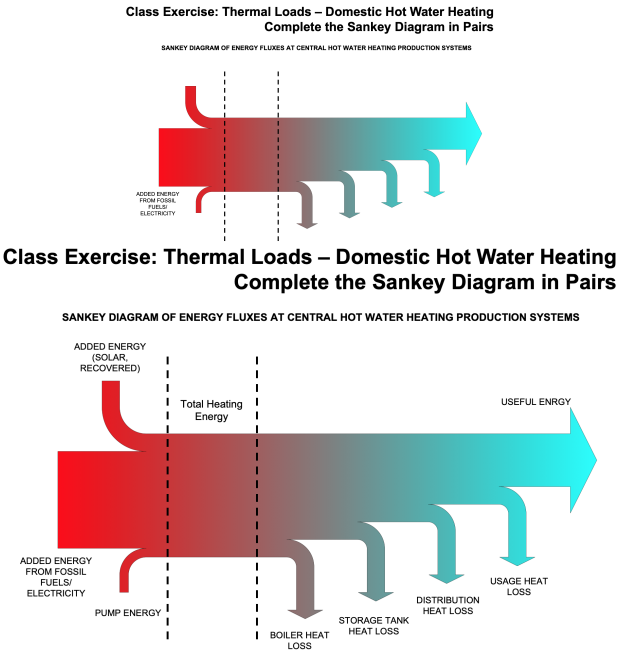

Figure 4: Example exercise used to develop holistic performance reasoning: (top) student attempt, (bottom) reference solution.

Figure 4 illustrates an in-class exercise used to develop the threshold concept of holistic building performance analysis. Students begin with an incomplete reasoning chain and must account for direct and indirect changes to energy flows and building physics under a trigger event. The exercise is used to prepare students to interpret simulation results as a system response rather than as isolated outputs.

Transferable rubric structure for the project

To make expectations explicit and to support consistent grading, the project assessment can be structured around decision-quality criteria. Table 2 provides a compact rubric structure consistent with the milestone design and

the intended learning outcomes. The intent is to reward assumption transparency, diagnosis, and interpretation rather than output volume.

Table 2: Rubric structure for the retrofit project report and defence.

Criterion (evidence in report, model, and defence)	Weight (%)
Baseline model definition and traceable assumptions	20
Plausibility checks and diagnosis (benchmarks and drivers)	20
Retrofit option definition and feasibility under constraints	15
Comfort evaluation and interpretation against stated criteria	15
Economic analysis (NPV structure and consistency checks)	15
Communication and oral defence (technical justification)	15

Supporting cohort evidence

Data sources and methodology

The evaluation draws on two data sources: project grade records spanning eleven years and institutional module feedback surveys covering four delivery years. The analysis is descriptive. The intent is to characterise outcome patterns across the pre-change and post-change periods. Two summary measures are reported: central tendency, represented by the median of the midpoint-proxy distribution within each period, and spread, represented by the interquartile range. These measures are appropriate for ordinal data and are robust to the unequal band widths in the institutional grade scale. No parametric tests are applied because the pre-period data consist of grade-frequency counts rather than individual records, and because the comparison is across cohorts of different sizes rather than matched individuals. The comparison is therefore descriptive and is intended to characterise whether the pattern of outcomes changed between periods in a way that is consistent with the intended effects of the module redesign. The evaluation is a design-led case study. It covers one module at one institution over one programme. No control group is available because the module redesign was applied to the full cohort in each year. The pre-post comparison conflates the effect of the assessment redesign with other changes over the same period, including changes in cohort composition, programme structure, and the shift to online delivery during 2020/21. These confounds are acknowledged and the cohort evidence is presented as supporting rather than confirmatory.

Project outcomes

To provide supporting evidence for the assessment redesign, project outcomes were compared across two periods: 2014–2021 (pre-change) and 2022–2025 (post-change). The pre-period records were available as grade-frequency counts from archived spreadsheets, while post-period records include numeric project marks for 2022–2024 and letter grades for 2025. Where numeric marks were available, they were converted to letter grades using the institutional grading scheme. To enable a single visual comparison across the full cohort history, each letter grade was then assigned the midpoint of its numeric band as a 0–100 proxy (UCD, 2026). The resulting scale is ordinal and descriptive: the midpoint values are used only to characterise the distribution shape and spread and are not used to make proportional claims about performance differences between grade levels. The comparison is therefore descriptive and is intended to characterise outcome patterns rather than to estimate causal learning effects.

Figure 5 shows that the central tendency of project outcomes is similar across periods, while the spread is lower in the post period. The reduced spread is consistent with a more structured project delivery and milestone-driven pacing, where most groups reach an expected standard of analysis and reporting (Figure 6).

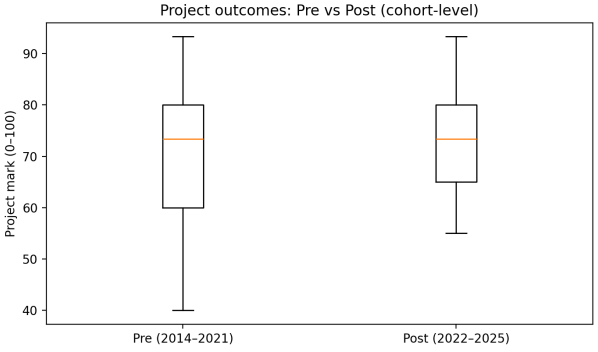

Figure 5: Project outcomes pre (2014–2021) versus post (2022–2025). Pre-period values are derived from grade-frequency records mapped to a 0–100 proxy for visual comparability.

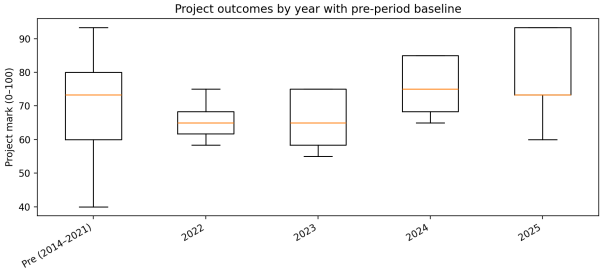

Figure 6: Project outcomes by year for 2022–2025 shown against the aggregated pre-period baseline (2014–2021).

Student module feedback

Module feedback surveys were administered to students across all delivery years using the institutional survey instrument. The survey covers five core questions on a Likert scale from one to five: Q1 subject understanding, Q2 assessment relevance, Q3 learning outcomes achieved,

Q4 teaching supported learning, and Q5 overall satisfaction. Table 3 reports the mean scores for MEEN40200 across four trimester cohorts alongside the school-level MEEN benchmark for comparison. Figure 7 shows the year-by-year trend.

Table 3: Mean Likert scores (1–5) for MEEN40200 across four delivery years and MEEN school benchmark (mean of Q1–Q5 per year).

Year	Q1	Q2	Q3	Q4	Q5	n
2020/21	4.50	4.00	3.75	4.00	3.50	4
2021/22	5.00	5.00	5.00	5.00	5.00	2
2022/23	4.67	4.33	4.33	5.00	4.33	3
2023/24	5.00	5.00	4.00	4.00	4.00	1
MEEN avg	4.07	4.07	3.86	3.83	3.73	–

Across all four years, module scores on Q1 to Q5 are at or above the MEEN school average. Q4 (teaching supported learning) and Q1 (improved subject understanding) are consistently the strongest results. Response rates were lowacross all years, ranging from 4% to 17%, which is a known limitation of voluntary institutional survey systems. The feedback data are therefore treated as corroborating evidence rather than a rigorous evaluation of student experience or learning outcomes.

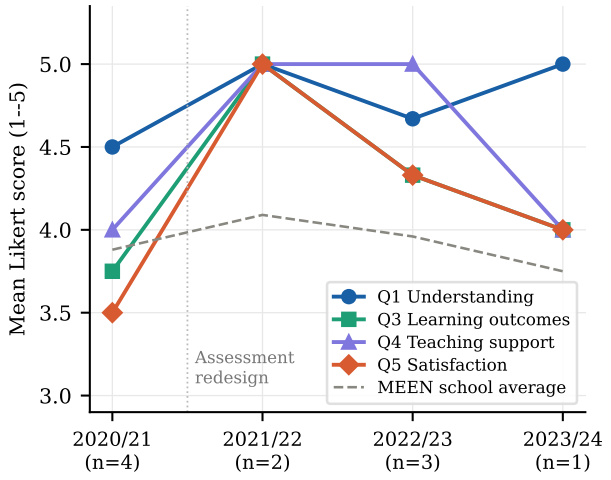

Figure 7: Mean student Likert responses for MEEN40200 across four delivery years compared against the MEEN school average. Response counts range from $n = 1$ to $n = 4$; results should be interpreted as corroborating evidence only.

Open-ended responses from 2020/21 provide qualitative context for one of the key design decisions described in this paper. Students identified the building energy simulation software as a source of significant friction, reporting that a large amount of time in the first weeks was spent on model construction rather than on analysis. This feedback informed the decision to provide a pre-built working model from the outset of the project and to shift early milestone tasks toward diagnosis and interpretation, as noted in the Workflow overview section above.

Implementation considerations

Three implementation considerations have shaped the module design. First, students can spend time on low-value tasks that do not improve the validity of conclusions, particularly when early modelling tasks are overly open-ended. This has been addressed by providing a working base model and by using milestones that prioritise baseline behaviour, diagnosis, and interpretation. Second, software issues can shift attention away from learning objectives. This has been mitigated by reducing the amount of custom model construction required early in the trimester and by placing emphasis on analysis and justification in assessment criteria. Third, students differ in study patterns. The milestone design and mid-term checkpoint reduce the risk that project work is deferred until late in the semester.

Implications for education and assessment

The lecture - project structure supports an explicit pathway from theory to application. The design makes key concepts reappear as modelling decisions and report arguments, and uses milestones to support iteration. For competency assurance, the dual assessment structure provides two complementary views: conceptual reasoning under time constraints and applied modelling judgement evidenced through a report and oral defence. If minimum competence is required in both domains, a practical policy option is to require a minimum pass standard in both components. If improved grading resolution is required within the project, the rubric weight can be shifted further toward assumption traceability, plausibility checking, and interpretation. Another option could be the application of peer review within each project group.

Conclusions

This paper presented a curriculum design for a masters level building energy systems module delivered through a coupled lecture-project format and assessed through an individual written examination and a group retrofit simulation project. The design is organised around threshold concepts and staged milestones, including a mid-term feedback and a final oral defence and reporting. The intent is that lecture content is not treated as separate theory, but is applied in the project through explicit assumptions, plausibility checks, and reporting that links model outputs to energy, comfort, and economic reasoning.

The contribution to the teaching domain is an explicit, transferable design pattern for simulation-based building energy education. The paper specifies how a lecture sequence can be aligned to a project workflow from the start of the semester, how milestones can be used to stabilise baseline models before retrofit comparison, and how questioning can be used to assess the reasoning behind modelling choices and interpretation. This addresses a recurring difficulty in simulation teaching: students may be able to generate outputs, yet struggle to explain why results change, whether outputs are plausible, and how con-

clusions follow from assumptions and controls.

The cohort evidence provides practical insight into assessment behaviour under this design. A pre and post comparison of project outcomes indicates similar central tendency across periods, with reduced spread in the post period. This is consistent with a more structured, milestone-driven delivery in which most groups reach the expected standard of analysis and understanding. At the same time, examination outcomes provide a stronger basis for individual differentiation, which supports the rationale for dual assessment when programme requirements include both conceptual mastery and applied modelling judgement. The implication is that project and examination components should be treated as complementary measures rather than substitutes, and that overall grades alone are not sufficient to infer competence because weighting policies and component dispersion affect how final outcomes are formed.

For future teaching practices, the results support three specific recommendations. First, define project marking around decision quality criteria. Second, retain an early quality gate with timely feedback to reduce late-stage rework and protect time for interpretation and justification. Third, where minimum competence is required in both domains, consider minimum thresholds for each component to avoid systematic compensation. Together, these recommendations frame building energy simulation education as a professional reasoning task supported by a structured project workflow and an assessment model that makes competence observable.

ANALYSING GREEN AND DIGITAL SKILLS IN THE TWIN TRANSITION

Farina Koller, Niels Bartels, and Claudia Ziller
TH Köln, University of Applied Sciences, Cologne, Germany

Abstract

The building sector is undergoing a twin transition that combines digital and sustainable transformation. This process requires professionals with integrated green and digital skills. However, their systematic integration into education and professional practice remains limited. This paper addresses this gap through a qualitative case study based on 53 expert interviews and a validation workshop in the Cologne metropolitan region. The findings reveal significant competency gaps and form the basis for a framework supporting the integrated development of green and digital skills.

Introduction

The building sector accounts for approximately 35 % of energy consumption and 30 % of CO2 emissions in Germany (United Nations, 2024).

To address these challenges, the sector is undergoing a twin transition, that combines digitalisation and sustainability (Hofmann et al., 2023). This transformation requires integrated green and digital skills, yet their implementation in education and practice remains insufficiently understood (Ziegler et al., 2023).

This study analyses existing and required skills and explores their integration into higher education.

Design and method

A qualitative research design combining semi-structured expert interviews and a validation workshop was applied. Stakeholders from planning, construction, operation, education, and regulation were included. In total, 53 interviews were analysed using qualitative content analysis (Kuckartz, 2018) and discussed in a workshop with 30 participants from academia and industry. In this study, green skills are defined as job-related skills supporting sustainable construction, while digital skills comprise the effective use of digital technologies and data throughout the building lifecycle, as shown in Figure 1.

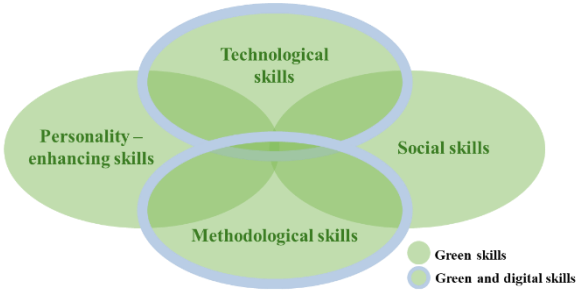

Figure 1: Used definition of green and digital skills

Results

The findings reveal a mismatch between existing and required skills. While basic technical green skills are generally present, they remain fragmented and are rarely integrated into lifecycle-oriented approaches.

A major deficit concerns methodological skils. Experts highlighted limited capabilities in applying lifecycle assessment, lifecycle costing, and data-based sustainability evaluations. Analytical and evidence-based decision-making skills are often lacking.

These deficits are closely linked to insufficient digital skills. Although digital are increasingly available, their potential for supporting sustainability goals remains underutilised. Skills related to digital planning tools, data interpretation, and simulation-based analyses are frequently underdeveloped and rarely connected to sustainability objectives.

The analysis also identified significant gaps in interdisciplinary skills. Strong discipline-specific expertise exists, but knowledge exchange across professions and lifecycle phases remains limited. As a result, coordination challenges emerge and integrated solutions are difficult to implement. Communication and collaboration skills were identified as critical requirements for successful transformation processes.

The analysis highlights the important role of higher education in preparing professionals for the twin transition but reveals significant shortcomings. Sustainability and digitalisation are often treated as isolated topics rather than integrated skills. In addition, interdisciplinary and practice-oriented learning formats remain limited, and teaching staff frequently lack up-to-date expertise. As a result, current education systems are not yet fully aligned with the competency requirements of the twin transition.

The findings indicate that the prevailing education and training systems are not yet fully aligned with the skills required for the twin transition, particularly with regard to the integration of green and digital skills as interconnected domains.

Conclusion and recommendations for action

The study demonstrates that the twin transition is constrained by a mismatch between existing and required skills. Green and digital skills should not be considered separate domains; rather, digitalisation acts as an important enabler of sustainability.

To address current deficits, green and digital skills should be embedded as cross-cutting skills throughout higher education and professional training. Key measures include:

- integration of sustainability and digitalisation across curricula
- strengthening data-driven and methodological skills
- expanding interdisciplinary and practice-oriented learning formats
- fostering close collaboration between academia and industry

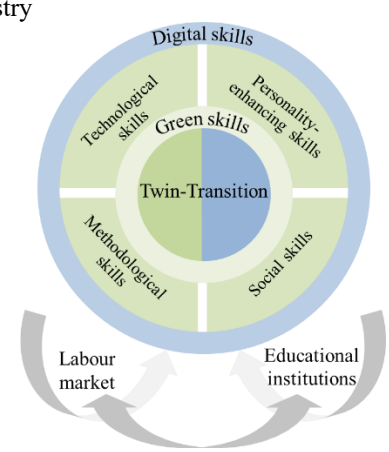

Figure 2: Framework for the integrated development of green and digital skills

The conceptual underpinnings of this integration are delineated by the framework depicted in Figure 2. It is recommended that future research efforts concentrate on the implementation and evaluation of integrated competence models.

Acknowledgments

This study is part of a project funded by the RheinEnergie Foundation in cooperation with the University of Applied Sciences Cologne and the University of Cologne.

BLOCKCHAIN-ENABLED DIGITAL TWINS FOR ENHANCED LIFECYCLE MANAGEMENT IN BUILDING HANDOVER

Yutian Yi[1], Davide Lombardi[1] and Theodoros Dounas[2]
[1]Xi'an Jiaotong-Liverpool University, Suzhou, China
[2]Heriot-Watt University, Edinburgh, Scotland

Abstract

Building handover is a critical stage in the building lifecycle, yet project information is often fragmented, difficult to verify, and hard to reuse in later operation and maintenance. Digital Twins (DTs) can improve lifecycle visibility, while BC can strengthen trust and traceability(Dounas et al., 2020). However, current studies rarely combine these with semantic knowledge representation. This work proposes a Blockchain-enabled semantic DT framework for building handover, using a five-layer architecture and a knowledge graph to structure building information. A lightweight prototype demonstrates trusted data admission and auditable event recording. The contribution is a practical and reproducible framework for improving lifecycle continuity beyond handover.

Introduction

Building handover is the point where responsibility moves from design and construction teams to owners, operators, and facility managers (Adu-Amankwa et al., 2023). At this stage, large amounts of information must be transferred, including room data, asset details, commissioning evidence, sensor information, and maintenance-related records. In practice, this transfer is often incomplete, inconsistent, or difficult to verify. As a result, valuable information is lost or underused after project delivery, which weakens later operation and maintenance (Boje et al., 2020).

DTs offer a way to organise and connect lifecycle information in a living digital environment (Opoku et al., 2021). Blockchain (BC) can complement DTs by providing tamper-evident records and stronger trust in shared data. Yet many current DT–BC studies focus mainly on data exchange or on-chain records, with limited attention to semantic structure (Dounas et al., 2023). Without semantic enrichment, handover information remains difficult to interpret across systems and lifecycle stages.

This poster proposes a BC-enabled semantic DT framework for building handover. The framework combines a knowledge graph based on BOT, BRICK, and SAREF with BC-supported governance to improve trusted information transfer at the handover stage. The system is organised into five layers: data acquisition, data transmission, semantic, BC, and application.

Framework overview

The framework shown as fig. 1 is designed to connect physical building information, semantic context, and trusted digital services across the handover process.

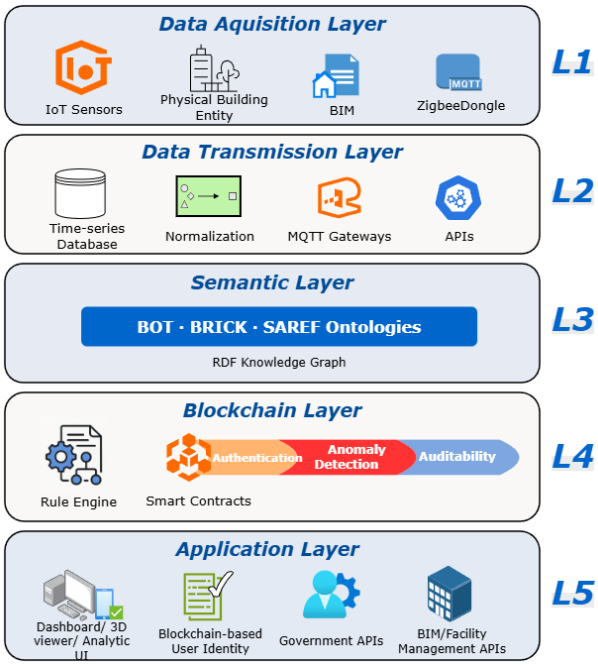

Figure 1: Methodology flowchart

The data acquisition layer gathers building and asset information from physical entities, BIM-related data, and IoT devices. The data transmission layer moves this information through standardised workflows and prepares it for processing. The semantic layer uses a knowledge graph to connect spaces, devices, and measured properties in a machine-readable form. The BC layer adds trust by verifying data sources and recording important lifecycle events. The application layer supports dashboards, analytics, and service integration for later building use. This structure allows data to move from fragmented project delivery information toward a more connected and trustworthy handover process.

Methodology

The proposed methodology integrates DT and BC through a structured three-stage workflow: data acquisition, BC access, and system enrichment, as illustrated in Fig. 2.

