PREFACE

The 2026 European Conference on Computing in Construction (EC³) was held from July 12–15, 2026, at the Corfu Holiday Palace in Corfu, Greece. The conference brought together researchers, practitioners, and industry professionals from around the world to present their latest work and exchange ideas in the broad field of Computing in Construction. This book contains the papers submitted to the conference and accepted after a rigorous double-blind peer-review process.

The EC³ conference is a core activity of the European Council for Computing in Construction (EC³). The conference organisation is managed independently by a group of volunteers. The present conference marks the 8th edition of bringing together the international Computing in Construction community to discuss emerging research, innovation, and practice.

The EC³ 2026 proceedings present an overview of the conference programme, together with the names of the organisations and individuals who contributed to the technical programme. The peer-review process was conducted in two phases. First, 78 optional abstracts were submitted and reviewed by the respective Area Chairs. This was followed by a rigorous full-paper review process, in which each submission was evaluated by at least two reviewers from the Scientific Committee of international experts. Final acceptance decisions were made jointly by the corresponding Track Chairs and Programme Chairs. Following two rounds of peer review, 174 high-quality full papers, selected from a total of 257 full-paper submissions, were accepted for publication in these proceedings and presented at the conference.

The manuscripts were presented across 23 technical paper sessions, covering topics including:

- Artificial Intelligence in AEC
- Industrialisation, Automation and Robotics
- Decentralised Data, Cybersecurity and Trustworthy Automation
- Sustainability and Climate Action
- Human–Data Interaction
- Digital Twins and Asset Intelligence
- Education, Policy and Standardisation

Additionally, the conference included a poster session, where 24 posters were presented following a peer-reviewed selection process. The proceedings include these poster presentations as extended abstracts in a dedicated section.

Please note: all EC³ proceedings and conference materials are made openly available through the EC³ website (https://ec-3.org/publications/conference/?id=EC32026). Each conference paper is assigned a unique DOI and comprehensively meta-tagged to ensure easy discovery through commonly used academic search and indexing services.

One further track allowed participants to communicate embryonic and thesis-related research, with 21 young researchers participating in the Thesis-in-3 competition. Parallel presentation sessions were followed by a final competition session, providing students with an opportunity to present their research in a concise and engaging format.

Furthermore, the conference included four sessions dedicated to the technical committee work of the EC^3 and these included:

- Data Sensing and Analysis (DSA) Committee
- Modelling and Standards (M&S) Committee
- Education (EDU) Committee
- Human-Data Interaction (HDI) Committee

In addition to the above, a research paper writing workshop for early-career researchers was delivered by Prof. Mirosław J. Skibniewski. The workshop, Academic Writing for Early-Career Researchers, consisted of two complementary parts: Part I: How to Become an Effective Author of Highly Ranked, Peer-Reviewed Scholarly Journal Papers, and Part II: The Research Paper Clinic, where participants received practical guidance on developing high-quality scholarly manuscripts and strengthening their publication strategies.

The conference also featured six technical workshops, covering a diverse range of emerging research topics:

- A Guided Workflow for Integrating BIM and Geospatial Data in Digital Twins
- Aligning "Material" and "Product" Concepts Across Lifecycle Phases and Use Cases
- Temporal Sensor Fusion and State Reconstruction for Actionable Digital Twins
- How to Efficiently Generate RDF Graphs for Automation in AEC with IFC2LBD-Neo
- CoLAB 5.0: Human–Data Interaction for Ethical Electronic Performance Monitoring on Construction Sites
- Building Data Hubs for Circular Material Flows in Construction Logistics

In addition to the technical programme detailed above, the conference provided numerous opportunities for professional networking, collaboration, and fellowship through a variety of informal social events.

We would like to thank the EC³ scientific community, including both academic and industry members, for their contributions and continued support. We hope this conference provided opportunities to strengthen existing collaborations, establish new professional connections, inspire innovative research ideas, and enjoy the unique culture and natural beauty of Corfu. We look forward to welcoming you again at future EC³ conferences.

Dr. Ranjith K. Soman, TU Delft, EC^3 Programme Chair;
Dr. Ekaterina Petrova, TU Eindhoven, EC^3 Conference Chair, and
Dr. Jennifer Li, TU Delft, EC^3 Dissemination Chair.

We would like to thank our industry and academic partners for their generous contributions to the conference.

TU Delft Delft University of Technology

EUROPEAN COUNCIL FOR COMPUTING IN CONSTRUCTION

The **European Council for Computing in Construction (EC^3)** is a society of construction professionals, academics, researchers and national Professional Bodies, aspiring to become the leading European forum in the area of information technology in construction engineering and management.

Role of EC^3

The **European Council for Computing in Construction (EC^3)** advances professional knowledge and improves engineering practice in the built environment by fostering research, education and policy in current and emerging computing and information technologies.

EC^3 is founded on the following four pillars and corresponding Technical Committees:

- DSA: Data Sensing & Analysis
- M&S: Modelling & Standards
- HDI: Human Data Interaction
- EDU: Education

EC^3 interacts strongly with other Architecture, Engineering, Construction and Facility Management (AEC/FM) societies in related areas, strengthen the collaborations between academia and industry in topics related to **EC^3**'s mission, spearhead research on such topics, identify and promote effective ways to advance the state of knowledge and the level of education and practice in these topics, assist in the making of policy, and support existing and new related specialty conferences and publications.

Technical Committees

The role of all technical committees is to:

- Gather, maintain and disseminate information on the application of the committee's area to AEC/FM
- Organise and support joint research activities in the committee's area
- Organise and support conference sessions, workshops, and meetings in the committee's area
- Disseminate innovation in the committee's area through position papers, white papers, grand challenges reports and policy work throughout the European spectrum
- Keep the SPAs aware of developments in the committee's area

CONFERENCE COMMITTEE

Dr. Ekaterina Petrova, TU Eindhoven (NL) *(Conference Chair)*
Dr. Ranjith Soman, TU Delft (NL) *(Programme Chair)*
Dr. Jennifer Li, TU Delft (NL) *(Dissemination Chair)*
Dr. Daniel Hall, TU Delft (NL) *(Publications Chair)*

ACKNOWLEDGEMENTS

The organisers would like to thank the Track Chairs and the members of the Scientific Committee of the European Council for Computing in Construction (EC³) for their invaluable contributions to the paper review and selection process. We also extend our sincere appreciation to the members of the EC³ Technical Committees and workshop organisers for their dedication in delivering a rich technical programme that extended well beyond the paper presentation sessions.

We are particularly grateful to the student assistants Krista van Zandwijk, Stella Yongxue Tian, Irfan Čustović, Emilio Murillo Sierra, and Wahib Saif, whose professionalism, enthusiasm, and commitment greatly contributed to the smooth preparation and successful delivery of the conference. We also sincerely thank Sobia Bano for her invaluable support in maintaining the conference website and providing IT support throughout the preparation and delivery of the conference.

Track Chairs

Artificial Intelligence in AEC:
Prof. Jenn McArthur, Toronto Metropolitan University (CA)
Dr. Edlira Vakaj, Birmingham City University (UK)

Industrialisation, Automation and Robotics:
Prof. Daniel Hall, TU Delft (NL)
Dr. Jianpeng Cao, The University of Hong Kong (HK)

Decentralised Data, Cybersecurity and Trustworthy Automation:
Dr. Theo Dounas, Heriot-Watt University (UK)
Dr. Mantha Bharadwaj, University of Sharjah (UAE)

Sustainability and Climate Action:
Prof. Dimitrios Rovas, University College London (UK)
Dr. Kasimir Forth, ETH Zürich (CH)

Human–Data Interaction:
Dr. Diego Calvetti, University of Porto (PT)
Dr. Andrew Sonta, EPFL (CH)

Digital Twins and Asset Intelligence:
Dr. Sebastian Esser, Technical University of Munich (DE)
Dr. Karim Farghaly, University College London (UK)

Education, Policy and Standardisation:
Dr. Dragana Nikolić, University of Reading (UK)
Dr. Marzia Bolpagni, Mace / Northumbria University (UK)

Poster Series:
Dr. Judith Fauth, Eindhoven University of Technology (NL)
Dr. Pedro Meda, University of Porto (PT)

Thesis-in-3 Competition:
Dr. Nicola Moretti, University College London (UK)

TABLE OF CONTENTS

Artificial Intelligence in AEC 1

Prescriptive Maintenance Of Sewer Systems Based On Large Language Models - Thamer Al-Zuriqat, Dhananjay Birmole, Kosmas Dragos, and Kay Smarsly 2