First, real-time data are collected from physical assets and IoT sensors, including temperature, energy, and occupancy. These data are transmitted, pre-processed, and partially handled at the edge to reduce latency and ensure a consistent format.

Second, the processed data enter the BC access stage, where key information is cryptographically hashed and anchored to the BC. Smart contracts are used to automate permissions, validation, and transaction logic, while an immutable ledger records critical events to ensure traceability and trust.

Finally, in the system enrichment stage, validated data are integrated into the Digital Twin model, enabling synchronised updates of building states. This enriched DT environment supports advanced analytics, simulation, and user-oriented visualisation. Through this workflow, the methodology ensures that building data are not only collected and processed efficiently but also verified and made trustworthy for lifecycle management.

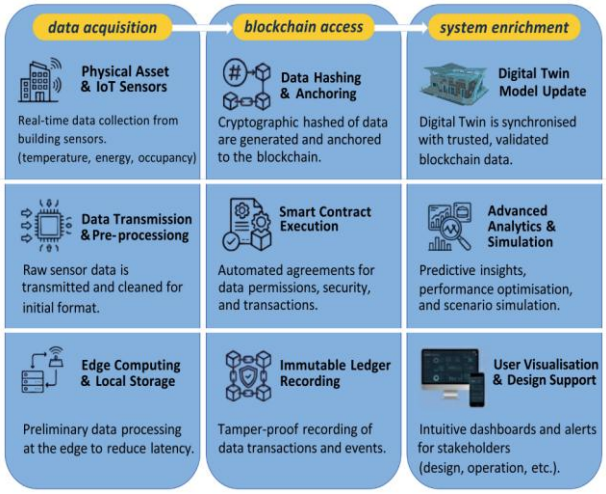

Figure 2: Methodology flowchart

Simulation and experiment

A lightweight prototype was developed in a containerised environment to demonstrate the feasibility of the framework. The prototype combines a knowledge graph, a time-series database, a workflow engine, and a local BC service. Rather than trying to represent all handover documents, the prototype focuses on one key principle: trusted entry of lifecycle information into the DT.

A semantic knowledge graph was prepared to represent rooms, devices, and measured properties. BC services were used to verify whether an information source was authorised before its data could enter the DT workflow.

Conclusion

This study presents a BC-enabled semantic DT framework for building handover. The proposed five-layer structure integrates semantic enrichment and BC-supported trust into one lightweight and reproducible system. The proof of concept shows that authorised information sources can be admitted while unknown sources can be blocked before entering the DT workflow.

The framework contributes a practical way to strengthen lifecycle continuity at handover by improving both interoperability and trust. Future work will extend the approach to richer handover data types, broader stakeholder workflows, and AI-supported lifecycle services.

FROM CAPTURE TO CO-CONSTRUCTION: A SCOT- INFORMED ANALYSIS OF DIGITAL TWIN PRACTICES IN CEMETERY SCANNING

Ekpenyong Ekpo, Nikolic Dragana, and Green Martin
University of Reading, United Kingdom

Abstract

Although digital twins (DT) have been promoted as technical solutions in facility management, their adoption is a social process. This study addresses the gap in the socio-technical understanding of how DTs are enacted in practice. To understand how practices emerge, this study uses Social Construction of Technology (SCOT) framework and its interpretative flexibility component to present the development of a DT of a cemetery. Using vignette-based ethnography, the findings illustrate how the DT creation process is shaped by user interpretations, as well as social and environmental conditions. Overall, this study contributes an empirically grounded sociotechnical account of a DT creation.

Introduction

Digital twins have attracted growing attention in facility management because of their data centric pairing of digital models to physical assets. However, much of the current discourse largely focuses on technical capacities such as data integration, visualization and system performance (Asare Kofi et al., 2024). While these technology-focused approaches are helpful, adoption of digital twins in practice, as of any novel technologies, is rarely straightforward (Nikolić and Ewart, 2025, Schweber and Harty, 2010). Hence, processes and practices for developing and using digital twins are often fluid and emergent before they become routines.

To understand how these processes and practices unfold, this study draws on the SCOT framework, and using vignette-based evidence, presents moments were meanings, decisions, and practices were negotiated.

Aim and objectives

To explore how practices emerge, a pilot case study was conducted to create a digital twin for a local cemetery. Specifically, the study aimed to:

1. Examine how social constructs shape the DT creation process.
2. Identify moments of negotiation and adaptation that occur during the scanning process.

Understanding how these practices emerge is critical for moving beyond a deterministic view of DT implementation towards frameworks that support their situated adoption.

Methodology

This study examines the DT creation as a sociotechnical process and using SCOT as a lens, presents the scanning process of a local cemetery as a negotiation between technology, site conditions, environment and users. The cemetery as a space rich in history and meaning offers a pertinent case study to explore social constructs such as purpose, privacy concerns, and interactions between diverse stakeholders.

The study adopts interpretive reflexivity as a key component of SCOT (Bijker, 2015), both as a theoretical position and a methodological strategy. Ethnographic vignettes, which represent short stories that describe situations (Azman and Mahadhir, 2017), are adopted to foreground moments where technology's meaning and use were negotiated.

Results

The findings present reflexive ethnographic vignettes that highlight the emergent nature of practices surrounding the creation of the digital twin of a local cemetery.

Scan density

Vignette 1: Trees resisting technology (Figures 1, 2, and 3)

In the densely wooded section, tree branches swayed continuously in the wind, repeatedly disrupting scan alignment. The scanner was repositioned multiple times and additional scans were required to be able to align scans properly.

This represents moments of interpretive flexibility in how the technology is understood and used. The correct way to capture the space became dependent on environmental conditions rather than technical protocols. The repeated repositioning of the scanner and increased scan density reflects a process of negotiation between the user, the technology and the material environment, highlighting SCOT's emphasis on context and social factors shaping technological practices.

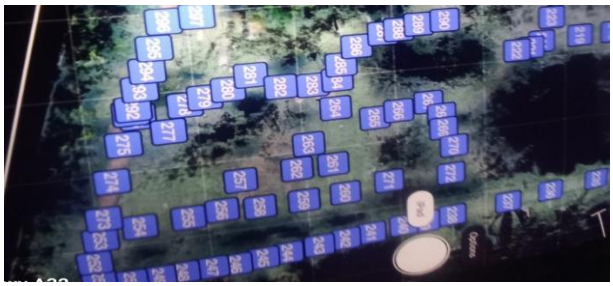

Figure 1: Scan density at dense portion of the cemetery

Figure 2: Image of dense portion of the cemetery

Figure 3: Scan density at open terrain portion of the cemetery

Negotiating Privacy

Vignette: Negotiating Privacy (Figures 4&5)

A group of visitors arrived and gathered around a particular monument while scanning was underway. Sensing their discomfort with my presence and the proximity of the scanner, I relocated the equipment to another part of the cemetery to afford them privacy.

At this moment, the digital twin did not passively capture space; it was actively shaped through ethical judgement embedded in practice. The DT produced is co-constituted through social responsibility, showing where technological operation becomes inseparable from situated ethical awareness.

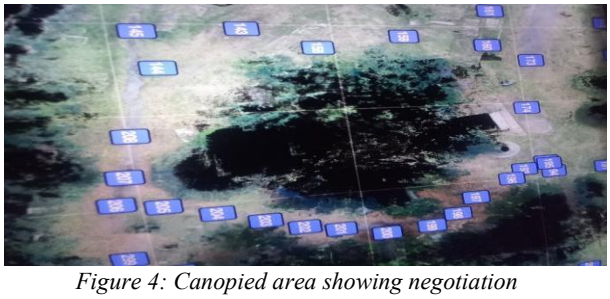

Figure 4: Canopied area showing negotiation

Figure 5: Non serial scanning points showing pause due to presence of visitors

Discussion

The aim of this study was to explore the socio-technical processes involved in the creation of a DT. The findings reveal that the emerging practices surrounding DT creation are closely linked to the process of interpretive flexibility, where the meaning of the technology is not fixed but continuously evolving.

Conclusion

This study demonstrates that DT adoption is rarely a purely technical endeavour, but rather grounded in sociotechnical negotiation. The findings show that data capture for DT creation is shaped by social interactions. DTs can be seen not as a static product, but as a dynamic, socially mediated, and negotiated outcome.

Hence, it recommends an approach to DT adoption that recognises co-production through the interaction of technological, human, social and environmental factors.

PARSING CONSTRUCTION STANDARDS INTO MACHINE-PROCESSABLE FORMAT

Mohamed Helmy Ammar and Merna Emara
Technische Universität Dresden, Dresden, Germany

Abstract

Manual compliance checking in construction remains challenging due to the complexity and unstructured nature of regulatory documents. This research presents an NLP-based pipeline that automatically extracts structured Information Requirements (IRs) from German construction standards (DIN 4108-2, -3, -4). A fine-tuned T5 transformer model is trained on 1,007 annotated sentences, achieving an F1-score of 92.86% on test data and 88.03% on unseen regulations. The extracted rules are converted into SPARQL queries and integrated into a BIM-based compliance checking workflow, enabling automated verification of IFC models.

Introduction

Construction compliance checking is still largely manual, requiring engineers to interpret lengthy and complex regulatory documents. Although BIM improves design coordination, the integration of regulatory requirements into automated workflows remains limited. Existing approaches often rely on manually formalized rules, restricting scalability and adaptability.

This research proposes an end-to-end NLP-based pipeline that transforms unstructured regulatory text into structured, machine-processable representations and directly integrates them into BIM-based compliance checking. The approach combines transformer-based information extraction with semantic rule execution, enabling automated and scalable regulatory validation.

Literature review

Previous research in automated compliance checking has explored rule-based, ontology-driven, and NLP-based approaches. While rule-based methods provide interpretability, they require extensive manual modeling. Recent transformer-based models improve information extraction but are often limited to text-level evaluation without integration into executable BIM workflows.

Methodology

The proposed pipeline extracts structured Information Requirements (IRs) from regulatory text using a supervised learning approach. German construction standards (DIN 4108-2, -3, and -4) are translated into English, and 1,007 sentences are manually annotated using four components: entity, property, relation, and value.

The dataset is split into training (80%), validation (10%), and testing (10%) sets. A T5-base transformer model is fine-tuned to convert raw sentences into structured outputs. T5 is selected due to its strong performance in sequence-to-sequence tasks and prior success in regulatory text parsing.

The extracted IRs are transformed into SPARQL queries for automated rule execution. BIM models in IFC format are converted into RDF to enable semantic querying, and compliance checks are executed using Apache Jena Fuseki, with results visualized in BIMvision. The overall pipeline connects regulation parsing, structured representation, and BIM-based compliance checking in a unified workflow. The overall workflow is illustrated in Figure 1.

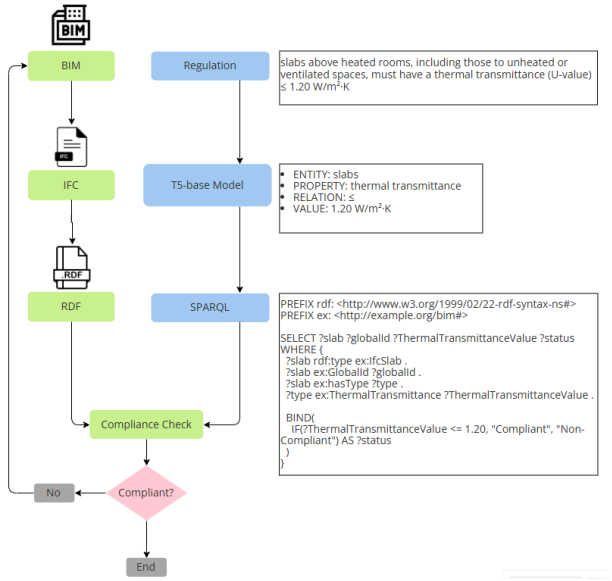

Figure 1: Overall Workflow of the Proposed Compliance Checking Process, (Adapted from [(Chen et al., 2024)])

Implementation and results

A total of 1,155 sentences are extracted from DIN 4108 standards, of which 1,007 are used for training and evaluation. Sentences are manually annotated in Excel to capture semantic components required for rule generation.

The dataset includes various building elements and thermal performance requirements, ensuring coverage of energy efficiency regulations. Preprocessing includes

normalization and cleaning, while model training is conducted using the Hugging Face Transformers library.

The fine-tuned T5 model achieves strong performance across all evaluation metrics. On the test dataset, the model reaches an F1-score of 92.86%, with high precision (92.51%) and recall (93.22%).

To evaluate generalization, the model is applied to an unseen dataset of 150 sentences, achieving an F1-score of 88.03%. These results demonstrate the model's ability to accurately extract structured Information Requirements from new regulatory content. Errors primarily occur in sentences with complex structures or multiple conditions. Additionally, transformer-based models may introduce hallucinations, generating incomplete or incorrect outputs in rare cases.

Rule compliance checking case study

A case study is conducted using a BIM model of a school building in Germany to evaluate the practical applicability of the pipeline. Extracted IRs are converted into SPARQL queries and executed on an RDF representation of the IFC model.

The system automatically identifies non-compliant elements based on thermal performance requirements. Results are visualized in BIMvision, where non-compliant building elements are automatically highlighted, as shown in Figure 2. This visual representation enables designers and reviewers to quickly identify violations and understand their spatial context within the building model, supporting efficient decision-making during the design review process.

A comparison with Solibri Model Checker confirms that the generated results are consistent with established compliance checking tools, demonstrating the reliability and practical applicability of the proposed approach.

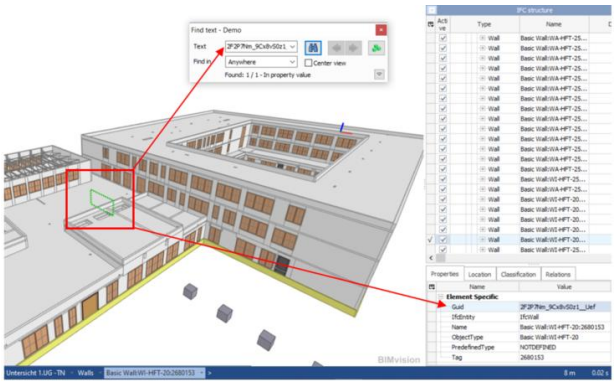

Figure 2: Visualization of query results in BIMvision

Conclusions

This research presents an NLP-based pipeline for transforming unstructured construction regulations into machine-processable rules and integrating them into BIM-based compliance checking. The results demonstrate high extraction accuracy and successful application in a real-world case study.

The approach reduces manual effort and improves the scalability of compliance checking workflows. Future work will focus on extending the method to additional regulatory domains, improving robustness for complex sentences, and reducing reliance on manual annotation.

A WORKFLOW FOR FEM GENERATION FROM BIM MODELS BASED ON GEOMETRIC VERIFICATION

Villem Vaktskjold, Marcin Luczkowski, and Lars Olav Toppe
Norwegian University of Science and Technology (NTNU), Trondheim, Norway

Abstract

This extended abstract addresses the persistent gap between geometric BIM exchange and analysis-ready structural models. Although IFC supports analytical entities, exchanged models often contain geometry without the grids, axes, and connectivity definitions required for finite element analysis (FEA). A geometry-driven workflow is presented for reconstructing local axes, inferring structural grids, correcting alignment, and generating FEM models directly from IFC-derived geometry. A multistorey case study demonstrates that the reconstructed analytical model can be used for numerical analysis and produces structurally meaningful response fields. The contribution is a practical abstraction workflow that improves BIM–FEA interoperability without requiring manually authored analytical models.

Introduction

BIM and the Industry Foundation Classes (IFC) (International Organization for Standardization, 2018) standard are widely used for information exchange in the AEC sector. In structural engineering, however, exchanged IFC models frequently provide detailed geometry while lacking the analytical abstractions required for finite element analysis, including reference axes, structural grids, and consistent connectivity (Dean, 2010; Fedorik et al., 2016; Gomes et al., 2022). This forces engineers to reconstruct the analytical model manually before numerical assessment can begin.

This problem has been discussed in earlier work on IFC interoperability in the structural domain. While IFC aims to support object-based exchange, the reliable transfer of analytically relevant information remains limited, particularly across heterogeneous software workflows (Dean, 2010; Fedorik et al., 2016). More broadly, BIM models are often shaped by coordination and visualisation requirements rather than analytical needs, which can further reduce their suitability for structural assessment (Holzer, 2011). As a result, geometric completeness should not be confused with analytical readiness. The objective of this work is therefore to present a workflow that reconstructs minimal analytical reference systems directly from geometric information and uses them to generate a finite element model.

Related work

Previous BIM–FEA integration approaches have primarily focused on direct mapping between IFC entities and structural analysis software, or on proprietary workflows within specific software environments. These approaches can transfer geometry and selected metadata but typically depend on either predefined analytical models or substantial manual preprocessing (Fedorik et al., 2016; Gomes et al., 2022). Earlier studies have also shown that missing or inconsistent object mappings, unsupported attributes, and incomplete analytical entities remain recurring issues in IFC-based structural exchange (Dean, 2010; Ciccone et al., 2023).

Although IFC includes concepts for analytical representations, these are inconsistently implemented in practice. Consequently, current workflows do not adequately address the common case in which only geometric information can be assumed to be reliably available. The present work differs from direct conversion approaches by treating analytical abstraction itself as the central problem, rather than assuming it has already been solved upstream.

Method

The proposed workflow consists of four steps (A–D), as illustrated in Figure 1.

Step A: Element identification. Structural elements relevant for analysis (columns, beams, slabs) are extracted from the IFC model. Their geometric representations are used as the primary input, independent of analytical entities.

Step B: Axis estimation and grid point generation. Local axes are estimated from geometry using principal directions and element extents. Based on these axes, candidate grid points representing potential analytical node lo-cations are generated.

Step C: Grid inference and alignment. The generated points are grouped using geometric regularity, dominant directions, and spacing consistency to infer a global structural grid. Structural elements are then projected onto this grid to enforce consistent alignment and connectivity.

Step D: FEM model generation. The corrected analytical representation is converted into an FEM model with aligned axes and consistent connectivity, enabling numerical structural analysis.

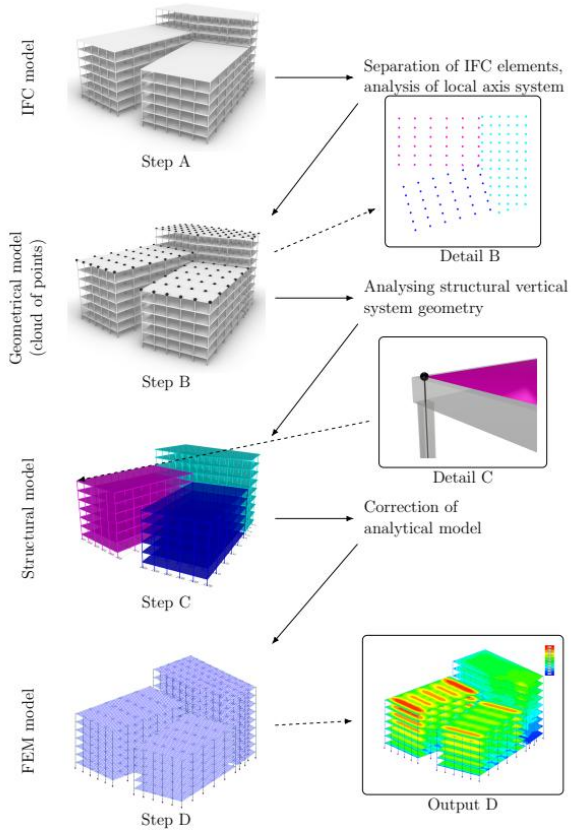

Figure 1: Geometry-driven workflow for FEM generation from IFC data. (A) Extraction of structural elements. (B) Estimation of local axes and generation of grid points. (C) Inference and correction using a global structural grid. (D) Generation of an FEM model and structural response.

Results and discussion

The workflow was applied to a multistorey building model represented in IFC. The input model contained geometrically detailed structural components but did not provide a directly usable analytical grid or consistent axis system. The geometry-based procedure successfully identified the primary structural components, estimated their orientations, and reconstructed a coherent structural grid.

Using this reconstructed grid as a global reference reduced ambiguity in member alignment and improved consistency at intended connections between beams, slabs, and columns. The corrected analytical representation was then used to generate a finite element model that could be analysed without requiring manual redefinition of the global structural layout. Representative analysis output showed stable and physically meaningful structural response.

The main benefit of the workflow is that it does not depend on manually authored analytical entities in the exchanged BIM model. This is important because many practical BIM workflows prioritise coordination and geometric detail rather than structural abstraction. At the same time, the approach has limitations. The current workflow is best suited to structural systems in which geometric regularity is sufficient to infer dominant reference directions. Future development will focus on extending the approach to highly irregular layouts, improving the treatment of sup-port conditions, and incorporating structural walls.

Conclusions

This extended abstract has presented a geometry-driven workflow for reconstructing analytical reference systems and generating FEM models from IFC data. By explicitly recovering local axes, structural grids, and alignment from geometry, the method supports structural model generation even when exchanged BIM models are not analysis-ready. The results indicate that analytical abstraction can be treated as a recoverable step in the workflow, improving BIM–FEA interoperability while remaining compatible with existing modelling practice.

A BIM-BASED DIAGNOSTIC DIGITAL TWIN FOR PREVENTIVE SEISMIC RETROFIT OF OCCUPIED SCHOOL BUILDINGS

Lavinia Chiara Tagliabue[1], Alessandro Zichi[2], Silvia Meschini[1], Stefano Rinaldi[3], and Hira Ovais[1]
[1]University of Turin, Turin, Italy
[2]Zichi Engineering, Milan, Italy
[3]University of Brescia, Brescia, Italy

Abstract

Preventive seismic retrofit of school buildings requires diagnostic-driven uncertainty reduction and planning compatible with continuous use. BIM and Digital Twin often address isolated tasks (geometry, monitoring, retrofit), while integrated workflows linking diagnostics, seismic verification, and construction safety in occupied schools remain limited. The work presents a BIM-based Diagnostic DT combining survey, in-situ testing, seismic modelling, and phased retrofit planning. A Milan school case demonstrates how diagnostic evidence can be mapped to BIM objects and used to calibrate key modelling assumptions for seismic verification. The workflow is replicable across school portfolios and supports tender-evaluable deliverables for safe execution and as-built consolidation.

Introduction

School buildings are critical public infrastructure with vulnerable users and high occupancy. In Italy, a large share of the school stock predates modern seismic provisions, motivating preventive assessment and retrofit. Unlike other building typologies, schools cannot be easily closed for long periods; therefore, feasibility depends on operational constraints such as segregation of work areas, protected circulation and emergency routes, and limited time windows for disruptive tasks. While BIM enables structured integration of geometry and semantics (Volk et al., 2014) and Digital Twin (DT) research increasingly focuses on data-driven representations (Liu et al., 2024), diagnostic evidence and execution records are often managed as stand-alone reports, limiting traceability across design revisions and as-built handover. This work proposes a BIM-centred Diagnostic DT linking survey, in-situ diagnostics, seismic assessment and phased retrofit planning for an occupied school, consistent with existing-building verification practice (MIT, 2018; CEN, 2005).

Methodology and case study

The proposed BIM-based Diagnostic DT integrates four components: (i) BIM-based geometric and semantic modelling, (ii) integration of diagnostic investigations, (iii) seismic assessment and intervention design, and (iv) construction-phase organisation and safety management. The overall Diagnostic DT workflow follows a structured progression from geometric survey and in-situ diagnostics to seismic verification, retrofit design, construction-phase phasing, and final traceability (Figure 1). It is conceived as iterative: diagnostic and execution evidence feed back into model calibration, ensuring transparency between observed conditions, modelling assumptions, and implemented interventions.

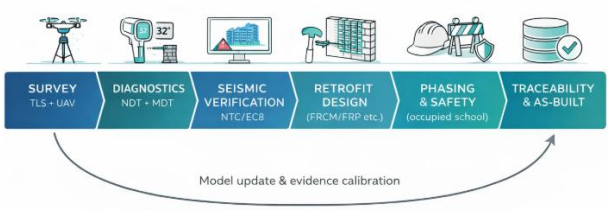

Figure 1. Diagnostic DT workflow

Survey and BIM modelling rely on terrestrial laser scanning and drone photogrammetry to support BIM reconstruction and to locate structural discontinuities (Figure 2). Diagnostic investigations (thermography, endoscopy, sonic tests, and single/double flat-jack tests for masonry, plus targeted tests on reinforced concrete members) reduce epistemic uncertainty on materials, stress state, and hidden stratigraphy (Sousa et al., 2014). Test outputs are mapped to BIM objects using consistent identifiers and stored as structured properties to ensure object-level traceability.

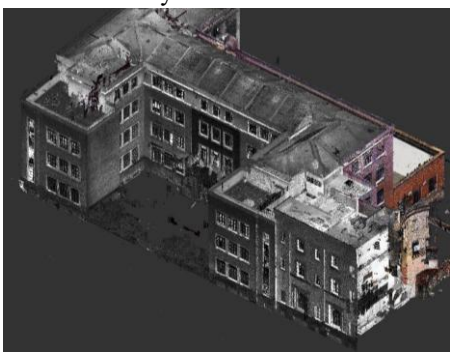

Figure 2. Terrestrial laser scanning point cloud supporting BIM reconstruction

A structural model derived from BIM supports seismic verification within an existing-building workflow; diagnostics inform material parameters and detailing assumptions used in checks (MIT, 2018; CEN, 2005). Phased scenarios are defined to minimise interference with educational activities by modelling safety zones and protected routes in BIM. Finally, the proposed award-

criteria matrix (Table 1) translates these requirements into tender-evaluable deliverables. Weighting prioritises life-safety and retrofit effectiveness while recognising phasing and safety governance as decisive constraints in occupied schools (Italian Republic, 2023; MIMS, 2021; Meschini et al., 2022). The framework is demonstrated on the listed Istituto Spinelli school in Milan, which remained operational during diagnostics and design.

Table 1. Proposed award-criteria matrix for procurement of seismic retrofit works in occupied schools

Award criterion	Weight (%)	Why it matters (occupied school)	Example evidence - deliverables
Structural effectiveness & compatibility	30	Primary objective: risk reduction; compatibility with existing systems and constraints	Retrofit design report; compatibility sheets
Construction phasing & continuity plan	20	Keeps school operational; reduces interference and downtime	Phasing plan; area-use schedule; route maps
Safety management (users & workers)	20	Segregation, protected egress, dust/noise/vibration control	Safety zoning; emergency route plan; mitigation measures
Digital deliverables & traceability	15	Verifiable progress, object-level records, as-built consolidation	BIM/DT schema; mobile checklists; update protocol
Environmental management (CAM-oriented)	10	Controlled site practices and documentation where CAM applies	Waste/material tracking; CAM records
Stakeholder communication plan	5	Coordination with school community reduces conflicts and delays	Communication protocol; notices; escalation plan

Survey and diagnostic data supported BIM reconstruction, seismic verification and the identification of critical masonry and reinforced-concrete elements (MIT, 2018; CEN, 2005). Retrofit and phasing measures were then coordinated in BIM to ensure compatibility, limited invasiveness and safety-oriented execution with protected routes, safety zones and temporary access constraints (Figure 3).

Replicability and conclusions

The Diagnostic DT is conceived for portfolio-scale use through standardised diagnostic protocols, reusable data structures and object-level identifiers, enabling comparison across school buildings and supporting preventive seismic planning. In the Milan case study, survey, diagnostics, seismic verification and phased execution are linked within a single traceable information environment. The main contribution is to make diagnostic evidence auditable and actionable, connecting uncertainty reduction to modelling assumptions, retrofit choices and safe execution in occupied schools. Future work will test transferability across additional typologies and quantify uncertainty reduction, execution traceability and portfolio-level prioritisation.

A LARGE LANGUAGE MODEL-BASED MULTI-AGENT SYSTEM FOR ENHANCED INFORMATION RETRIEVAL IN CIVIL ENGINEERING

Sebastian Kunz, Benedikt Justin Kandler, and Uwe Rüppel
Technical University of Darmstadt, Darmstadt, Germany

Introduction

The construction industry is characterized by heterogeneous data sources (Cisterna & Haghsheno, 2024), including Building Information Modeling (BIM) models, technical standards, and various project-related documents. Efficiently retrieving information from these disparate sources remains a major challenge. Recent advances in Large Language Models (LLMs), particularly through Retrieval-Augmented Generation (RAG) (Lewis et al., 2020), offer promising opportunities to address this issue. This work presents an LLM-based multi-agent system (MAS) designed to enhance information retrieval across heterogeneous data environments in civil engineering.

The objective of the proposed system is to process complex user queries, decompose them into subtasks, and retrieve relevant information from multiple data sources using specialized agents and tools. The system follows a hierarchical architecture centered around a host agent. Upon receiving a query, the host agent interprets the request, determines the required data sources, and delegates subtasks to appropriate sub-agents or tools. The retrieved information is then aggregated into a coherent and context-aware response.

To evaluate the feasibility of the approach, BIM models and technical standards are selected as exemplary data sources due to their fundamentally different characteristics. BIM models are structured, dynamic, and project-specific, whereas technical standards are typically unstructured or semi-structured documents, often provided as PDFs and updated less frequently (Borrmann et al., 2021; Wang et al., 2025). This contrast provides a suitable testbed for assessing the system's ability to integrate heterogeneous data types.

Retrieval methods

For technical standards, a classical RAG approach is implemented. Documents are transformed into vector embeddings, enabling similarity-based retrieval of relevant text passages. The retrieved content is then used by the LLM to generate responses. (Lewis et al., 2020; Gao et al., 2023) To improve contextual understanding, document chunks are enriched with hierarchical information derived from tables of contents. This approach balances implementation simplicity with retrieval performance while ensuring traceability of results.

In contrast, BIM models require a different retrieval strategy due to their complex internal structures. The system employs LLM agents that translate natural language queries into tool calls. These tools are provided via the Model Context Protocol (MCP), a standardized interface that enables LLMs to access external functionalities (Anthropic PBC, 2024; Hou et al., 2025; Singh et al., 2025; Ray, 2025). Specifically, MCP servers such as revit-mcp (Revit MCP, 2025) and Bonsai-mcp (Rodriguez, 2025) allow interaction with BIM models in Autodesk Revit and IFC-based environments. The LLM-based model sub-agent autonomously selects and invokes these tools to extract model information.

Multi-agent system architecture

The MAS architecture consists of host agent, standards retrieval tool, and BIM sub-agent (Figure 1). The host agent orchestrates the workflow, while the standards tool performs retrieval from technical documents. The model sub-agent is responsible for BIM-related queries and interacts with MCP-based tools. This modular design enables the integration of additional data sources and retrieval methods, supporting system extensibility.

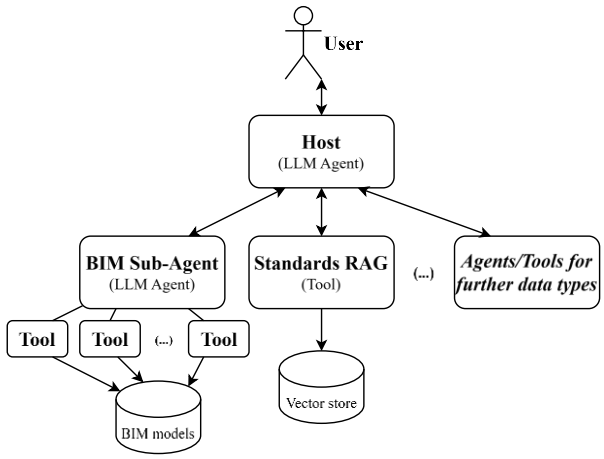

Figure 1: Simplified system architecture

Experiment

As a proof of concept, experiments are conducted using a BIM model in both RVT and IFC formats and selected

standards stored in a vector database. The LLM employed is GPT-4.1, and a zero-shot prompting strategy (Brown et al., 2020; Wang et al., 2021) is used for all agents.

Explorative test cases show that the system can answer complex queries that require combining information from both BIM models and standards. For example, the system successfully determines whether a fatigue analysis is required for a selected structural component by integrating model-specific data with relevant standard provisions.

However, the results also reveal limitations. In some cases, the system produces only partially correct answers due to suboptimal reasoning or incomplete information retrieval. For instance, when identifying applicable standards for model elements, the system fails to infer material properties correctly, highlighting challenges in query decomposition and decision-making.

Discussion, result analysis, and conclusion

While the proposed MAS demonstrates strong potential, its performance depends on numerous design choices, including chunking strategies, prompting techniques, and tool configurations. The use of zero-shot prompting contributes to high agent autonomy but can also lead to inconsistent results. Furthermore, the lack of systematic evaluation limits the ability to quantify performance and compare alternative approaches.

In conclusion, the study demonstrates that LLM-based multi-agent systems can serve as a viable approach for information retrieval across heterogeneous data sources in civil engineering. Even relatively simple system architectures can integrate multiple retrieval methods and provide unified responses. Nevertheless, further research is required to improve reliability, optimize system components, and evaluate performance systematically. Future work should also explore the integration of additional data sources and the combination of multiple retrieval methods per data type. The adoption of standardized protocols such as MCP may play a key role in enabling scalable and interoperable solutions for advanced digital workflows in the construction industry.

FROM CULTURAL DATA TO POLICY NARRATIVE: A SEMANTIC FRAMEWORK FOR URBAN TRANSFORMATION

Hira Ovais, Lavinia Chiara Tagliabue, Silvia Meschini, and Vincenzo Lombardo
Department of Computer Science, University of Turin, Italy

Abstract

Data-driven approaches increasingly inform urban policy, yet the integration of intangible cultural heritage remains limited due to object-centric documentation and the separation of tangible and intangible domains. Existing frameworks conceptualize data as static records, inadequately supporting the semantic articulation of cultural meaning within urban contexts. This paper applies a semantic narrative approach based on a triadic model linking physical elements, procedural knowledge, and social practices. The framework structures heterogeneous cultural data into interpretable relational sequences. Through ecclesiastical heritage in Karachi, Pakistan, the study shows improved coherence between cultural data and policy-oriented interpretation and contributes to knowledge applicable to urban transformation.

Introduction

Approaches to cultural heritage digitization increasingly seek to transform collected information into accessible and meaningful resources by integrating both tangible and intangible heritage dimensions (Lupo, et al., 2023). In urban contexts, heritage is no longer perceived as a static collection of relics but as a dynamic system embedded in community identity and development processes (Ripp & Clifford, 2025). Cultural heritage reflects a synchronized relationship between society, norms, and values, where tangible elements act as expressions of underlying meanings. Within this relationship, intangible heritage provides the broader framework through which tangible heritage acquires significance (Bouchenaki, 2003).

Despite this recognition, urban heritage policies continue to privilege physically measurable assets due to their ease of regulation and conservation within planning systems (Sarihan, 2021). This imbalance is reflected in contemporary documentation practices, where intangible dimensions such as ritual practices, symbolic meanings, and social use of space remain underrepresented (Labrador, 2022).

This limitation is particularly evident in Karachi, Pakistan, where heritage governance has traditionally focused on architectural conservation and monument listing (Naeem, 2013). Existing measures prioritize material condition and stylistic value, offering limited scope to document living traditions and symbolic meanings (Afridi, et al., 2025). Ecclesiastical architecture, as a minority typology, inherently embodies interdependencies between architectural form, ritual practice, and collective memory (Adeboye, 2015).

The paper proposes a semantic, data-driven storytelling approach that models these interdependencies, structuring cultural data into narrative layers aligned with UNESCO ICH domains and semantic heritage standards to support conservation and urban transformation processes (Schmitt, 2008).

Methodology

The study adopts a semantic methodology grounded in the principles of the CIDOC CRM and its architectural extension CRMba, which enable modelling cultural heritage as networks of entities and relationships across time and space (Bekiari, et al., 2021). Building on this foundation, a triadic model is introduced, linking physical elements, procedural knowledge, and social practices as the core analytical unit as shown in Figure 1.

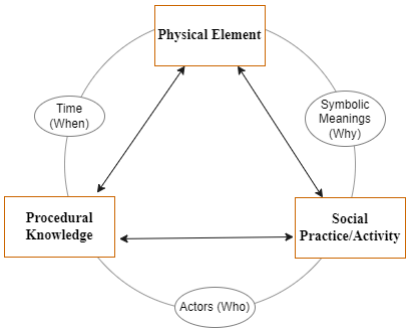

Figure 1: Triadic Semantic Model

The methodological process involves: (1) identifying tangible architectural elements, (2) documenting associated procedural knowledge such as craft techniques, and (3) identifying recurring social practices linked to these elements. These components are semantically connected using CIDOC CRM relationships, forming triadic units that represent tangible–intangible interdependencies. Cultural practices are further categorized according to UNESCO Intangible Cultural Heritage domains.

The structured data is implemented within a digital environment using Omeka-S, enabling navigation across elements, practices, actors, and spatial contexts. The methodology is applied to three colonial-era churches in

Table 1: Relational Matrix of Tangible-Intangible Interdependency

Tangible Element (E24 / CRMba)	Procedural Knowledge (E29)	Social Practice (E7)	Actors (E39)	Spatial Context	ICH Domain
Stained glass window	Glass-cutting and glazing technique	Interpretive viewing during worship	Clergy, visitors	Bay Window	Traditional Craftsmanship / Knowledge & Practices
Hymn boards	Display procedure	Congregational hymn recitation	Priest, congregation	Nave Columns	Oral Traditions

Karachi constructed between 1852 and 1900. Primary data collection included field surveys, photographic documentation, and observational analysis of spatial use, ritual practices, and symbolic interpretation. Among these, Holy Trinity Cathedral was selected as the pilot case due to its continuity of use and concentration of cultural practices.

Results and Discussions

During the investigation at the Holy Trinity Cathedral, tangible architectural features were examined in relation to the practices and procedures through which they acquire cultural significance. As outlined in Table 1, elements such as stained glass windows, hymn boards, the pipe organ, baptismal font, memorials, and carved stonework are consistently associated with recurring activities rather than existing as isolated objects.

Furthermore, the semantic structuring process revealed that tangible–intangible interdependencies may correspond to either a single UNESCO ICH domain or span multiple domains simultaneously, depending on how cultural meaning is enacted and interpreted. The stained glass window exemplifies this multi-domain structuring. It is modelled as an instance of E24 Physical Human-Made Thing, produced through specialized craft procedures (E29 Design or Procedure) aligned with the Traditional Craftsmanship domain. At the same time, its ongoing engagement through theological interpretation and commemorative reading is modelled as E7 Activity, situating the same element within the Knowledge & Practices domain.

In contrast, hymn boards demonstrate a more contained semantic alignment. While also represented as E24, their primary significance lies in facilitating congregational recitation, structured through a display procedure (E29) and enacted as a recurring oral practice (E7), corresponding predominantly to the Oral Traditions & Expressions domain.

The application of this framework demonstrates that semantically structured data can support relational knowledge systems beyond geometric modelling. The implementation in Omeka-S enables data traversal through relationships, supporting interoperability with digital environments and knowledge representation across systems.

Conclusions

A redefined understanding of cultural heritage is advanced by positioning architectural elements within interconnected systems of practice and knowledge through which significance is constituted. The proposed semantic structuring enables cultural data to be interpreted beyond static representation, supporting governance and digitally mediated heritage management. While grounded in a single case and interpretive analysis, the framework establishes a basis for scalable integration within computational environments and broader urban contexts.

PREDICTIVE FRAMEWORK FOR DOMINANT DELAY RISKS IN METALLURGICAL PROJECTS

Shivam Pandey, Sahil Garg
Indian Institute of Technology Delhi, Delhi, India

Abstract

Indian steel and aluminium megaprojects frequently experience multi-year schedule overruns despite detailed planning and risk registers. This paper presents a predictive delay-risk framework that learns from 20 completed projects using contextual similarity and interaction-aware modelling of 39 delay events. Projects are encoded through execution context, while events are represented using normalised delay impacts and a structured dependency network derived from empirical co-occurrence and expert judgement. A prototype tool generates probabilistic completion envelopes and ranked, interaction-aware risk lists for new projects. Initial results align with observed completion behaviour and highlight a small set of high-leverage risks for targeted mitigation.

Introduction

Industrial projects in the steel and aluminium sector continue to experience persistent schedule overruns, often extending several years beyond baseline plans. Although prior research identifies numerous delay causes such as approvals, procurement disruptions, contractor performance, and labour issues, these are typically analysed as independent factors or through isolated case studies.

In practice, project teams rely on schedules, Earned Value indicators, and qualitative risk registers, which do not indicate which risks will dominate or how combinations of risks propagate delays. This limits proactive decision-making and leads to reactive control.

This study addresses this gap by proposing a predictive framework that identifies dominant delay risks and models their interaction using limited but structured historical data.

Empirical dataset and delay structure

The framework is developed using an empirical dataset of 20 completed steel and aluminium projects, including greenfield plants and brownfield expansions. Observed schedule overruns range from moderate (6–12 months) to multi-year delays.

A structured library of 39 delay events is defined, covering approvals, procurement, logistics, execution, and governance-related disruptions. Each event is characterised by its phase and delay impact using triangular estimates. Projects are linked to events through a project event matrix, enabling consistent modelling of delay behaviour.

Methodology

Contextual Similarity Learning

Each project is represented by a context vector including plant type, project nature, capacity, region, climate, and contracting model. Similarity between a new project and historical projects is computed using weighted categorical matching and Gaussian similarity for numerical attributes.

Similarity scores are transformed into normalized weights, ensuring that contextually similar projects exert greater influence on delay estimation.