Fast-Asset: A Real Time Scan-To-3D Point Cloud BIM-Ready Asset Generation Method For Small MEP Elements - Urueña, Asier; Eskudero, Ibon; Sagasti, Diego; and Noyé, Sarah 10

Automated Dimension-Aware 2D-To-BIM Reconstruction Through Cross-Modal Text-Geometry Alignment - Xing Liang, Tomohiro Fukuda, and Nobuyoshi Yabuki 18

A BIM-Integrated Adaptive Surrogate Framework For Efficient Uncertainty Quantification In Building Energy Simulation - Arash B. Naamrudi, Reihaneh Aghamolaei 26

Ontology-Supported Bridge Component Design: Implementation Of Bridge Cap Design Rules - Tim Noack, Han Qian, Chongjie Kang and Steffen Marx 34

Exploring Adaptable Office Fit-Out Layouts Using Configurable Floor Plan Graphs And Large Language Models - Mikhael Johanes, Simona Kocour, Siyu Tang, and Catherine De Wolf 42

Few-Shot Building Element Detection With Vision Transformers: Improving Energy Retrofit Matching - Tom Slik, Raphae¨l Gueulet, Christos Lathourakis 50

AI-Assisted Bridge Conceptual Design: A Hybrid Knowledge- And Learning-Based Approach To Automated Span Planning - Han Qian, Tim Noack, Mengyan Peng, Marx Steffen and Chongjie Kang 58

Open-Source VLMs For Engineering Drawing Metadata: QWEN-VL Title-Block Detection And Information Extraction - Mengyan Peng, Angran Cui, Steffen Marx, and Chongjie Kang 66

Automated BIM LOD Inferencing: A Hybrid Approach Using Knowledge Graphs And Multimodal Large Language Models - Taeyoon Kim, Ghang Lee 74

Automated P&ID Compliance Checking Via LLM-Based Code Generation - Heejun Youn, Miyoung Uhm, Juho Han, Justin S. Lee, H. David Jeong, and Ghang Lee 82

Actor-Network Theory For Evaluating BIM-AI Implementation In Design Firms - Federica Crosato, Alireza Borhani, and Luciana Burdi 90

Fabrication-Aware Generative Design For Hybrid Prefabrication Using Stable Diffusion XL - Hang Zhang, Jianpeng Cao, Anton Savov, and Benjamin Dillenburger 98

SYN3D-LLM: Synthetic 3D Point Clouds Generated Through LLM Discussion - Nils Soeren Krause, Joern Ploennigs 105

Bibimbap: A Benchmark For Instructional BIM-Based Automated Programming - Clemens Kujat, Bharathi Kannan Nithyanantham, Stefan Telgmann, Tobias Sesterhenn Jörn Plönnigs, Stefan Lüdtke, Christian Bartelt 113

A Semantic Framework For Formalizing Stakeholder Information Requests In Construction - Timur Weilbach-Eyüboglu, Cornelius Preidel, and Simon Vilgertshofer 121

Exploring The Applicability Of Computer Vision Models For Automated Code Compliance Checking - Asaf Talor Shnay, Guy Austern, Tanya Bloch 129

Aligning Heterogeneous Views: Stakeholder Terminology And Multi-Level Mappings In The AEC Industry - Jakob Martin, Cornelius Preidel, Simon Vilgertshofer, André Borrmann 137

Parametric VPINN Framework For Rapid Design Exploration Of Thin Slabs - Ahmad Arafat, Dimosthenis Kifokeris, and Mohamad Omar Alzokani 145

Potential Of Large Language Models For Construction Quotation Workflows - Anja Brelih, Žiga Krvina, and Robert Klinc 153

Multidimensional Weighted Ranking Recommendation System For Circular Material Matchmaking - Noah Gerber, Ibrahim Al-Hazwani, and Pei-Yu Wu 160

Turning Construction Checklists Into Machine-Readable Inspection Schema - Till Weist, Leon Pfenning, and Prof. Sven Rogalski 168

Vision–Language Models In Construction: Assessing Prompt Robustness In Open-Vocabulary Object Detection - Federica Madaschi, Gelare Taherian, Marco Lorenzo Agostino Trani and Ehsan Rezazadeh Azar 176