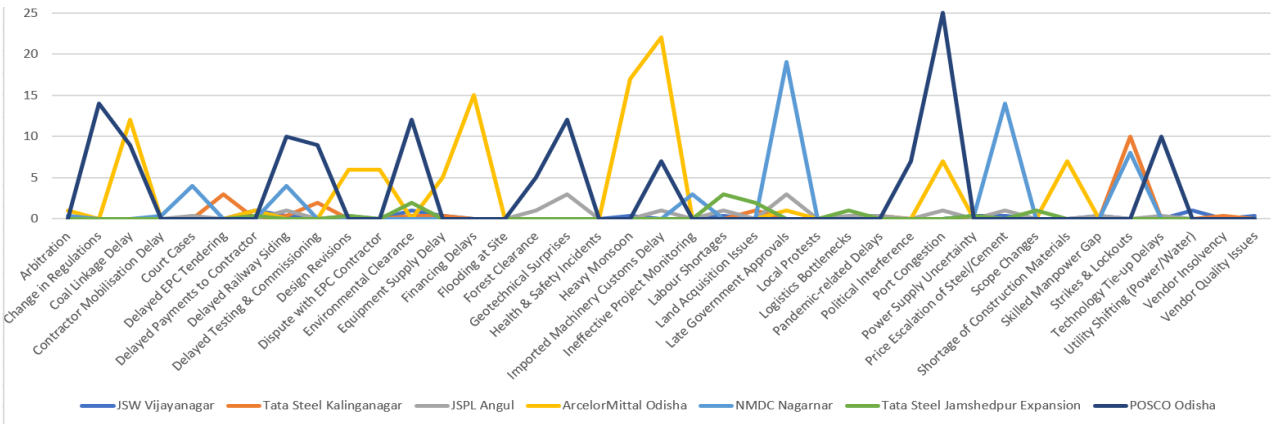

Figure 1: Multi-project delay profile for dominant events showing mean schedule impact (months)

Dominance Estimation of delay events

Delay events are treated as contributors to total delay rather than independent occurrences. For each project, event impacts are normalised to represent their relative contribution to overall delay. For a new project, dominance scores are computed by aggregating these contributions across similar projects.

Table 1: Top delay events ranked by probability, contribution, and mean impact.

Delay events	Probability	Contribution (%)	Mean impact (month)
Price Escalation of Steel/Cement	0.21	8.8	1.04
Shortage of Construction Materials	0.39	8.0	0.94
Delayed Payments to Contractor	0.61	6.6	0.61
Local Protests	0.39	6.2	0.39

Interaction and Amplification Modelling

Delay events are often interdependent. To capture this, a dependency network is defined representing trigger response relationships between events. Amplification factors, derived from empirical co-occurrence and expert judgement, adjust probabilities and impacts of dependent events during simulation.

This enables modelling of cascading effects, where upstream risks propagate across project phases and create clustered delay scenarios.

Predictive Simulation

The model is evaluated using Monte Carlo simulation. Event impacts are sampled from triangular distributions, modified by dependency relationships, and aggregated to estimate total project delay.

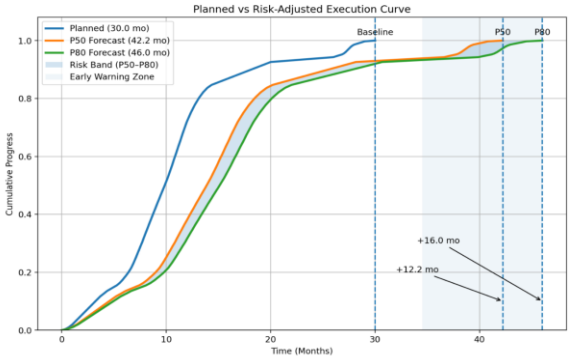

Figure 2: Baseline vs probabilistic completion curves (P50, P80) with risk band

Results and Implementation

The predicted P50 and P80 completion times fall between baseline and actual values, indicating realistic estimation of delay magnitude and uncertainty. Results show that a small subset of risks dominates total delay, while interaction modelling captures cascading effects that produce heavy-tailed outcomes.

The framework is implemented as a Python/Streamlit prototype, generating completion curves, dominant risk rankings, and phase-wise delay insights to support targeted mitigation.

Conclusions

This study presents a predictive framework for delay behaviour in metallurgical projects using contextual similarity, dominance estimation, and interaction-aware simulation. The results show that delay is driven by a small set of dominant and interacting risks, and that modelling these interactions improves realism. The framework enables early identification of high-impact risks, supporting proactive project control.

A SYSTEMATIC REVIEW OF DISTRIBUTED REINFORCEMENT LEARNING FOR BUILDING-TO-DISTRICT ENERGY NETWORKS

Katharina Steib[1], Thomas Ohlson Timoudas[2], and Qian Wang[1]
[1]Department of Civil and Architectural Engineering, KTH Royal Institute of Technology, Sweden
[2]RISE Research Institutes of Sweden, Kista, Sweden

Abstract

Distributed Reinforcement Learning (RL) enables coordinated HVAC control in district energy systems but existing approaches vary in architecture, addressed challenges, and practical feasibility. This review classifies recent studies by distribution level and problem dimensions and uses a research map to identify trends, research gaps, and future directions for practical, privacy-aware, and safe distributed control.

Framework definition for distribution levels

We introduce a framework that categorizes RL approaches in Building Energy System (BES) by distribution level:

- *L0 Centralized Single-Agent RL* [Zhou et al. (2022), Bao and Xu (2023), Ojand and Dagdougui (2022), Ding et al. (2022)]
- *L1 Partially distributed RL with central Coordination* [Qin et al. (2022), Ahrarinouri et al. (2022), Ruan et al. (2023), Huo et al. (2024), Tomin et al. (2022)]
- *L2 Coordinated distributed RL* [Zhang et al. (2025), Miao et al. (2024), Shen et al. (2022), Bo et al. (2023), Zhu et al. (2024), Tomin et al. (2024), Nweye et al. (2025), Rezazadeh and Bartzoudis (2022)]
- *L3 Fully distributed RL* [Pei et al. (2025), Sun et al. (2024), Zhang et al. (2022b), Tariq et al. (2025), Zhang et al. (2022a)]

Problem categorization

We define system-level core problem dimensions, covering challenges from classical HVAC control, limitations addressed by RL, and new challenges introduced by distributed RL: P1 Scalability, system size and complexity; P2 Coordination and communication; P3 Privacy and Data access; P4 Safety, Stability and Constraint satisfaction; P5 Training efficiency, adaptability and generalization.

Comparison using a research map

Table 1 presents a two-dimensional research map of the 22 reviewed studies, organized by distribution architecture and problem focus. Primary and secondary problems are indicated by filled and unfilled circles, respectively.

With the research matrix we identified the following gaps: 1) limited attention to P3–P5, particularly at higher distribution levels; 2) except for Miao et al. (2024), all reviewed studies rely solely on simulation; 3) few L3 studies and no work addressing all five problems simultaneously.

Table 1: Distribution matrix

	P1	P2	P3	P4	P5
L0	○	○	○	○	○
L1	●	●	○	○	●
L2	●	●	○	○	○
L3	●	●	●	○	○

● primary focus ○ secondary focus

Discussion and conclusion

Rezazadeh and Bartzoudis (2022) combines RL and federated learning for privacy-preserving multi-owner districts. Huo et al. (2024) and Sun et al. (2024) propose safe RL for safety-critical HVAC systems. Ruan et al. (2023) uses offline training on historical data to reduce online exploration.

This work reviewed distributed RL for HVAC control in district energy systems. The key takeaways are: 1) Distributed RL enables scalable and coordinated multi-building control; 2) Major challenges remain: privacy, safety, training efficiency, and real-world deployability; 3) studies address only a subset of problems, highlighting the need for holistic, system-level approaches; 4) Future work should focus on integrated architectures and real-world validation under multi-owner constraints.

TOWARDS AUTOMATED BUILDING MAINTENANCE AND RENOVATION: A MULTI-AGENT LLM-BASED APPROACH

Jiaxin Ling[1] and Weiwei Chen[1,2]
[1]University College London, London, United Kingdom
[2]University of Cambridge, Cambridge, United Kingdom

Abstract

This study presents a multi-agent AI framework for automating building maintenance and renovation recommendations. Given inputs such as building location, type, and reported issues, a task identification agent classifies cases as maintenance or renovation. A knowledge agent retrieves and interprets relevant building codes, standards, and guidelines, while a solution generation agent produces maintenance recommendations, renovation strategies, or compliance assessments. By integrating task classification, regulation interpretation, and recommendation generation through large language models (LLMs), the framework automates key decision-making processes traditionally performed by human experts.

Introduction

Europe's building stock is ageing, with over 40% constructed before the 1960s, and the sector accounts for more than 40% of final energy consumption and 36% of greenhouse gas emissions (European Parliament, 2016; Vendel et al., 2025). As a result, the Repair, Maintenance and Improvement (RM&I) sector is identified as a key growth area (Gov.UK, 2025). Building maintenance and renovation are knowledge-intensive processes requiring integration of fragmented information from multiple sources. While digital technologies such as BIM and AR improve data accessibility, they remain largely data-driven and lack the ability to capture and reason over regulations, standards, and expert knowledge.

To address this gap, this study proposes a multi-agent LLM-based framework for maintenance and renovation decision-making. The framework decomposes complex tasks into specialised agents, including task identification, knowledge retrieval, and solution generation. By coordinating these agents, it enables context-aware and structured decision workflows, supporting more intelligent and efficient maintenance and renovation processes.

Methodology

This study proposes a multi-agent LLM-based framework for automated maintenance and renovation decision-making in buildings. Figure 1 presents the workflow of the proposed multi-agent framework for enhanced building maintenance and renovation decision-making.

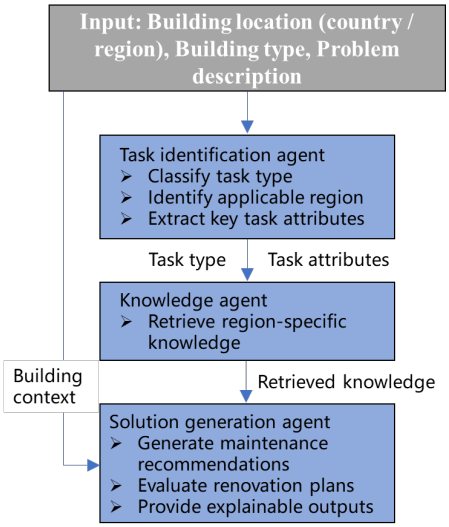

Figure 1: Workflow of the proposed multi-agent LLMs

Case study

The case study focuses on a heritage building located in Poland, originally constructed in 1928. As a historically protected structure, the building presents typical challenges associated with ageing construction, including material deterioration and constraints imposed by conservation requirements.

LLM agent development

The proposed multi-agent framework is implemented using the GPT-4o large language model, which serves as the core reasoning engine for all agents. GPT-4o was selected due to its strong capability in understanding technical text, handling contextual information, and generating coherent and explainable outputs (Dai et al., 2025).

Results

Maintenance recommendation

Table 1 summarizes the outputs of the task identification agent and the solution generation agent for the façade crack maintenance scenario.

Based on these outputs, the solution generation agent produces corresponding maintenance recommendations that prioritise minimal intervention and material compatibility.

Table 1: Maintenance recommendation for façade cracks (heritage building)

Agent	Results
Task identification agent	Task type: Maintenance (façade condition) Context: Heritage building in Poland (likely protected/subject to conservator oversight) Observed issue: Surface cracks + local material degradation on external wall/facade (image-supported) Decision constraint: Minimal intervention, reversible where possible, retain historic fabric; ensure traceability of actions and rationale (documentation)
Solution generation agent	(1) Immediate, low-intrusion actions Condition recording and baseline survey: photo log, crack mapping (location, length, width), and date-stamped documentation before any intervention. Traceability basis: conservation actions should be documented; maintaining best possible condition requires evidence-based monitoring. (2) Heritage-compatible repair measures Localized plaster/finish repair using compatible materials (e.g., lime-based where historically appropriate; avoid hard cement-rich patches that can trap moisture and accelerate decay). If cracks indicate structural instability: prioritize stabilization measures designed to minimize loss of historic fabric (e.g., local reinforcement only where necessary, reversible techniques where possible).

Limitations and Future Directions

Despite the promising results, this study has several limitations. First, the proposed framework relies on the reasoning capabilities of LLMs. Although it's effective for interpreting unstructured regulatory text and contextual information, it does not replace formal regulatory approval or expert judgement. The generated maintenance recommendations and renovation compliance assessments are intended to support early-stage decision-making rather than serve as definitive or legally binding conclusions. In addition, the evaluation is based on a single heritage building case study, and broader validation across different building types, regulatory contexts, and levels of data availability is required to further assess generalisability.

Future work will focus on extending the framework in several directions. Additional case studies across multiple regions and building typologies will be conducted to evaluate scalability and robustness. Moreover, future research will explore tighter coupling between LLM-based agents and quantitative analysis modules, such as structural assessment using numerical simulation or energy performance evaluation, as well as the incorporation of human feedback to support iterative and collaborative decision-making in maintenance and renovation workflows.

Conclusions

This paper presents a multi-agent LLM-based framework to support building maintenance and renovation decision-making, with a focus on heritage buildings. By decomposing complex tasks into specialised agents for task identification, knowledge handling, and solution generation, the approach enables structured and explainable decision support, addressing the challenge of integrating domain knowledge into current workflows.

AN ARCHITECTURAL WORKFLOW DATABASE FOR GENERATING EVIDENCE-BASED HEALTHCARE FACILITIES' DESIGN VIA TRANSFER LEARNING

Julia Zieleniewska[1] and Dimosthenis Kifokeris[2]
[1]Poznan University of Technology, Poznan, Poland
[2]Chalmers University of Technology, Gothenburg, Sweden

Abstract

Evidence-based design (EBD) principles can help overcome legislative shortcomings and long-standing challenges in designing healthcare units. Leveraging these principles through transfer learning can utilize pre-trained knowledge to generate optimal spatial arrangements, yet the dataset-formulating factors remain scarcely investigated. Mixed methods (including workflow analysis and behavioral mapping in an emergency care unit) are employed to generate a highly contextual EBD database. Using four actor flow scenarios, dead zones, nodes, collision points, approximate nursing distances, and zone mapping were identified as key contextual factors. This study contributes to informing design considerations and the contextual training of transfer learning in generative healthcare architecture.

Introduction

The emergency department spatial organization affects patients and personnel. ERs play a key role in healthcare systems (Zieleniewska et al., 2026). Comparing Swedish and Polish ERs reveals certain design factors, which mostly originate from evidence-based design (EBD) (Gawlak and Stankiewicz, 2022).

The information base for architectural factors remains fragmented and difficult to transfer between case studies. Machine learning and data-driven methods were proposed for synthesizing a knowledge base. Study aims to propose an architectural approach including combination of workflow, plan analysis and behavior mapping (Grzywiński et al., 2020; Mahmeen et al., 2024) of selected ER, as a method of generating the basis for transfer learning-assisted design space generation. Transfer learning (TL) can be promising for extracting operational and spatial patterns from existing ER layouts.

Research method and materials

Analyzing ERs enables identification of design patterns and transferable data extraction. Employing mixed methods, a literature review (Pruszewicz-Sipińska et al., 2023) and walkthrough analyses (field observations, staff interviews) (Niezabitowska, 2014) were conducted in four Polish and one Swedish hospital case studies. The case selected in this extended abstract comprises the currently under-construction ER extension of a provincial hospital in western Poland, with a daily admission of 200-300 patients and a capacity of 24-30 beds, which features a combined hospital and ER registration impacting the flow of personnel and patients. Due to confidentiality, the unit's name and location are not disclosed. Workflow and behavior mapping were conducted using ArchiCAD29 on plans and via staff interviews. The 2D plans contributed to flow diagrams and critical point analysis. Combined with focus interviews, this served for behavior mapping, revealing scenarios linking rooms and inter-zone flow, establishing action sequencing. For pattern identification, functional zones (registration, medical, urgent, staff), key users, their roles and behaviors were defined. Study was limited to main patient scenarios (Figure 1): short stay, admission, emergency pathways and personnel maintenance. The next step includes creating a visual pathway for users.

Results

The patient flow is mostly linear, while the staff's is mainly circular. Results stemming from the workflow and behavior mapping were identified (Figure 1):

1. Dead zones:
   a. Niches in the foyer - need to verify actual usage through post occupancy evaluation (POE).
   b. The break room is located close, but outside ER; distances may discourage from regular breaks.
2. Nodes:
   a. Corridor bend connecting the urgent track with the rest of the hospital.
   b. Corridor bend connecting the main corridor and the urgent track, limiting distances and clarifying orientation. Possible paths collisions.
3. Collision points:
   a. One large nurse station; better supervision, may generate staff crowding.
   b. Operational disturbance between procurement staff and transported patients
4. Bottlenecks: Registration, triage, transfer corridor

Mapping clarifies context, revealing processes, scalable factors related in circulation, zoning and visibility:

1. Waiting area for both scheduled and emergency patients (risks: chaos, paths collisions)
2. Larger isolation room without access to exterior area: possible problems in the event of pandemic
3. Single observation area: increased supervision

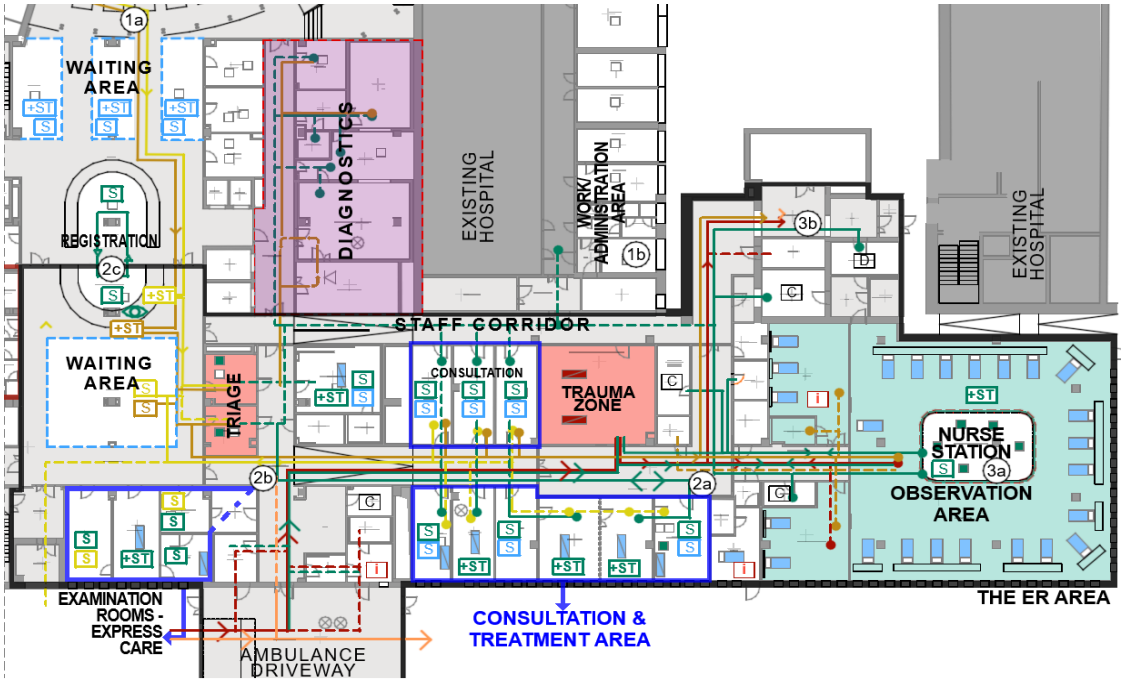

Figure 1: Workflow and behavior mapping (own work). Blue: patients in general; red: urgent patients; yellow: few-hours patients; brown: mild cases; green: personnel; orange: paramedics; navy blue: zones; i: isolation; c: clean storage; d: dirty storage; ST: standing; S: sitting; Alternatives: dashed. lines.

4. Trauma zone nearby observation: quick transfer.
5. Diagnostics located nearby reduce distances
6. Separate express care eliminates unnecessary patient influx into medical zone.
7. Nursing distances: ~38m (staff corridor), ~41m (main corridor, urgent part: ~35m), ~44m (triage to observation room). Communication covers ~26% of the area.

Discussion – transfer learning

Transfer learning may address the limited generalizability of ER layouts, using workflow mapping data as structured input for relational patterns (Khodaee et al., 2024) and decision-making. Mapping methods, coupled with normative knowledge can form a hybrid training dataset for transfer learning: relational determinants compatible with graph-based models, sequence learning, and hybrid-symbolic systems (Rahbar et al., 2022), supporting transferability and replicability.

Conclusions

ERs' spatial organization shapes clinical performance and patient experience. Workflow reveals spatial issues and supports structured data for TL-assisted design.

The main limitation is that ER is under construction. Future studies should include POE using live tracking. Kernel density analysis may support further investigation of contextual factors not examined at this stage.

RGB-D BASED WORK AREA RECOGNITION MODEL FOR FIREPROOFING SPRAY ROBOT

Sangmin Lee, Kangmin Bae, Minseung Cha, Sebeen Yoon, and Taehoon Kim
Seoul National University of Science and Technology, Seoul, Republic of Korea

Abstract

Fireproofing spray on steel structures is essential for fire resistance, yet it is still manual, exposing workers to hazardous and dusty conditions. Robots have been developed to address these issues, but some systems depend on work area map, which limits real time adaptation. In addition, object level recognition cannot provide surface level work areas. Therefore, we propose an RGB D work area recognition model that classifies work area surfaces on a steel structure beam. On experiment, the model achieves a macro average F1 score of 0.8682. Finally, the proposed model provides surface level work area for fireproofing spray robot.

Introduction

Fireproofing spray on steel structures is a required process to secure fire resistance. Because it is frequently performed at height and under dusty conditions, workers can be exposed to safety risks, and spraying quality can vary with worker's skill level.

Fireproofing spray robots have been developed to address these issues. However, some systems depend on offline preparation, where spraying work files are generated from structural design data in advance and the robot operates only after a working area map is created beforehand (Ikeda et al., 2020). Because the work area must be set up before each spraying task and updated when site conditions change, productivity can drop and real time adaptation during spraying remains limited.

To improve real-time adaptation, recent studies use vision sensing to segment steel structures, but results remain at the object level(Zhu et al.,2022). Such object level recognition does not provide surface level work areas for robot spraying.

Therefore, unlike prior approaches that depend on offline work area map preparation or remain at the object level, this study proposes an RGB-D based work area recognition model that classifies five work area surfaces on a steel structure beam for fireproofing spray robot.

RGB-D based Work Area Recognition Model

This study proposes an RGB-D based work area model for fireproofing spray robot(Figure 1).

Data Preparation

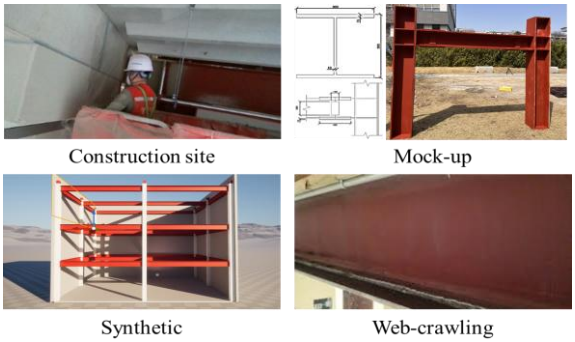

Figure 2: Four types of train dataset

For data preparation, RGB-D videos are recorded during fireproofing spray using an RGB-D camera, and RGB images and depth maps are extracted at 30 fps. Also, a YOLOv11 segmentation model is trained for steel structure beam segmentation using four types of train dataset, with a total of 480 images(Figure 2).

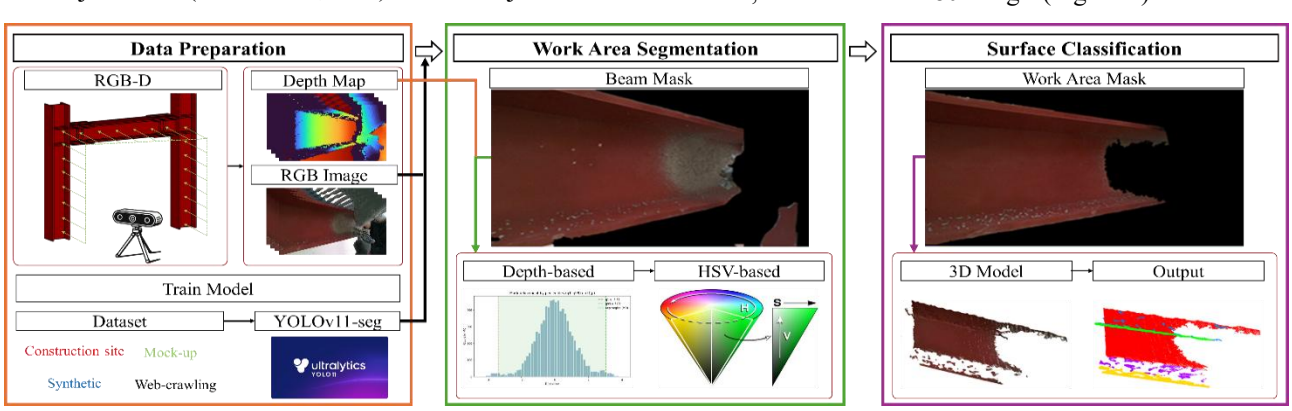

Figure 1: RGB-D work area recognition model framework

Work Area Segmentation

A trained YOLOv11 segmentation model generates an initial mask of the steel structure beam from the RGB image. The mask is refined using the depth map by expanding the boundary and keeping only pixels within the 1st–99th percentile depth range inside the mask. Within the refined region, HSV-based rules separate unworked and worked areas: unworked area is selected by red Hue ranges (0–20 or 160–180) with sufficient saturation and value, while worked area is excluded using low saturation and high value without constraining Hue. The final work area mask is obtained by removing worked area pixels.

Surface Classification

A 3D point cloud is reconstructed from the final work area mask and the depth map. RANdom Sample Consensus(RANSAC; web: thresh = 0.01 m, minPoints = 5000, maxIteration = 4000; flange: thresh = 0.008 m, minPoints = 1500, maxIteration = 3000) iteratively extracts planar surfaces by selecting the plane with the largest inlier set, removing its inliers, and repeating on the remaining points. Density-based spatial clustering of applications with noise(DBSCAN; eps = 0.02, min_points = 10) then clusters inliers on each plane into spatially consistent groups, yielding five classified work area surfaces on the steel structure beam.

Experiment

Experiment was conducted using the setup shown in Table 1, with 51 pairs of RGB image and depth map separately collected for evaluation.

Table 1: Experimental setup

Subject	Medium-density fibreboard((MDF) mock-up beam(H-300×300×10×15)	
Data Acquisition	Sensor	Intel RealSense D455
	View Direction	Same as the spray direction
	Distance	300~600mm
Time of Recording	During fireproofing spray operation	
Data	Resolution	RGB Image 1280×720, Depth map 848×480
	Quantity	51 Pairs of RGB Image&Depth map

Result Analysis

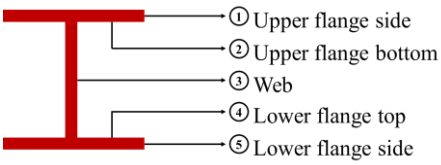

Figure 3: Steel structure beam surfaces

We defined five work surface classes on the steel structure beam, as illustrated in Figure 3. The five surface classification performance was evaluated using precision, recall, and F1-score computed on the 3D point cloud by aggregating outcomes for each class. Overall performance was summarized using the macro average across the five surfaces. Each surface results are reported in Table 2.

Table 2. Experiment results

Surface	Precision	Recall	F1-score	Macro Average
①	0.9992	0.9958	0.9771	0.8682
②	0.8398	0.4995	0.6264	
③	0.9794	0.9238	0.9508	
④	0.9469	0.7385	0.8298	
⑤	0.9758	0.9385	0.9567	

Surface ② showed the lowest recall, likely because one inner flange surface was captured at an unfavorable viewing angle under the current setup. As the camera was positioned approximately perpendicular to the web, the opposite inner flange surface was less visible, resulting in sparse depth points and more difficult surface separation.

Conclusion

This study proposed RGB-D based work area recognition model for a fireproofing spray robot that classifies five work area surfaces on a steel structure beam. It outputs surface level work areas and achieved a macro average of 0.8682 during spraying. Therefore, the proposed model provided surface level work area information for fireproofing spray robot.

However, the experiment was conducted in a controlled environment and did not fully reflect varying site conditions such as illumination changes, dust, and occlusions. Future work will include an ablation study to evaluate the contribution of each pipeline component, improve the model, and validate robot integration for progress monitoring and spray path generation.

Introduction

Human-Data Interaction (HDI) is a transformative research agenda that also represents a critical gap in current digital transformation efforts. Such transformation efforts have produced complex digital ecosystems that raise questions of, *e.g.,* trust, agency, and ethics, but the predominantly technocentric approaches tend to prioritise system performance over human-centric aspects. The Built Environment (BE) is data-rich but insufficiently human-centred in how data are accessed, interpreted, governed, and acted upon.

The HDI Committee, a permanent technical committee of the European Council on Computing in Construction (EC^3), is dedicated to exploring the intricate relationship between humans and data in the BE. It investigates a wide range of topics, including user experience, change enablement, ethical data practices, and technological advancements that enhance our interaction with data. The Committee focuses on fostering dialogue and promoting leadership practices in HDI. It seeks to prioritise HDI-related research and educational initiatives, promoting practical applications across key areas.

Theoretical Foundations

As illustrated in Figure 1, throughout the Built Asset Lifecycle (BAL), humans serve as enablers, decision-makers, and users across various processes. The adoption of advanced digital technologies (*e.g.,* AI-based solutions, robotics, digital twins) has improved the efficiency and effectiveness of work processes while generating vast streams of digital data (Atuahene et al., 2023). In increasingly data-driven systems, it is not only the role of technology that matters, but the ways in which humans engage with the data these systems generate, transform, and act upon.

HDI addresses this gap by highlighting how users interact with digital data, focusing on access, interpretation, action, and ethical management in everyday tasks. Mortier et al.'s (2014) seminal paper identified the three foundational pillars of HDI (*legibility*, *agency*, *negotiability*) within the wider context of information systems. With the aim of adapting these pillars to the context of the BE's digitalisation, recent scholarly contributions (Li et al., 2024) have unpacked them to derive operational dimensions, including *trust, human empowerment, safety, understanding, and privacy*. These dimensions, grounded in BE research, can be linked to these pillars to establish overarching principles for HDI tailored to digitalisation efforts across BAL. Taken together, this theoretical direction aims to reinforce HDI's relevance in settings where digital solutions are technically developed (*e.g.,* requirement gathering and analysis) and/or implemented to inform individual decisions and behaviours across BAL.

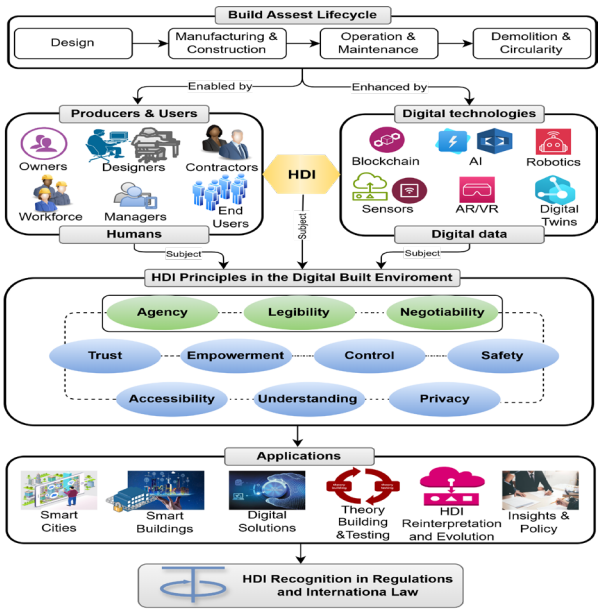

Figure 1: HDI Principles in the BE

From an enabler perspective, HDI emphasises that those managing change, through platform configurations, standards, and workflows, enhance data's findability, interoperability, and trustworthiness, shaping conditions for effective and responsible use. From a decision-maker perspective, HDI highlights the importance of timely, clear, and ethically governed data for evaluating trade-offs and making lifecycle decisions.

The overarching aim of HDI in the BE is to develop theoretical foundations while extending its applicability across diverse contexts. Contexts include smart cities, global policy development, and the reinterpretation of HDI principles in relation to cognition-driven intelligent systems like generative AI and autonomous DTw.

Committee's Contributions

HDI is a vital framework for understanding user-data relationships throughout the BAL within the context of computing in construction. Committee members contribute to knowledge dissemination through multiple scientific papers and outreach activities through engaging with and supporting all EC[3] conferences, delivering knowledge through presentations, track sessions, and discussions on computing in construction.

In September 2024, the Committee launched its premier webinar introducing HDI in the BE, featuring presentations on HDI theory, generative AI, intelligent environments, and industry-academia collaboration. The Committee's White Paper (Kassem and Kifokeris, 2024) serves as a *Call to Action*, establishing HDI as a central research domain that unifies various interaction models under a human-centred approach. This *Call to Action* illustrates the shift from data as a neutral concept to understanding how data is constructed, interpreted and contested across stakeholders.

Committee members have collectively advanced theory and application through research. Li et al. (2024) developed an HDI theory for construction contexts incorporating trust, empowerment, safety, accessibility, and understanding, alongside the three pillars of HDI. Li et al. (2023) examined the implications of HDI for blockchain implementation, highlighting how stakeholder interactions shape immutability, transparency, and governance. Calvetti et al. (2023) proposed maturity levels for HDI in Digital Twins (DTw), also emphasising HDI's role in electronic performance monitoring at sensored construction sites, addressing data ownership and GDPR compliance (Calvetti et al., 2021, 2024). Rogage et al. (2025) highlighted the need for responsible data practices to manage the data carbon footprint in construction. Kifokeris (2025) explored HDI's potential to transform regenerative building production processes. Saif et al. (2025) advocated for sociotechnical approaches in DTw that balance technology with stakeholder engagement. Lastly, Munir et al. (2025) identified gaps in HDI strategies concerning sustainability and social good to drive purposeful digital implementations. Collectively, these contributions provide a foundation for future research to further integrate HDI into scalable, responsible, and human-centred digitalisation across the BE.

GENERATING IFC-BASED THERMAL MODELS FOR INDUSTRIAL FACILITIES

Adolfo Sánchez, Eduardo Adán, and Antonio Adán
Department of Electrical Engineering, Electronics, Automation and Communications
University of Castilla La Mancha. Spain

Abstract

Recent LiDAR-based technologies provide accurate geometric data of indoor scenes and facility interiors (e.g., factories, halls, or large rooms), which can be processed to obtain standard BIM models in various formats, resulting in a basic digital twin of the environment. A step beyond conventional digital twins is the creation of scene models incorporating dense thermal information at a given time. This study proposes a methodology to generate BIM models of building interiors in IFC format, embedding temperature as a property of each architectural or functional element.

Introduction

Although multiple studies have reported the generation of 3D thermal maps using digitization systems that include one or more infrared cameras (Ramón, Adán and Javier Castilla, 2022), existing work on indoor environments has so far been limited to floor-level representations (essentially multiple rooms connected by corridors) in the resulting thermal point clouds (Collins et al., 2024). Autonomous robotic systems (Adán, López-Rey and Ramón, 2023) and UAV-based platforms (Zhang et al., 2023) capable of thermally digitizing parts of building interiors and exteriors have also been proposed; however, most of these systems fail to generate fully omnidirectional thermal models covering the entire visible surface of the environment.

Research on thermal digital twins is still very limited, particularly at the scale of an entire building floor. Studies addressing the generation of standard IFC formats enriched with temperature properties did not appear until 2026, as reported in (Ramón-Constantí et al., 2026), which can be considered an initial contribution in this field. In that work, a process was designed to generate an open IFC file in which average surface temperatures were embedded as native properties of architectural elements of a curtain wall.

Methodology and experimentation

The proposed methodology in our study is structured into three phases, as shown in Figure 1(a). In the first phase, an omnidirectional thermal point cloud of the environment is acquired using a LiDAR-based sensing platform referred to as MoPAD. In the second phase, an engineer or architect models the interior space using an appropriate modelling tool. Finally, in the third phase, the results of the two previous stages are integrated by associating a temperature value with each structural element, all within an open standardized format widely used in the AEC domain, namely IFC (Industry Foundation Classes). This poster is specifically focused on this third integration phase. In turn, the creation of the Thermal-IFC model comprises three main steps, which are summarized as follows. 1) Extraction of the coordinates of the centroids and vertices of each geometric element contained in the IFC file; 2)

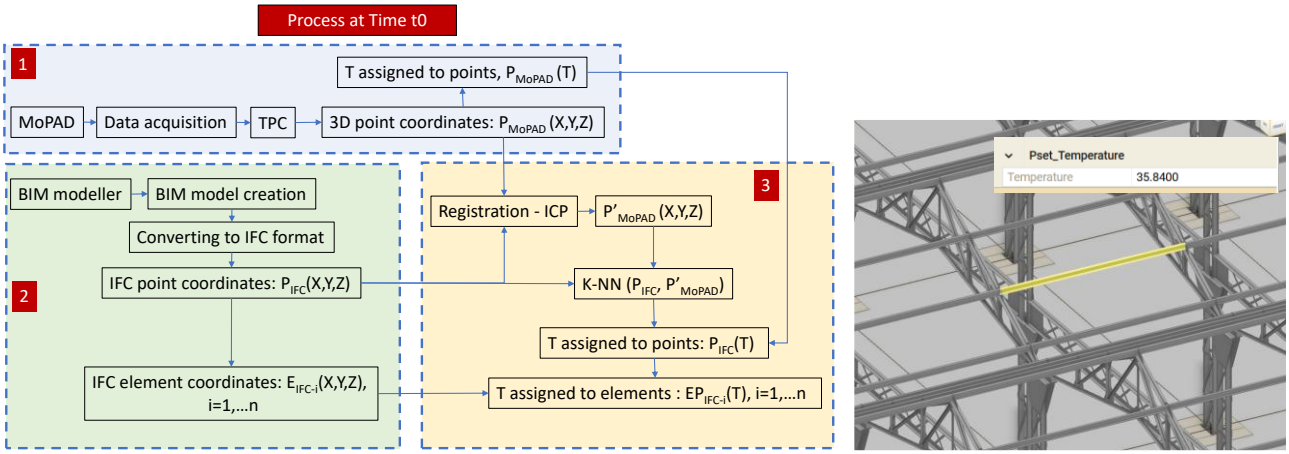

Figure 1: a) Flowchart of the proposed methodology, illustrating its three main steps. b) Steel load-bearing structure. Detail of a steel bar with a highlighted region showing the measured temperature

Assignment of temperature values to the elements through automatic registration between the element vertices and the thermal point cloud; 3) Generation of the IFC file by integrating temperature attributes into the corresponding elements. The two basic algorithms used in the step 2) were the ICP (Iterative Closest Point) algorithm for point registration between those captured by the digitising platform and the vertices of the elements in the IFC file, and the k-NN (k-nearest neighbours). The ICP algorithm yielded a registration RMSE below 2 cm.

This methodology has been successfully tested in various indoor environments (buildings, industrial halls, boiler rooms, etc.). As a representative high-complexity case study, the poster presents results from a large industrial hall (39 × 88 × 10 m) containing 10,377 IFC elements, each assigned a temperature value. The resulting thermal IFC model was successfully visualised in BIM platforms, enabling thermal behaviour analysis. Temperature calibration relied on a contact sensor (0.5 °C accuracy), ensuring a final temperature error below this threshold. Figure 1(b) illustrates the generated thermal IFC model.

Conclusions and contributions

This work presents a practical and scalable methodology for embedding dense thermal information into IFC-based BIM models by automatically associating temperature data with architectural elements, enabling enriched thermal digital twins. Validation in large-scale indoor environments demonstrates its applicability to real-world scenarios and its potential for energy analysis and building performance assessment in the AEC domain.

Since temperature in IFC models is inherently temporal, as it corresponds to a specific time instant, the proposed approach can be understood as a temporal digital model suitable for applications such as thermal monitoring and indoor thermal simulation.

The main contributions of this work can be summarized as follows:

- This study advances the integration of thermal models within the construction context, improving the efficiency of previous approaches.
- The proposed integration method is automatic and accessible to AEC professionals, without requiring specialized computer or programming skills.
- The resulting thermal IFC models can be directly used by AEC professionals to analyse building thermal behaviour, supporting energy efficiency and occupant comfort assessment.

A Self-Verification Framework Toward Reliable Text-to-BIM Generation

Tobias Sesterhenn[1], Bharathi Kannan Nithyanantham[2], Stefan Lüdtke[2], and Christian Bartelt[1]
[1]Institute for Software and Systems Engineering, TU Clausthal, Germany
[2]Institute for Visual and Analytic Computing, University of Rostock, Germany

Abstract

Recent advances in generative AI have enabled Text-to-BIM systems that generate building models from natural-language prompts; however, these systems typically lack automated verification, requiring manual inspection and iterative error correction. To improve the reliability of LLM-generated BIM outputs, we propose a Text-to-BIM workflow with integrated self-verification. For each prompt, the system derives two complementary validations: an Information Delivery Specification (IDS) for rule-based checking, and LLM-driven code-based verification for requirements beyond IDS. The resulting feedback is used to refine the IFC model in a closed loop. The framework is implemented and evaluated through a case study, demonstrating improvements in model quality.

Introduction

Text-to-BIM systems generate Building Information Models (BIM) from natural language instructions (Deng et al., 2025), but despite their capabilities, current approaches lack a task-specific self-verification component that ensures the final BIM model actually meets the request of the human user. For example, Text2BIM (Du et al., 2026) includes a rule-based model checker, but all checks are predefined and may lose task-specific requirements. Consequently, users must manually inspect IFC models and iteratively correct deviations, limiting reliability and scalability of such systems.

To address this, inspired by self-verification (Gou et al., 2024), we propose a closed-loop, LLM-assisted Specification-Modification-Verification framework. For each prompt, a *Specifier* agent derives two complementary specifications: (i) an automatically checkable Information Delivery Specification (IDS) encoding all formally verifiable, schema-level constraints, and (ii) a higher-level specification capturing semantic and contextual requirements that are evaluated by a *Verifier* agent. This allows a *Modifier* agent creating a BIM model to iteratively receive automated feedback by the *Verifier*, to finally output a model that meets the given specification. Our contributions are as follows:

- A fully automated Text-to-BIM framework with integrated self-verification.
- A novel Text-to-IDS module that turns natural-language requirements into valid IDS constraints.
- A simple case study demonstrating the framework.