Benchmarking Deep Learning Approaches For AEC Engineering Drawing Layout Detection And Information Extraction - Tianyang Huang, Alessio Lombardi, Ahmed Elnagar, Ahmed Zalouk, George Paul, Sepehr Najjarpour Arvid Sigurdsson, Khalid Ismail, Mohamed Ragab, Edlira Vakaj 184

IDS-Constrained Text-To-Graph Querying For IFC Models - Ivan Smirnov, Tanya Bloch, Fulvio Re Cecconi, Sebastiano Maltese, Lavinia Chiara Tagliabue, Silvia Meschini and Shabtai Isaac 192

Automated Schedule Enrichment From Daily Progress Reports: A Bi-Directional Neuro-Symbolic AI Approach - Sudheer Kumar Nanduri, Venkata Santosh Kumar Delhi 200

Assessing The Viability Of LLM Agents For Generating Reusable Compliance Checking Functions - Stefan Fuchs, Sylvain Hellin, and André Borrmann 208

A Multi-Agent RAG-Enabled Knowledge System For National-Scale Whole-Life Carbon Assessment Of Residential Retrofits - Sobia Bano, Usman Ali, Conor Shaw, Tobias Maile, Fatemeh Golpayegani and James O'Donnell 216

Do Buildings Really Need Comprehensive Sensor Networks? A Graph Theory-Based Framework For Physical Consistency Modeling - Yangzhe Chen, Qinglu Zeng, Nan Hu, Thomas Ohlson Timoudas, and Qian Wang 224

Semantic Mapping Of Request For Information (Rfi) To BIM Elements With Large Language Models - Limon Paul Joy, Farzaneh Zarei, and Mazdak Nik-Bakht 232

Explainable AI For Requirement Traceability In Construction Systems Engineering - Timon Kuijper, Ranjith K. Soman, Tong Wang, and Sander van Nederveen 240

Enabling Cross-Study Comparison: A Framework For Automated BIM-Qa Evaluation - Sylvain Hellin, Stefan Fuchs, Stavros Nousias, André Borrmann 248

Comparison Of Segmentation Models For Pothole Detection Using UAV Imagery - Varshney Muskan, Singh Aryan Raj, Garg Sahil 256

Seeing In The Dark: Low-Light Image Enhancement For Modular Construction - Yuanyang Qi, Jie Hong, Tingtian Li, and Xiao Li 262

From General Space Planner To Learning-Based Generation: A Systematic Mapping Of Representation, Objectives, And Control - Suhyung Jang and André Borrmann 270

A Neuro-Symbolic AI Pipeline For Generating SHACL-Based Digital Building Regulations - Alex Donkers and Ekaterina Petrova 278

An LLM-Driven Agent-Based Framework For Cross-Regional Construction Policy Evaluation In The Greater Bay Area - Wentao Zhu, Xiao Li, Juan Wang, and Mingtian Xiong 286

VLM-Augmented RAG Framework With Ontology-Constrained LLM Reasoning For Existing Building Material Documentation - Julia Kaltenegger, Stavros Nousias, Ekaterina Petrova, Andre´ Borrmann and Pieter Pauwels 294

Multi-Class Prediction Of Occupational Accident Types Using XGBoost In Pipeline Construction - Ahmet Eren Ünlü, Recep Özkan, and Onur Behzat Tokdemir 302

Physics-Constrained Reinforcement Learning For Individualized And Biomechanically Feasible Task-Motion Optimization - Kangrui Ren, Ali Golabchi, and Gaang Lee 309

Text-To-AR For Home Remodeling: An End-To-End Pipeline From Natural Language To AR-Compatible 3D Assets - Vamsi Sai Kalasapudi, Bharadwaj R. K. Mantha, Hassan Odeh and Alekhya Seelam 316

A Zero-Shot Approach To Decomposing Graphical Rules In Accessibility Regulations - Yonghan Kim, Ghang Lee, and André Borrmann 324

Shared Embedding Spaces For AEC Ontologies: An Empirical Study Of Discovery And Alignment - Tobias Heimig-Elschner, Jyrki Oraskari, and Jakob Beetz 332

A Semi-Automated Scan-To-BIM Approach To Fire Compartmentation In Existing Buildings - Jorge Magalhães, Rafael Cabral, Jéssica Reis, Rui Gavina, José Aidos Rocha, Vaidotas Sarka, Tatjana Vilutiene, Ricardo Santos and Diogo Ribeiro 1iBuilt, Instituto Superior de Engenharia do Porto, Politécnico do Porto, Porto, Portugal 340