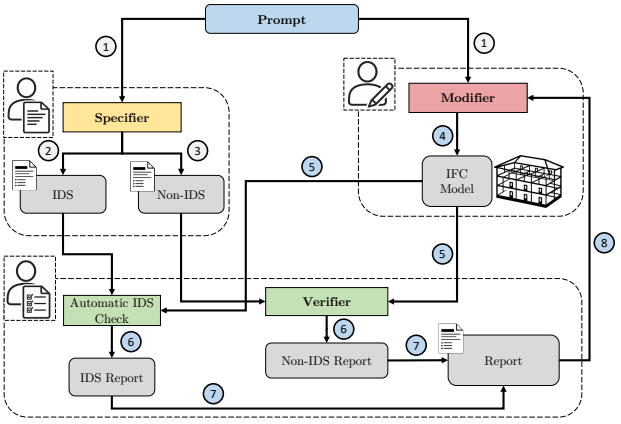

Figure 1: The Modifier-Specifier-Verifier Framework. Steps 4-8 are colored blue to indicate they are repeated in each iteration of the Modifier-Verifier Loop. The Specifier is only required in the first iteration to produce the specification documents.

Framework

As shown in Figure 1, the framework coordinates three agents – the *Specifier*, *Modifier*, and *Verifier* – within a closed-loop architecture to translate a user's design prompt into an iteratively refined IFC model. Given a human prompt (①), the *Specifier* Agent derives two complementary artifacts: (i) an IDS document encoding all formally expressible, schema-level requirements (e.g., properties, simple relations) (②), and (ii) a less formal non-IDS specification capturing constraints that cannot be represented in IDS form, such as geometric, topological, or complex relational conditions (③).

The *Modifier* Agent generates and iteratively updates an IFC model based on the prompt and – in following iterations – subsequent feedback (④). In each iteration, validation on the current IFC model is then performed at two levels (⑤). An automated IDS checker evaluates the model against the IDS document, producing an IDS Report (⑥). In parallel, the *Verifier* Agent operationalizes the non-IDS specification by generating and executing custom verification code (i.e., programmatic checks over the IFC structure), also producing a report. Both reports are consolidated into a unified feedback report (⑦), which is returned to the Modifier Agent to guide model revision (⑧). The loop continues until the IFC Model satisfies both the formal IDS constraints and the non-IDS requirements, or until

a predefined iteration limit is reached.

Case Study

To demonstrate the framework, we conduct a case study using the prompt: *"Create a simple but realistic house, 4 rooms per level, 2 levels, made out of wood. The roof should be a gable roof."*[1]

We use GPT-5.2 for five iterative refinement cycles. The *Modifier* and *Verifier* agents are equipped with a toolbox based on MCP4IFC (Nithyanantham et al., 2025), enabling iterative programmatic IFC model construction and querying. Concretely, both agents can interact with a python interpreter and run code using either available functions from the toolbox (e.g. `create_wall()`) or by writing own `ifcopenshell-python`[2] code. In each iteration the agent is allowed to make multiple tool calls and to incorporate the results into its reasoning process, as formalized by the ReAct framework (Yao et al., 2022). Automated IDS validation is performed using the open-source `ifctester`[2] implementation.

As illustrated in Figure 2, the system progressively resolves detected violations. For instance, the IDS requirement of eight `IFCSpace` entities fails in Iteration 1 and is satisfied by Iteration 3. Similarly, the geometric verification of the gable roof initially fails and is corrected by Iteration 3, together with the assignment of the material attribute "*Timber*" to relevant wall and slab elements. By Iteration 5, the roof geometry and overall building envelope are further refined.

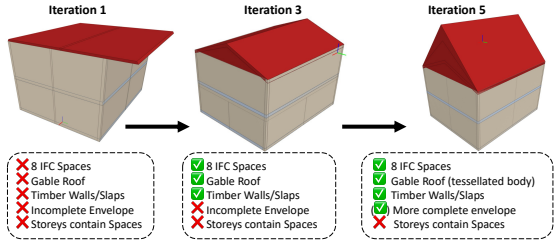

Figure 2: Iterative refinement in the case study. The boxes indicate compliance with individual IDS and non-IDS requirements at each iteration of the self-verification loop.

Discussion

The case study provides a proof of concept for the proposed framework; however, a comprehensive evaluation is required to assess its robustness and generalizability. In the presented experiment, several limitations became apparent. For instance, the system exhibited difficulties in reliably deleting existing elements and failed to resolve certain constraint violations across iterations, such as the missing relationship between the eight `IFCSpace` entities and their corresponding `IFCBuildingStorey` elements. Moreover, complete coverage of all formal and non-IDS requirements during specification generation cannot be guaranteed, and any errors or omissions at this stage directly impact subsequent validation and refinement.

Conclusion & Future Work

We presented an agent-based Text-to-BIM framework centered on self-verification. For each prompt, the system derives checkable constraints and leverages automated feedback to iteratively revise the IFC model until detected violations are minimized or resolved. The simple case study suggests that this specification-modification-verification loop improves model quality and reliability, while also highlighting the need for further evaluation and refinement to ensure robustness and broader applicability. Future work should therefore focus on systematic evaluation and strengthening of the individual agents. The *Specifier* agent could be assessed through a dedicated Text-to-IDS benchmark to measure completeness and correctness of constraint extraction. The *Verifier* agent may benefit from integrating deterministic geometry and topology checks to reduce reliance on purely reasoning-based validation. In addition, hybrid validation strategies should be explored, combining LLM-generated specifications with predefined or human-authored rule sets to improve reliability.

INTEGRATING PARAMETRIC MODELING, COMPUTER VISION, AND MIXED REALITY: REAL-TIME QUALITY CONTROL IN CRAFTSMANSHIP

Simon K. Hoeng, Christoph J. Holzfurtner, Anne-Sophie Saffert,
Florian Weininger, Thomas Linner and Mathias Obergriesser
Ostbayerische Technische Hochschule Regensburg, Regensburg, Germany

Abstract

European craftsmanship suffers from shrinking apprenticeships and skill shortages while project demands continue to grow. High tech, hands on workflows can both modernize existing practices and renew interest among potential future workers. We present and evaluate an end-to-end framework that couples Parametric Modeling, Artificial Intelligence (AI) in the form of Computer Vision (CV), and Mixed Reality (MR) to support real time assistive quality control in stone paving, serving as a representative, under-digitized craft domain. The work also demonstrates how the core CV pipeline can be embedded in a course format for students or craftspeople to cultivate practical AI skills, highlighting the demand for high-tech integration in craftsmanship and related education.

Background and Motivation

As the European construction sector progresses toward Construction 4.0, it faces severe labor shortages driven by an aging workforce and a demographic decline in available apprentices (Brucker Juricic et al., 2021). Concurrently, the industry struggles to attract and retain young professionals, often due to a disconnect between modern digital ideals and traditional working conditions. Recent research identifies educational reform and innovative teaching methods as the strongest factors in improving the sector's career attractiveness (McDonough, 2026) In parallel, automated construction inspection and progress monitoring has been widely identified as a promising means improve reliability in quality control, with computer vision emerging as a core enabling technology (Samsami, 2024). Prior construction research further shows that AR/MR systems are well suited for contextual, task-level guidance at the point of work (Asmar et al., 2021). Together, these findings motivate the integration of CV-based inspection with mixed reality feedback in this work, enabling quality-related information to be communicated directly in the worker's field of view under controlled conditions. Consequently, embedding assistive technologies like AI and MR into manual trades is not merely a technical upgrade, but a strategic way to modernize curricula and secure a future-ready workforce.

Method: Interconnected Technologies

This work demonstrates a closed loop framework for quality control in paving that links the digital model and real-world status: (1) a parametric as planned model encodes per stone geometry and rotations; (2) a real time instance segmentation pipeline infers as built stone states from a monocular video stream; (3) QR based registration maps pixel detections into model coordinates via homography; (4) deviation metrics (position/rotation) are computed against tolerances and the model is updated; (5) MR overlays communicate per stone status and deviation to the worker. The framework is validated in a controlled experiment setting and embedded in an academic course to generate labeled data, train models, and test the pipeline.

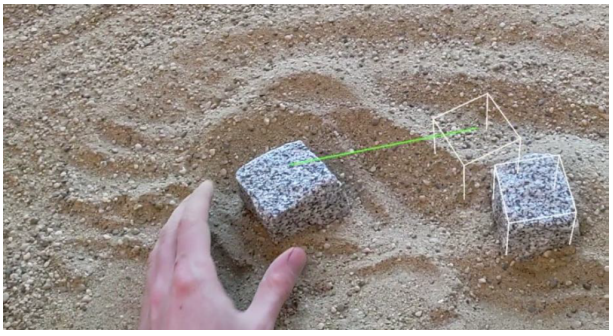

Figure 1: View through MR device view with AI-based guidance

Experimental Setup and Workflow

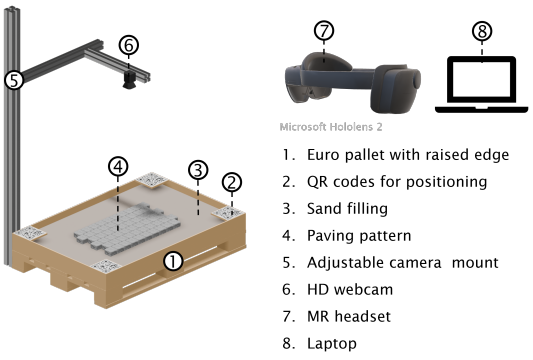

Figure 2: Schematic laboratory setup

The experimental setup consists of a portable paving box with sand bedding mounted on a Euro pallet, a consumer grade HD webcam, and a standard work laptop that hosts both the AI and the parametric pipeline; MR output is streamed to a MR-Device (HoloLens 2) over WLAN. The planned paving pattern is authored in Rhino 8 with Grasshopper as a data driven parametric model in which each stone is assigned an ID, Cartesian coor-

dinates (X, Y, Z), and rotations (Rx, Ry, Rz). Within this environment, Grasshopper components structure the input and output, perform perspective rectification, compute tolerances, and drive MR materials and state logic so that feedback appears immediately in the headset. For execution, a YOLOv11n seg model tracks stones (centroid, Z rotation) via a custom Python script, streaming results to Grasshopper. Four corner QR markers establish a 2D homography, allowing the system to map these video detections to model coordinates and compute deviations against the planned pattern. Finally, Fologram on HoloLens 2 visualizes this feedback, overlaying per stone status (e.g., position/rotation error) and providing interactive controls for the worker to adjust tolerances or reset the workflow.

Educational Integration

The framework was embedded in an academic course in which master's-level civil engineering student teams produced labeled datasets and trained vision models for the demonstrator. The course exposed students to the full CV pipeline, including data acquisition, labeling, training/validation, and deployment. By experimenting with different labeling strategies, including synthetic data, students generated multiple individual vision models as well as a shared dataset enabling more robust combined model training. This approach enables scalable training data generation while illustrating the practical steps required to apply CV methods in a traditionally low-tech craft.

Demo-Test and Results

The integrated setup was tested in a laboratory setting by a small group of experienced paving professionals using the full technology stack, including live CV inference and MR feedback. Under these controlled conditions, the pipeline achieved interactive update rates, providing stable 2D position feedback within centimeter-level tolerances for most stones. The configuration was considered sufficiently realistic to serve as a viable demonstrator for high-tech assistive tools. The combined use of parametric modeling, AI-based instance segmentation, and mixed reality was considered suitable for addressing a central challenge in paving: placing stones precisely while maintaining the intended pattern. A more comprehensive study with rigorous scientific evaluation is planned.

Discussion and Conclusions

The prototype demonstrates that real time 2D position control is feasible with low cost, readily available hardware; coupling a parametric model with AI in Grasshopper provided a transparent logic, and MR made tolerances legible directly at the point of work. At the same time, rotation estimates were not yet robust, QR markers were sensitive to dirt and glare, and tracking stability degraded under occlusions, which are limitations that could surface on real construction sites. Planned refinements include more reliable rotation cues, ruggedized relief markers, multi camera views, and the addition of depth sensing (e.g., LiDAR) to progress toward full 3D quality assurance and a more formal evaluation in follow up studies. This work contributes (i) an end-to-end, reproducible Parametric-CV-MR pipeline for craft scale quality control built on widely accessible tools, (ii) a didactic blueprint that can be adapted from a semester course to compact workshops and transferred beyond paving to related crafts, and (iii) an experimental setup to further investigate empirical evidence to clarify current strengths and gaps, providing a concrete roadmap toward field ready systems in under-digitized crafts.

CATEGORIZING RECURRING TASKS FOR FASTER AND CONSISTENT EMBODIED CARBON ASSESSMENTS

Eleni Alexandraki[1], Giulia Scagliotti[1], Calvin Kam[1, 2], Joy Li[2], and Martin Fischer[1]
[1]Stanford University, Stanford, Unites States of America
[2]Strategic Building Innovation (SBI), Palo Alto, United States of America

Abstract

Embodied carbon (EC) assessments are slowed by fragmented information handover, requiring extensive information-retrieval effort. This study decomposes EC workflows for windows across four building projects by categorizing recurring life cycle assessment (LCA) tasks. Results show that 71-81% of tasks involve data extraction and data wrangling rather than requiring EC expertise. Standardized EC property sets and consolidating data into one information source could reduce EC workflow tasks by 41-67%, improving assessment speed and consistency.

Introduction

The absence of standardized information handover slows embodied carbon (EC) assessments, despite rising demand driven by EC regulations (One Click LCA, 2022).

To complete an EC assessment, Life Cycle Assessment (LCA) specialists refine the Bill of Quantities (BoQ) and compile additional LCA-relevant information (Tam et al., 2022). This involves substantial effort in information-retrieval tasks such as data extraction (Matillion, 2024) and data wrangling (Wickham, 2014), often requiring consultation of multiple sources, including Building Information Models (BIM), 2D drawings, and project stakeholders (Scagliotti & Fischer, 2025).

Existing standards provide high-level guidance on BIM-based information management (ISO, 2018) and building LCA (Papakosta & Sturgis, 2017). Nevertheless, no standards developed from the LCA specialist's perspective define the LCA-relevant information that architecture, engineering and construction (AEC) stakeholders should provide for each building component (Abdelaal & Guo, 2022). Furthermore, the success of BIM to LCA data exchange through standardized file formats, such as Industry Foundation Classes, depends on whether the models have been properly enriched with LCA-relevant information (Theißen et al., 2020).

Given these insufficient requirements, it is necessary to determine what information should be included in the BIM (Guntermann et al., 2025). This study decomposes the EC workflow LCA specialists follow by categorizing the tasks completed, measuring their recurrence, and deriving LCA-relevant information in the case of windows. Establishing this building component information as a BIM requirement for AEC stakeholders would improve information handover and enable faster, more consistent EC assessments.

Methodology

To better understand where LCA specialists expend the most effort and why, we conducted cradle-to-gate EC assessments for windows in four residential projects, ranging from single-family houses to low- and high-rise multifamily buildings. We selected windows as a representative component because they are a carbon intensive element of the building envelope and are present in all residential buildings.

We systematically decomposed EC assessment workflows by analyzing recurrent LCA tasks and grouping them into three categories: (1) data extraction; (2) data wrangling; and (3) impact factor search and assignment. Each category includes several tasks typically performed by LCA specialists, leading to a total of 17 (A-Q), as shown in Figure 1.

Figure 1 shows the LCA tasks required to complete an EC assessment for windows in four projects. For example, in Case Study 1, out of 30 tasks, the LCA specialist requested five clarifications from the project team (data extraction) and performed six simple calculations (data wrangling). We hypothesize that many such tasks could be avoided through standardized information handover, enabling LCA specialists to focus on core activities, such as assigning environmental product declarations (EPDs).

Case Study Results and Discussion

Decomposing the EC assessment workflow for windows revealed that most LCA tasks revolve around creating or enriching a BoQ and do not require EC expertise. As shown in Figure 1, data extraction accounts for 24-30% of total tasks, while data wrangling represents 43-56%.

In contrast, tasks requiring genuine EC expertise, such as searching and assigning impact factors, account for only 9%-29% of total tasks. Therefore, AEC stakeholders should improve BoQ information handover, so LCA specialists can focus on tasks requiring their expertise.

Decomposing the EC workflow also revealed the LCA information requirements for windows. Multiple sources (e.g., BIM, 2D drawings) were used to compile the geometric (e.g., dimensions, area, volume) and non-geometric (e.g., number of panes, glass type) properties required for the EC assessment. The reliance on multiple

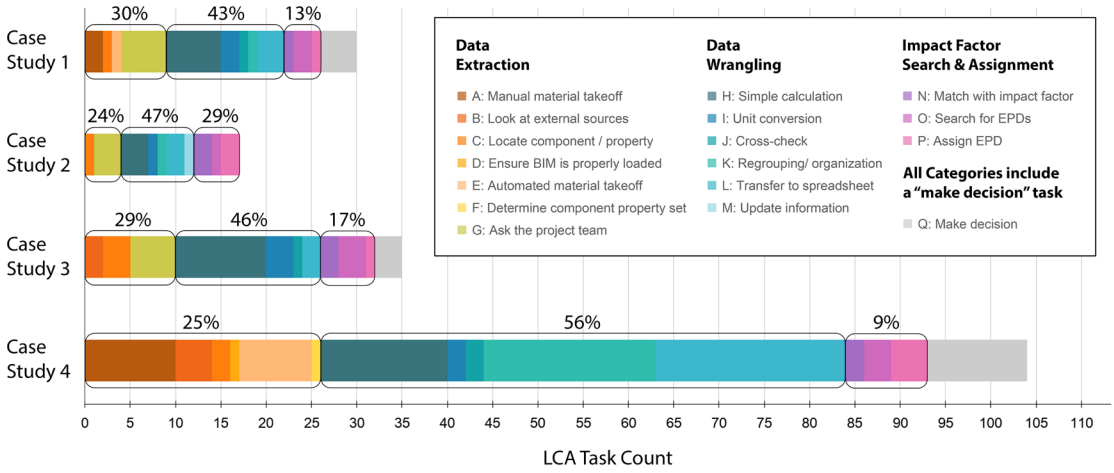

Figure 1: Recurring LCA tasks required to complete EC assessments for windows. Tableau color palette based on Arnold.

sources to retrieve LCA-relevant properties contribute to slower and inconsistent EC assessments.

Improving information handover can make EC workflows faster and more consistent. This can be achieved if project teams (1) have a standardized LCA-specific property set for each building component and (2) consolidate all LCA-relevant information into a single BIM. Building on existing BIM property set definitions (Guntermann et al., 2025), we defined an EC property set for windows. Revisiting the EC workflows for windows, we demonstrated that data extraction and wrangling tasks could be largely eliminated. This approach could reduce total task counts by 41%-67% across the four case studies, significantly streamlining EC assessments.

Conclusions

To make EC assessment faster and consistent, we identified and categorized recurring LCA tasks using windows as a representative building component from four case studies. Future work should extend this method to other components and building types to confirm the effort in data extraction and wrangling for completing EC assessments.

Our results demonstrate that providing completed and standardized EC property sets and consolidating data into a single BIM can reduce LCA task counts by roughly half. By shifting effort from data extraction and data wrangling to impact factor search and assignment, LCA specialists can focus on tasks requiring genuine EC expertise.

THICKNESS SIMULATION WITH KINEMATIC CONSTRAINTS FOR ROBOTIC FIREPROOFING SPRAY

Kangmin Bae[1], Sangmin Lee[1], Minseung Cha[1], Sebeen Yoon[1] and Taehoon Kim[1]
[1]Seoul National University of Science and Technology, Seoul, Republic of Korea

Abstract

Achieving precise thickness is essential for fireproofing performance. Insufficient thickness fails to secure the required fire resistance, whereas excessive thickness causes material waste and rework. This study proposes a simulation framework that combines a Gaussian accumulation model with a kinematic nozzle motion model. As a result of tests on a fixed raster path, kinematic constraints suppressed excess accumulation, increasing the within range area from 87.55% to 91.16% and reducing the over thickness area from 6.83% to 0%. These results show that spray quality should be evaluated using CV with under/over coverage, within range area to help ensure the required thickness.

Introduction

In fireproofing spray, keeping the thickness within the target range is important for both fireproofing performance and material efficiency. If the thickness is insufficient, the required fire resistance cannot be secured and additional repair or rework may be needed. In contrast, excessive thickness causes unnecessary consumption of spray material.

Recent automated spraying research has focused on trajectory generation and velocity optimization for complex free form surfaces (Verduyn et al., 2023; Nieto Bastida and Lin, 2023). However, unlike thin film paint, heavy construction materials such as wet mix shotcrete and fireproofing form thickness differently, and this process is influenced by spray dynamics (Ning et al., 2024). At corners, robot kinematic constraints such as acceleration and deceleration limits can reduce nozzle speed and increase local thickness, but this effect is not directly addressed in macroscale 3D trajectory planning.

This study presents a simulation framework for robotic fireproofing spray and evaluates how kinematic limit scaling near rounded corners affects thickness maps and the area with thickness within the target range.

Methodology

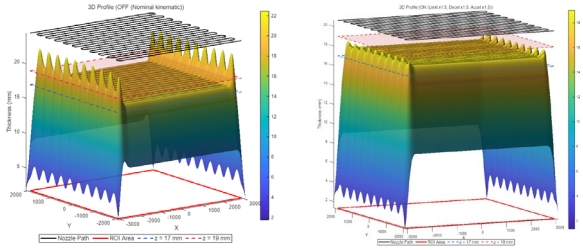
This study develops a thickness simulation with kinematic constraints for robotic fireproofing spray on a planar target surface. A fixed L shaped raster path with rounded corners is used, and the region of interest is evaluated on a 5 mm grid. A single elliptical Gaussian footprint is used for accumulation. The path is resampled at 1 mm intervals for kinematic profiling and 20 mm for accumulation.

This dual resampling balances motion precision with computational efficiency. According to Eq. (1), local thickness is accumulated along the path, with each accumulation contribution determined by the effective flow rate, the Gaussian footprint, and the inverse of the local travel speed.

$$T(x,y) = \int_s \frac{Q\eta}{v(s)} G(x,y,s)ds \quad (1)$$

Two motion settings are compared. OFF uses the nominal kinematic limits over the full path. ON applies corner speed, acceleration, and deceleration scaling of 1.5 near rounded corners. The predicted thickness map is evaluated using mean thickness, CV, under coverage below 17 mm, within range area for 17 to 19 mm, and over coverage above 19 mm.

Table 1: Baseline simulation settings



Parameter	Value	Description
Q	36 L/min	Volumetric flow rate
η	0.90	Transfer efficiency
h	300 mm	Standoff distance
α	30°	Nozzle half-angle
k_σ	0.70	Spread factor
Δ	5 mm	Grid resolution
ROI	6000x4000 mm	Spray region
s_{row}	200 mm	Row spacing
r_{turn}	150 mm	Turn radius
v_{min}, v_{max}	100 ~ 150 mm/s	Speed bounds
$a_{tan,max}$	200 mm/s^2	Tangential acceleration limit
$a_{lat,max}$	200 mm/s^2	Lateral acceleration limit
ds_{kin}, ds_{dep}	1 mm, 20 mm	Sampling steps
Footprint	285.51 mm^2	Calculated spray area

OFF	-	Normal limit
ON	1.5	Kinematic limit scaling factor
Mean	18 mm	Target thickness mean

Results

Figure 1 compares OFF and ON at 150 mm/s, the upper bound of the tested speed range reached in both settings. In the OFF case, ridge like peaks appear near the turn side boundary. In the ON case, these local peaks are suppressed and the boundary profile becomes flatter.

Compared with OFF, ON reduced mean thickness from 17.94 mm to 17.60 mm and increased CV from 5.46% to 6.88%, while over coverage decreased from 6.83% to 0.00% and within range area increased from 87.55% to 91.16%.

(a) (b)

Figure 1: 3D Profile OFF(a), ON(b)

Discussion

OFF shows a lower CV than ON, but ON shows lower over coverage and higher within range area. In ON, over coverage decreases from 6.83% to 0.00%, while under coverage increases from 5.62% to 8.84%, which lowers mean thickness and increases CV. Therefore, CV should be interpreted together with under coverage, within range area, and over coverage, especially near rounded corners.

Table 2: Sensitivity Analysis (ON setting)

Parameter	Variation	CV (%)	Target Range Compliance (%)
Baseline	-	6.88	91.16
k_σ	±10%	6.60 ~ 7.31	91.64 ~ 92.25
η	±5%	6.88 ~ 6.91	91.27 ~ 92.18
Kinematic limit	±20%	6.88 ~ 6.89	91.16 ~ 91.16
Δ	1, 10mm	6.74 / 7.06	91.26 / 90.86

Table 2 summarizes the results obtained by varying k_σ, η, kinematic limit scaling factor and Δ around their baseline values. For the tested variations, within range area remained between 90.86% and 92.25%, and CV remained between 6.60% and 7.31%. Notably, within the speed range specified in this study, no significant changes due to variations in the kinematic limits were observed.

Conclusions

This study presented a thickness simulation with kinematic constraints for robotic fireproofing spray on a planar target surface. The main finding is that kinematic limit scaling near rounded corners reduced over coverage and increased within range area, even though CV increased. This shows that CV alone is not sufficient for evaluating spray quality. Instead, it should be interpreted together with under coverage, within range area, and over coverage. These evaluation metrics can be used to contribute to securing the required fireproofing thickness. Future work will extend the present framework beyond the fixed assumptions used in this study by considering additional flow rates, standoff distances, and model and kinematic parameters. Experimental validation of the predicted thickness maps will also be conducted under practical fireproofing conditions.

RGB-ONLY WORK-AREA RECOGNITION FOR FIREPROOFING SPRAY ROBOT

Minseung Cha, Kangmin Bae, Sangmin Lee, Sebeen Yoon, and Taehoon Kim
Seoul National University of Science and Technology, Seoul, Republic of Korea

Abstract

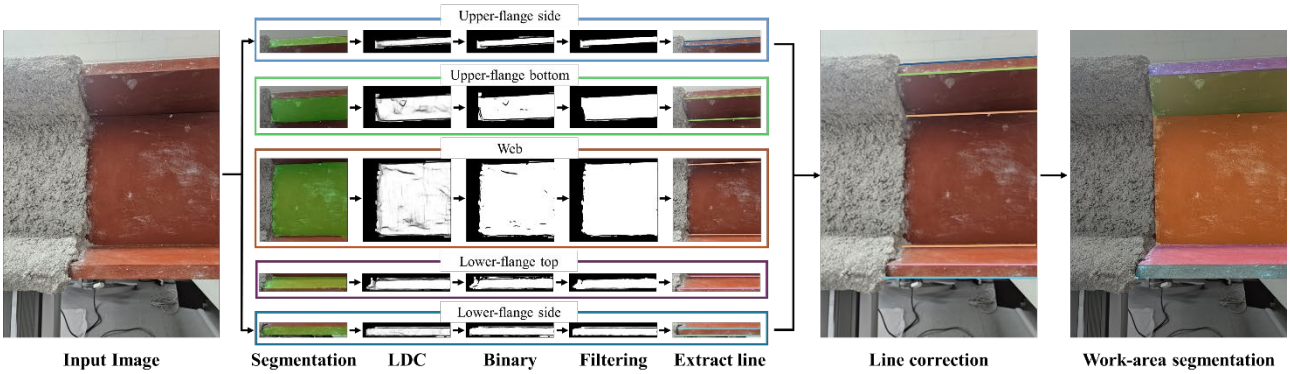
Deep learning–based segmentation is widely used for construction work-area recognition. But it may lead to mask boundary misalignment, degrading work quality in processes requiring precise work-area recognition, such as fireproofing spray. To address this limitation, we present a pipeline for accurate work-area recognition of steel structures. It uses deep learning for segmentation and edge detection, followed by computer vision for line extraction and work-area segmentation. Experiments show mean Intersection over Union (mIoU) gains of 4.47 pp before spraying and 4.51 pp during spraying over the segmentation model. These results indicate our pipeline enables more accurate work-area segmentation.

Introduction

Fireproofing spray is essential for delaying the loss of load-bearing capacity of steel structural members under fire exposure. However, it is still performed manually at height on many construction sites, posing substantial risks due to airborne dust and fall hazards. Accordingly, interest in fireproofing spray robots has increased (Ikeda et al., 2020). For reliable operation, the robot typically needs to know where to spray, which requires accurate work-area recognition. In construction robotics, work-area recognition is often treated as a deep learning-based segmentation task in which predicted masks are used directly for localization and downstream processing (Dung et al., 2019; Wu et al., 2024). However, in fireproofing spray, small boundary misalignment in these masks can degrade work quality. To improve boundary reliability, some approaches combine depth sensing and 3D processing. However, these pipelines typically require additional sensors such as RGB-D or LiDAR, increasing hardware cost (Schmidt et al., 2024). Moreover, a fireproofing spray robot must recognize each surface separately because the spray position and robot pose differ across surfaces such as the web and flanges. Therefore, this study proposes an RGB-only work-area recognition pipeline for a fireproofing spray robot in construction robotics, enabling separate work-area segmentation for each surface of steel structures.

Methodology

Figure 1 illustrates the overall framework of the proposed RGB-only work-area recognition pipeline. First, an instance segmentation model based on YOLOv11m-seg segments a steel structure into surface classes and outputs binary masks (Khanam et al., 2024). Next, for each class, we generate an edge map using a Lightweight Dense CNN for Edge Detection (LDC) model (Soria et al., 2022). Since the extracted edge map is produced in grayscale, we eliminate noise through binarization and contour-length–based filtering. From the refined edge maps, boundary lines are extracted through Random Sample Consensus (RANSAC) based line detection. Because the edge detector responds on both sides of the same physical boundary, RANSAC-based line detection produces a pair of nearby lines for one internal boundary. Therefore, we apply midpoint correction by averaging the endpoints of the neighboring line pair to obtain a single representative boundary line. Finally, the outer boundary lines and the corrected internal boundary lines are used to segment the



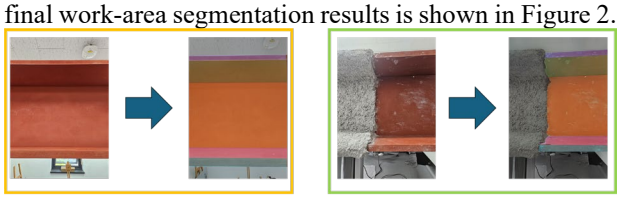


Figure 1: Framework

steel structures into surface work areas. An example of the final work-area segmentation results is shown in Figure 2.

Before spray During spray

Figure 2: Example of the final outputs

Experiment

Preparing Dataset

To evaluate the proposed pipeline, we fabricated a Medium Density Fiberboard (MDF) H-beam mock-up and collected RGB images from viewpoints relevant to robotic operation. A total of 250 images were used for model development, and an additional 20 images were used for quantitative evaluation. The evaluation set included both before-spraying and during-spraying conditions.

Train Segmentation Model

The YOLOv11m-seg model was trained using a 7:2:1 split for training/validation/test. During training, the segmentation classes were defined as five surfaces: Upper-flange side, Upper-flange bottom, Web, Lower-flange top, and Lower-flange side.

Evaluation metrics

Performance was measured using Intersection over Union (IoU) as in (1) and mean IoU (mIoU) as in (2).

$$IoU = \frac{|Prediction \cap Ground\ Truth|}{|Prediction \cup Ground\ Truth|} \quad (1)$$

$$mIoU = \frac{1}{N}\sum_{i=1}^{N} IoU_i \quad (2)$$

Results and Discussion

Table 1 summarizes the quantitative results by comparing the proposed pipeline with the segmentation model. It reports IoU for each of the five surfaces and mIoU averaged across the five surfaces, both before spraying and during spraying.

Table 1: Quantitative results

	Before spraying		During spraying	
	Proposed	Seg.model	Proposed	Seg.model
Upper-flange top	0.8877	0.9125	0.9509	0.9285
Upper-flange bottom	0.9846	0.8950	0.9718	0.9190
Web	0.9931	0.9210	0.9891	0.9274
Lower-flange top	0.9512	0.8988	0.9609	0.9216
Lower-flange bottom	0.9264	0.8923	0.9694	0.9200
mIoU	**0.9486**	**0.9039**	**0.9684**	**0.9233**

The quantitative results show that the proposed pipeline improves work-area recognition compared with the segmentation model. Before spraying, mIoU increases from 0.9039 to 0.9486, an improvement of 4.47 percentage points. During spraying, mIoU increases from 0.9233 to 0.9684, an improvement of 4.51 percentage points. These results indicate that the proposed pipeline enables more accurate separation of surface work areas on steel structures. However, the evaluation was conducted on an MDF H-beam mock-up rather than actual steel structures, and only 20 images were used for evaluation. In addition, the pipeline was sensitive to outdoor shadows, which were sometimes mistaken for structural edges and caused incorrect work-area segmentation.

Conclusions

This study presents an RGB-only work-area recognition pipeline for robotic fireproofing. The proposed pipeline uses deep learning for segmentation and edge detection, followed by line extraction and midpoint-based boundary refinement to derive final surface work areas on H-beams. Experiments on MDF mock-up showed improvements over the segmentation model, achieving mIoU 0.9486 before spraying and 0.9684 during spraying. These results suggest that the proposed method can provide more precise work-area recognition than using the segmentation model alone. Future work will validate the pipeline on actual steel structures under diverse field conditions and improve robustness to edge noise caused by shadows.

ANOMALY DETECTION IN INDOOR ENVIRONMENTAL SENSOR DATA BASED ON A DIGITAL TWIN

Arezoo Fathollahizenooz, Cornelius Preidel, and Simon Vilgertshofer
HM Munich University of Applied Sciences, Munich, Germany

Abstract

Anomaly detection in building sensor networks often relies on static thresholds that fail to capture temporal dependencies and system changes. This work combines a baseline model of expected indoor environmental behavior with anomaly detection to form a data-driven Digital Twin. In this framework, a regression model learns expected behavior from historical data, while deviations are quantified as multivariate residuals and analyzed using unsupervised and semi-supervised methods. Preliminary analysis on a representative campus sensor shows detection of anomalous behavior and associated distributional shifts, with sensor relocation serving as an illustrative system change.

Introduction

Sensor networks are used in modern buildings to monitor indoor environmental quality (IEQ). However, due to the scale of the data, manual inspection is insufficient to detect anomalies. Consequently, research has shifted toward data-driven anomaly detection. Unsupervised and semi-supervised methods are used to detect IEQ deviations without the need for large labeled datasets (Chen et al., 2023; Bi et al., 2024). Although methods such as Long Short-Term Memory can capture complex temporal dynamics, they often lack an integrated analysis of normal system operation (Wei et al., 2022; Rajabi and McArthur, 2023). To address this gap, this work investigates whether DT-based anomaly detection can identify environmental irregularities in indoor sensor data. Residual-based anomaly detection is integrated with a Digital Twin (DT) representing expected indoor environmental behavior, while anomalies are identified as deviations between physical observations and digital expectations, enabling detection of patterns suggestive of HVAC malfunctions or sustained humidity conditions associated with increased mold risk.

Dataset

The proposed framework incorporates indoor environmental data from a campus-wide sensor infrastructure that offers ongoing time-series data from various rooms in university buildings. Temperature, humidity, CO_2 concentration, illumination, and motion are included in the dataset. The possibility of sensor relocation, which adds uncertainty about the spatial context, is an important feature of this dataset.

Digital Twin

The physical layer in DT represents the building space, while sensors measuring indoor environmental variables serve as the interface between the physical asset and its digital representation. The digital layer consists of the recorded time-series data that describe the state of the system. A Random Forest regression model (Breiman, 2001) serves as the analysis component of the Digital Twin, producing predictions $\hat{y}_t = f_{\mathrm{RF}}(\mathrm{x}_t)$, where x_t comprises time-based and lagged features capturing temporal dependencies and non-linear relationships. Hyperparameters (n_estimators = 300, max_depth = 10, min_samples_leaf = 5) are selected with GridSearchCV with 5-fold time-series cross-validation, and the predictive performance is reported using MAE and R^2 on the final 20% of baseline data. This coupled physical-digital representation enables detection of distributional shifts indicative of structural changes, such as sensor relocation, while providing a learned baseline that adapts as system conditions evolve.

Residual-Based Anomaly Detection

Anomaly detection operates on residuals $r_t = y_t - \hat{y}_t$, where y_t are the observed measurements and $\hat{y}_t$ is the DT prediction at time t. Multivariate residuals represent these deviations, enabling identification of abnormal behavior relative to learned expectations. Anomaly detection is implemented using two methods: Unsupervised approaches based on Isolation Forest (Liu et al., 2008) are applied to identify deviations from learned temporal patterns in multivariate sensor data without requiring labeled anomalies. In addition, a semi-supervised setting using One-Class Support Vector Machines (OCSVM) (Schölkopf et al., 2001) is explored. For OCSVM training, domain knowledge determines inlier conditions (20–25 °C temperature, 20–60% humidity), whereas observations outside these ranges are used to assess anomaly-detection behavior.

Results and Discussion

Period segmentation is applied in the initial analysis of a particular sensor (S12) from June to October 2023. Gaps longer than six hours, which are unlikely under normal operations, are used as indicators of potential system disruption and divide the data into baseline (Jun–Jul; 56,738 measurements), relocation/sensor outage (July–October; 5,510 measurements), and post-relocation (October; 3,884 measurements) as shown in figure 1. The trained multivariate DT baseline model exhibits substantial increases

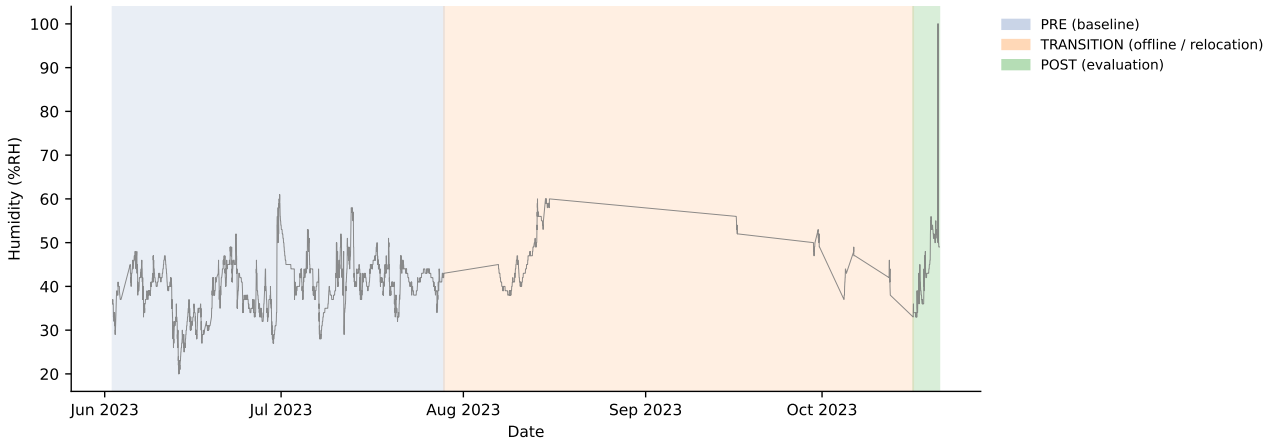

Figure 1: Period segmentation based on sensor gaps

in prediction error in all variables (temperature, humidity, and CO_2) when applied to post-relocation data, confirming a significant shift in distribution. Figure 2 shows this quantitative degradation by a clear shift in the residual distributions across the variables. During the first unsupervised phase of this framework, an Isolation Forest model identified every post-relocation observation as anomalous, indicating a distributional shift. Next, semi-supervised learning methods will be used to enhance the classification of these deviations. Although a representative, operationally stable sensor (S12) is selected from the network of 82 sensors to illustrate the framework, extension to the full sensor network is part of ongoing work.

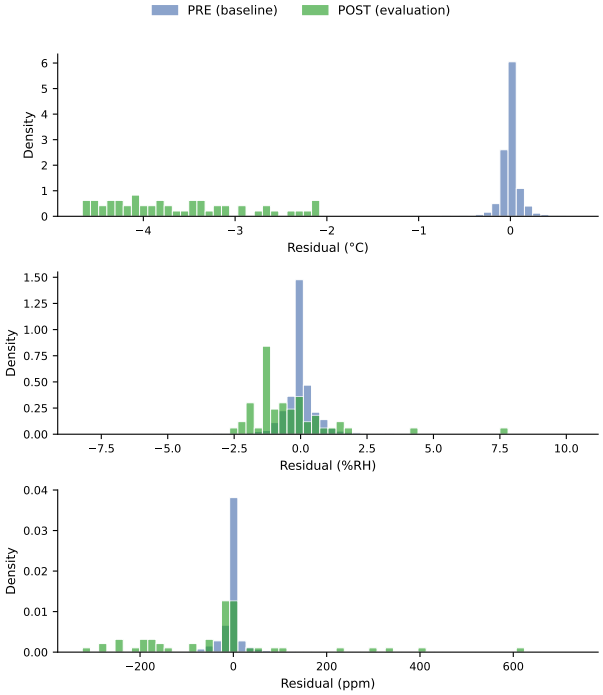

Figure 2: Residual distribution shift across variables

Summary

This research presents a DT-based framework for anomaly detection in indoor environmental sensor data. A Random Forest baseline learns expected behavior from historical data, and residual analysis detects distributional shifts with Isolation Forest. Semi-supervised OCSVM for environmental anomaly detection and adaptive DT updating are the next steps in ongoing work.