3D Segmentation Agent Integrating 3D Gaussian Splatting And Vision-Language Models For As-Built Analysis - Boyu Wang, Jun Ma, and Borja García de Soto 346

Agentic AI – The Transformation Of Decision-Making Processes Through Artifical Intelligence - Charlotte-Maria Esch, Marijana Srećković2, and Josef Windsperger 353

Neuro-Symbolic Reinforcement Learning For Multi-Category Construction Relationship With Reasoning And Sequence Planning - Akarsth Kumar Singh and Shang Hsien Heish 361

From Building Permit Review Comments To Comment-Based Process Indicators: An Estbert-Based Classification Workflow - Pille-Riin Peet, Ergo Pikas, and Aime Ruus 369

Structured Innovation In Construction Value Engineering Through LLM-Assisted TRIZ Reasoning - Fuhao Zu and Linghui Xie 377

Industrialization, Automation & Robotics 384

Forecasting Machine Working Times In Off-Site Construction: A Machine Learning Benchmark For Supporting Production Planning - Andrea Sbaragli, Xiang Xie, John Hedley and Mohamad Kassem 385

Emerging Business-Model Archetypes Of A Smart Mobile Factory For Construction 4.0 - Alexander N. Walzer, Irfan Čustović2, Konrad Graser and Daniel M. Hall 393

Experimenting With Digital Twins: A Lego®-Based Modular Testbed For Systematic Evaluation - Irfan Čustović 1, Emilio Murillo Sierra, Ranjith K. Soman, Daniel M. Hall 401

Enriching Version Increments With Engineering Intent For Enhanced BIM Model Checking - Sebastian Esser, Jiabin Wu, Suhyung Jang, Lena Fahrner, Robert Amor, and André Borrmann 409

A Computational DEA-Based Decision Support Framework For Green Supply Chain Management In Construction - Erawati Ravindra Kadam, and Ann Francis 417

Defining Demonstrator Projects For Digital Fabrication (DFAB) Adoption In Architecture, Engineering And Construction (AEC) - Jennifer Li, Konrad Graser, Alexander N. Walzer, and Daniel M. Hall 425

A Two-Stage MEP Installation Constructability Optimization System Integrating Dsm-Based Module Division And 4D Simulation - Ang Li, Zhengyi Chen, and Jack C.P. Cheng 432

Emerging Opportunities For Integrating Digital Product Passport Into Lean Construction Workflows: A Conceptual Perspective - Yanh Ribeiro, Pedro Mêda, and Jorge Teixeira 440

Automatic Mountain Tunnel Invert Excavation With Digital Twin Management In Non-Gnss Environments - Nobuyoshi Yabuki, Hitoshi Ishida, Sadatoshi Oomori, Yoichi Moriya, and Shinji Fujita 448

Proactive Safety Management In Earthwork Operations Using IoT-Driven Real-Time Risk Analysis - A N Ledin Ullah, Tulika Choudhury Puja, Jhonattan G. Martinez, Lorenzo Loyola, Istiaque Hossain and Freddy Perez 455

Perceived Benefits Of 5D BIM In Construction Cost Management: A Europe-Wide Survey - Enes Go¨nen and Semra C¸ omu 463

Data-Driven Decision Support For Construction Method Selection In Linear Infrastructure Projects: A Systematic Review - Maik Görgner, Simon Hoeng, Marc Schmailzl, Thomas Linner, Thomas Wolff, Mathias Obergrießer 471

Ontology-Based Cost Management In Public Infrastructure Projects: A Case Study On Transferability And Applicability - Anna Nast, Jacopo Cassandro, Claudio Mirarchi, and Jürgen Melzner 479

Graph-Based Generative Scheduling In Construction Project Management - Jianpeng Cao, Hisham Said 487

Integrated Many-Objective Optimization For Decision-Making And Dynamic Project Control - Aman Shukla, and Sahil Garg 495

Principles For The Industrialisation Of The Infrastructure Renovation And Replacement Assignment - Irfan Pottachola, Alexander Bletsis, and Trijntje Verschuuren Netherlands Organisation for Applied Scientific Research (TNO), Delft, The Netherlands 502

Model To Press: Digital Dataflow For The Design, Rationalization, And Manufacture Of Free-Form Glulam Beams - Tom Svilans, Edgars Rudzītis, Jānis Iejavs, Edvīns Grants, and Kristaps Zīverts 510