BIMCHAINED: A BLOCKCHAIN SUPPORTED DIGITAL FRAMEWORK FOR REAL-TIME CONSTRUCTION SITE MONITORING

Eleonora Vendetti, Giuseppe Piras
Sapienza University of Rome, DIEE Dpt-Lean Construction for the digital design of buildings and environment

Abstract

The construction industry uses BIM and Common Data Environments (CDE) for coordination, nevertheless struggles with data integrity, auditability, and trusted verification for safety compliance amid fragmented processes and BIM-blockchain oracle issues. This study proposes a hybrid framework integrating BIM, Dynamo-Python automation for parameter extraction and data validation, cryptographic hashing, and QR-codes linking physical assets to blockchain-ready records. In a Rome heritage refurbishment case study on mobile scaffolding, it produced verifiable inspection registers with compliance status and traceable hashes. The key contribution is a scalable prototype enhancing BIM safety monitoring traceability, enabling blockchain anchoring and openBIM-aligned digital twin provenance.

Introduction and background

The construction industry is currently undergoing a digital transformation to address systemic inefficiencies, fragmented information flows, and high accident rates. While BIM has established a foundational infrastructure for project coordination and clash detection, it still mostly depends on manually updated models and struggles to guarantee data integrity and auditability (Ng et al., 2025). In multi-stakeholder environments, manual verification and paper-based certifications persist, while digital records remain vulnerable to unauthorized modifications, which is particularly critical for safety and regulatory compliance.

CDE facilitate centralized repositories but lack immutable audit trails to link digital models reliably with physical on-site outputs. Integration with blockchain technology offers a distributed paradigm for information management, providing tamper-resistant records and verifiable transaction histories through cryptographic verification. Recent research explores hybrid architectures where large geometric datasets remain in BIM repositories while blockchain infrastructures secure metadata and hash-based fingerprints to help reduce risks of data inconsistency (Wang & Wang, 2025).

Despite this potential, significant gaps remain in the empirical implementation of these technologies within a cohesive, governed pipeline for safety workflows. A primary technical barrier is the oracle problem, the difficulty of ensuring off-chain site data accurately reflects physical conditions before blockchain anchoring (Khuc et al., 2024). To face this, the study employs Dynamo-based computational workflows to support the traceability of physical inspections through cryptographic validation; while visual programming is well-established in BIM design, its systematic application to safety compliance verification remains underexplored. The study targets quality improvement of H&S site inspections, which are labour-intensive, inherently exposed to human error, selecting mobile scaffolding as proof-of-concept, given its role among the leading causes of workplace injuries in construction making systematic and automated compliance verification both technically relevant and practically necessary.

Methodology

The methodology consists in an enhanced integration of BIM environments, Python-based Dynamo scripts, and cryptographic algorithm techniques. The primary objective is to improve transparency and traceability by creating structured, immutable compliance records for subsequent blockchain infrastructure addressing the need for data provenance in collaborative environments where shared datasets risk being revised, overwritten, or lost.

The initial stage focuses on the data modelling layer, defining BIM requirements and safety goals through regulatory analysis, to establish key design principles for parameter selection and rule-based validation logic.

The core of the operational methodology is a BIM–Dynamo pipeline designed for automated parameter extraction and compliance checking, while further developments of the Digital Twin (DT) paradigm could enable continuous synchronization with IoT sensors and actuators to support safety monitoring and data integration (Wu & Li, 2025). Safety-related parameters are extracted directly from the digital model and processed through a Python script integrated into the visual programming environment. In the case study conducted on a heritage masonry building refurbishment project in Rome, five safety-critical parameters were systematically extracted from the BIM model and evaluated against the requirements of UNI EN 1004:2021: configured height, load class, installation context, stabilizer configuration, and guardrail status. The pipeline produced structured inspection registers in which each scaffolding configuration is associated with a compliance label, a cryptographic hash functioning as a unique digital

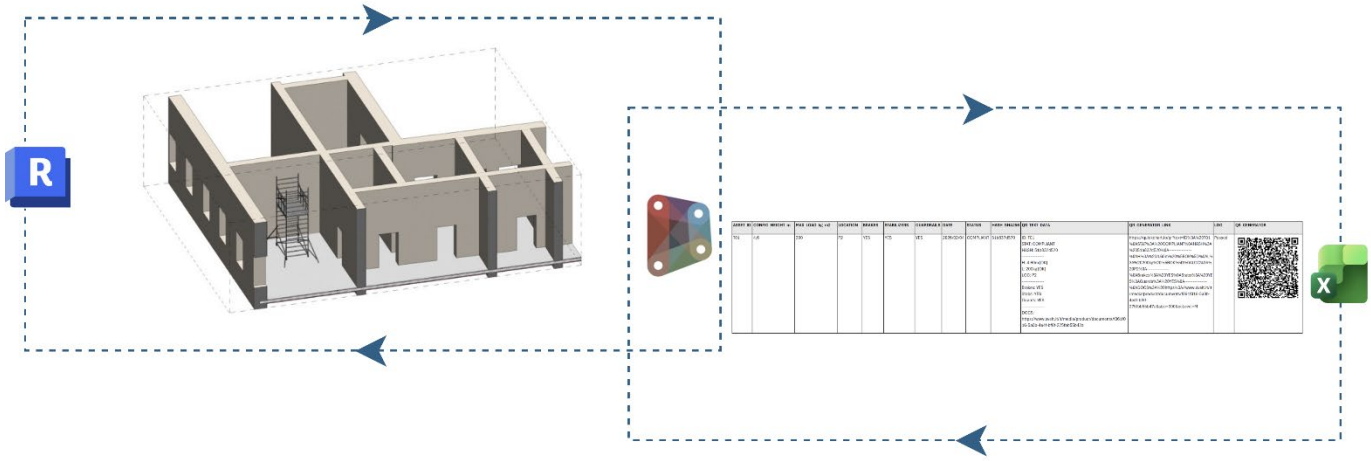

Figure 1: BIM–Dynamo workflow from Revit model to QR-coded inspection register in Excel for mobile scaffolding safety validation.

fingerprint, and a QR code enabling traceability between the physical asset and its digital record within the CDE.

This output represents a measurable improvement over conventional inspection documentation methods, reducing reliance on paper-based or informally managed records while ensuring that only validated, standardized data is prepared for subsequent blockchain checking stage.

Conclusion and discussion

The implementation of blockchain-enabled validation within BIM-based safety workflows contributes to the enhancement of data integrity and compliance documentation. By embedding validation logic directly into BIM platforms via Dynamo and Python, the system supports automated extraction of safety parameters and related compliance assessment. This configuration strengthens the reliability of inspection datasets while supporting structured documentation in multi-stakeholder environments. However, several systemic constraints persist, notably the *oracle problem*, which continues to pose challenges in establishing trusted links between physical site activities and digital verification systems. Additionally, interoperability limitations, scalability concerns, and organizational resistance remain significant barriers to sectoral adoption. Future research will focus on aligning this framework with openBIM specifications and developing more mature smart contract integration scenarios, guided by LLM capabilities integration.

A CROSS-DOMAIN FRAMEWORK FOR EXPLAINABLE STRUCTURAL INSPECTION

Vedant Girish Dalvi, Cornelius Preidel, and Simon Vilgertshofer
HM Munich University of Applied Sciences, Munich, Germany

Abstract

The digital transformation of structural inspection has led to the widespread use of image-based artificial intelligence for automated damage detection. Deep learning models, particularly convolutional neural networks, have demonstrated strong capability in identifying surface-level defects such as cracks from photographic data. However, although these systems provide pixel-level predictions, they lack mechanisms for semantic interpretation, cross-domain data integration, and structured knowledge representation. For deployment in civil engineering workflows, AI-based inspection must move beyond detection toward contextual reasoning and interoperable knowledge capturing.

Introduction

This paper presents a conceptual cross-domain framework that connects four layers of structural damage intelligence: (1) damage detection and quantification, (2) semantic damage captioning, (3) ontology-based data integration, and (4) knowledge graph population, as shown in Fig. 1. The proposed framework aims to bridge geometric, semantic, and relational representations of damage within digital construction environments.

Methodology

The proposed framework facilitates not only the detection and quantification of pixel-level damages and the explanation of contextual relationships in overlapping damage scenarios, but also the standardization of these damages through the modification of an existing ontology. This enables the population of a knowledge graph and, ultimately, the development of a digital twin, as discussed in the following sections.

Damage Detection and Quantification

The first layer focuses on multi-label damage detection from inspection images belonging to three different damage domains: concrete, steel, and glass. These domains differ in terms of damage type, causality, severity, complexity, and relationships. Custom multi-label semantic segmentation models are developed to detect damages across these domains, with domain-specific models later combined via deterministic orchestration or AI agents. Currently, models have been trained and successfully inferred on pre-existing concrete damage datasets like the

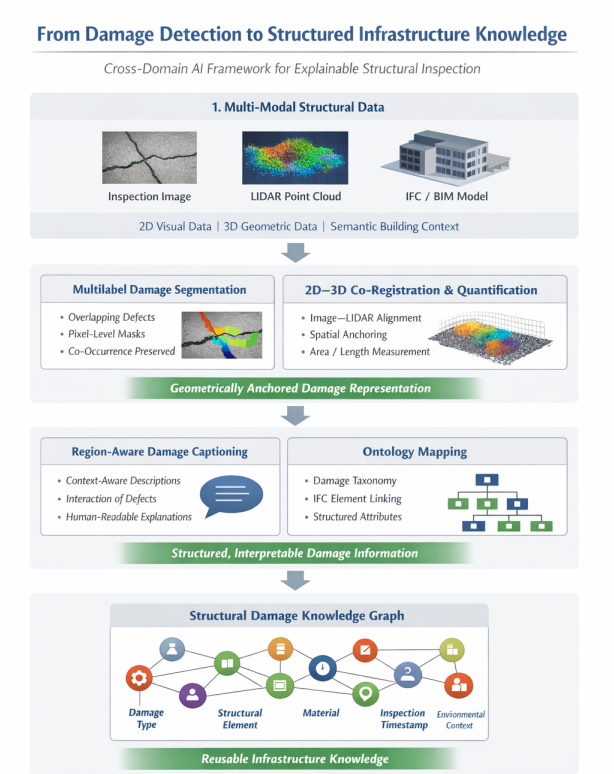

Figure 1: Proposed Methodology

DACL10k dataset introduced in Flotzinger et al. (2024) and new benchmark dataset created for this purpose, as described by Krefft et al. (2026).

Beyond 2D image analysis, the framework incorporates co-registration between image data and LiDAR-based geometric models. By aligning segmented damage regions with three-dimensional point clouds, damage localization can be anchored in spatially accurate structural coordinates. This integration enables the quantification of defect dimensions, and spatial orientation, as demonstrated by Krefft and Hoegner (2025). The result is a damage mask and parametric damage metadata, which can then be linked to a 3D model of the structure.

Semantic Damage Captioning

While detection provides spatial precision and quantification, engineering interpretation requires contextualization. The second layer introduces vision-language modeling for damage captioning. These captions can explain the over-

lapping patterns, and relative pixel positions among defects. Visual Language Models (VLMs) have been fine-tuned on a curated image captioning dataset to explain the context in overlapping concrete damages, and initial results have been presented by Dalvi et al. (2025). This layer enhances interoperability by transforming geometric predictions into human-readable contextual descriptions.

Ontology-based Data Integration

The third layer addresses the challenge of interoperability. AI outputs, whether masks or parametric data, must be aligned with construction-specific information standards to be usable. The proposed framework, therefore, incorporates ontology-based structuring of detected damages. The existing Damage Topology Ontology (DOT), proposed in Hamdan et al. (2019), is modified, and the detected damage categories are mapped to standardized taxonomies via ontology-aligned JSON templates and APIs and then linked to structural elements within digital building models, as described by Dalvi et al. (2026).

By structuring semantic outputs into ontologies, damage information becomes machine-readable and interoperable. This step enables alignment with Industry Foundation Classes (IFC)-based models and facilitates integration into a digital twin, a continuously coupled virtual representation of a physical structure that integrates geometry, damage observations, and structured knowledge to support inspection, reasoning, and long-term maintenance. The workflow assumes availability of a building model (e.g., IFC), but it can work with alternative structured data, such as classified point clouds or other spatial representations.

Knowledge Graph Population

The RDF (Resource Description Framework) graph explicitly models multiple relation types, representing information as a network of interconnected nodes and edges. These include spatial relationships (e.g., adjacency, overlap, containment), inspection timestamps, and hierarchical associations between damages and structural elements. Temporal evolution across inspections is represented by connecting damage instances over time, enabling tracking of progression, propagation, or mitigation effects.

In addition, the graph incorporates expert-defined causal relations that link observed damage patterns to potential causes, including environmental exposure, loading conditions, and material degradation mechanisms. Through this relational modeling, inspection data, digital building model information, and domain expertise converge into a unified structure. The resulting knowledge graph supports querying, and cross-project knowledge capturing, enabling analysis of recurring defect patterns, condition evolution trends, and intervention effectiveness.

Conclusion

This approach aims to transform visual damage detection into structured, explainable, and reusable infrastructure knowledge within digital construction workflows. Future work will focus on AI model orchestration, empirical validation of the integrated pipeline, refinement of ontology mappings, exploration of reasoning capabilities within the constructed knowledge graph, and development of a front-end application for visualizing all the detected damages and attributes.

EVALUATING LOCAL SMALL LANGUAGE MODELS FOR ARCHITECTURAL MEETING TRANSCRIPTION SUMMARIZATION AND ACTION EXTRACTION

Sean Bayly[1,2], Sneha Verma[1], Mohamad Kassem[1] and Huizhi Liang[1]
[1]Newcastle University, [2]Ryder Architecture

Abstract

This paper presents a locally hosted solution, for LLM driven summarization and action extraction for project-based meetings, that addresses the privacy, confidentiality, and cost concerns of externally hosted solutions. Developed for architectural project coordination, this system reduces the administrative burden of documenting multidisciplinary design meetings, tracking actions, and maintaining project records across distributed teams. Qwen3.6 27B was used as a judge to evaluate meeting transcript summarization and action extraction by Qwen3.5 4B and 9B SLMs in BF16 and AWQ INT4 formats. The 9B models achieved the best quality-speed tradeoff, producing accurate actions and concise, grounded summaries with lower wall-clock times.

Introduction and Related Research

Coordination between teams in the built environment involves frequent meetings with manual tracking of actions being onerous and prone to error (Ghimire et al., 2024). Many existing summarization workflows rely on external AI providers (e.g., Fireflies.ai and Otter.AI), requiring meeting transcripts and associated project discussions to be transmitted beyond the organisation's primary collaboration platform. In architectural practice, where meetings may contain commercially sensitive, contractual, or personally identifiable information, this can introduce additional privacy, data governance, and compliance concerns (Yan et al., 2024).

Table 1: Comparative Analysis of Meeting Intelligence Systems

Systems	Automatic Capture	Multi-Speaker Structuring	Project-Level Integration	Role-Based Access Control
Otter.ai	Yes	Strong	Limited	Platform-level
Fileflies.ai	Yes	Strong	Limited	Platform-level
Meeting Intelligence System	Yes (Graph Webhooks)	Structured Transcript Chunk	Deep relational embedding	Azure AD hierarchical role

This risk can be mitigated through the local deployment of LLM based models, which limits the egress of transcript data to third-party services during inference. The primary research challenge, therefore, is whether locally hosted SLMs can generate meeting summaries and action items of sufficient quality for use in architectural project coordination. In this paper, we investigated 4B and 9B parameter models from the Qwen3.5 family (Qwen Team, 2026). The impact of AWQ quantization on output quality is also evaluated.

Prototype: Development and Testing

Developed solution utilises three pipelines (Figure 1) to ingest and transform data atomically, from discovery through transcript ingestion and eventual summarisation.

30 transcripts were sampled, from project related

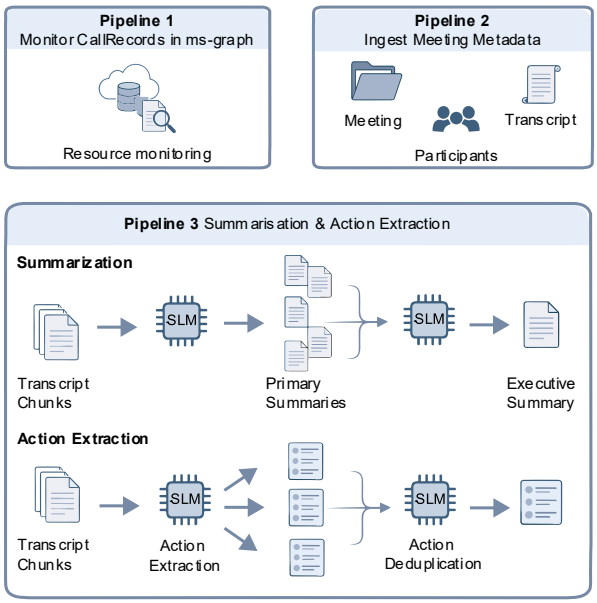

Figure 1: Architectural overview. The first two stages are concerned with data discovery and ingestion, with the third focused on processing transcripts into actions and summaries

meetings in an architectural practice, to form the evaluation dataset. They vary from 2000-30000 tokens and are stratified into three groups of 10 by token length at boundaries 8000 and 15000 tokens. The summarisation process is evaluated via LLM as a Judge (Zheng et al., 2023) in which a Qwen3.6-27B (Qwen Team et al. 2026) is tasked with scoring the summarisations on a scale of 0-5 (Li et al., 2026) on two categories: Faithfulness, and Completeness (Zheng et al., 2023). These metrics correspond to tendency to hallucinate, and inclusion of all available facts, respectively. For action extraction, the judge model produces its own actions and compares them to the actions of the candidate models. Finally, F1 score was calculated to represent agreement between the candidate and the judge model.

Result and Analysis: Action extraction F1 score (Figure 2) across all conditions was consistently above 0.85, indicating that the SLMs and the Judge were mostly in agreement. Though, the quantized models show larger variation in standard error. Upon inspection, this was caused by the AWQ models occasionally failing completely and generating zero actions, upsetting the

mean and reported standard error. In practice, a system can detect and retry under such circumstances. Scores were broadly flat across meeting lengths, validating the small window, high overlap and dedupe approach.

Faithfulness (Figure 2) for immediate summarizations of transcript windows are consistently strong across models with quantization having a minimal impact. Executive summaries exhibit a steep decline, likely due to the high compression and propagation of hallucinations from tier

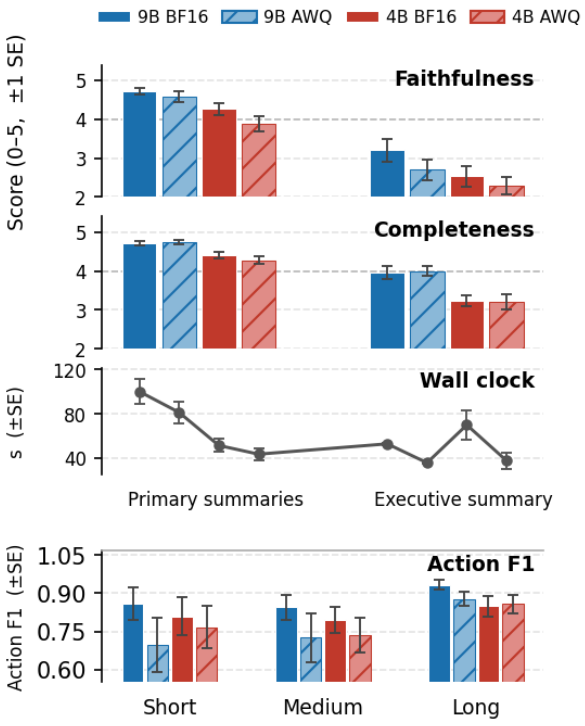

Figure 2: LLM Judge scores on Faithfulness and Completeness, Action F1 for 9B/4B variants of Qwen3.5 in BF16 and AWQ INT4. Wall clock time represents the mean average time taken for completion of a summary

one summarizations.

The 9B parameter models clearly outperform the 4B parameter models in Completeness (Figure 2) indicating that they tend to preserve more of the available information from the transcript.

Wall clock time (Figure 2) decreases steadily with reduction in model size, this is expected as LLM decode is memory bandwidth bound, smaller models are faster. However, for executive summaries, the 4B models break that trend, taking more time to produce summaries. This is because the smaller models are consistently producing longer outputs at that stage. Alongside a decline in Faithfulness, and a steeper decline in Completeness, this indicates that the outputs are not only longer, but less valuable.

Conclusion

This work presented a locally deployed LLM based summarisation system for architectural meetings, offering a privacy-conscious alternative to cloud-based documentation tools. The 9B model in quantization (INT4 AWQ) was identified as the optimal configuration, delivering acceptable summarisation quality with significant decode speedup over the BF16 variant, while producing more concise and consistent outputs than the 4B model. These results demonstrate the feasibility of locally deployed LLMs for supporting privacy-conscious architectural workflows and reducing manual meeting documentation overhead. Although, Meetings organised by external tenants cannot be automatically accessed through MS Graph due to tenant ownership restrictions, and users within meeting rooms cannot be directly identified. Additionally, the asynchronous architecture introduces eventual consistency delays. Future work will explore broader evaluation strategies using both open-source and frontier judge models to reduce model-family bias, alongside extending experiments to next-generation SLM families such as Gemma4.