Teleoperation Interfaces For Compact Demolition Robots: Results Of A Pilot Study With Construction Workers - Patrick Borges Rodrigues, Zihao Wang, Yiyang Fang, Gale Lucas, Shawn Roll, Burcin Becerik-Gerber, and Lucio Soibelman 518

Automized Planning & Data Exchange For Prefabricated Façade Renovation Processes - Julius Emig, Orjola Braholli, Dietmar Siegele and Dominik T. Matt 526

PRESCRIPTIVE MAINTENANCE OF SEWER SYSTEMS BASED ON LARGE LANGUAGE MODELS

Thamer Al-Zuriqat[1], Dhananjay Birmole[1], Kosmas Dragos[1], and Kay Smarsly[1]
[1]Institute of Digital and Autonomous Construction, Hamburg University of Technology,
Blohmstraße 15, 21079 Hamburg, Germany

Abstract

Sewer systems constitute urban infrastructure critical for public health, environmental protection, and flood prevention. Decision-making in sewer systems maintenance often fails to effectively and efficiently interpret heterogeneous and multimodal inspection data into actionable maintenance strategies. To improve decision-making in sewer systems maintenance, this paper introduces a prescriptive maintenance (RxM) framework, in which a pre-trained large language model (LLM) is adapted to the domain of sewer systems using adapter-based fine-tuning. As will be shown in this paper, the LLM is capable of interpreting heterogeneous, multimodal inspection data and recommending stepwise repair procedures of sewer systems, following the paradigm of RxM.

Introduction

Civil infrastructure plays an important role in shaping modern societies by providing services essential for public well-being, such as transportation, water supply, energy, and communication networks. Maintenance of civil infrastructure is vital to ensure long-lasting, healthy, and functional infrastructure. Sewage systems comprise infrastructure for collecting and transporting sewage ("sewer systems"), and facilities for treating and disposing sewage ("wastewater treatment plants") (Davis & Cornwell, 2018). Sewer systems consist of pipelines, manholes, and pumping stations, integrated into unified networks. The operational reliability of sewer systems may be compromised by degradation due to aging, increasing hydraulic loads, and overstressing, driven by urban development and climate change (Hartmann et al., 2024).

Maintenance of sewer systems is carried out using either reactive or proactive maintenance strategies (Hartmann et al., 2025). Reactive maintenance is performed after the occurrence of significant damage, emergencies, or functional disruptions in a sewer system. By contrast, proactive maintenance comprises measures implemented independently of damage, emergencies, or functional disruptions. Proactive maintenance strategies include (i) preventive maintenance, which relies on scheduled interventions independent of condition assessment, (ii) condition-based maintenance, which is triggered by condition-assessment observations, (iii) predictive maintenance, which incorporates forecasts of degradation progression to support maintenance planning (Errandonea et al., 2020), and (iv) prescriptive maintenance, which utilizes predicted system states together with technical, operational, and contextual constraints to recommend specific maintenance actions (Smarsly et al., 2025). Within proactive maintenance strategies, reliable decision-making is crucial, particularly in prescriptive maintenance, where actions depend on the interpretation of heterogeneous and multimodal inspection data. Such multimodal inspection data includes sensor data, closed-circuit television (CCTV) footage, inspection reports, and expert assessments, which must be translated into actionable stepwise repair procedures.

A variety of approaches toward decision-making in sewer system maintenance have been proposed and can be classified into (i) traditional methods and (ii) artificial-intelligence (AI)-based methods. Traditional methods comprise visual inspections (Yang et al., 2011), standardized "defect" (i.e. damage) coding schemes, and periodic condition assessment protocols (Cao et al., 2023), which have formed the foundation of early sewer system maintenance practices. Nonetheless, traditional methods are constrained in processing heterogeneous and multimodal data, exhibit subjectivity in defect classification, and lack systematic mechanisms for integrating sensor data, visual inspection data, and textual documentation into coherent maintenance actions. AI-based methods have gained increasing attention in recent years due to advances in sensing technologies, computational resources, and data availability. AI-based methods, such as convolutional neural networks (Wang et al., 2023), "you-only-look-once" (YOLO) models (Zhang et al., 2023), single-shot multi-box detectors (Shen et al., 2023), and semantic segmentation models (Wu et al., 2025) have demonstrated effectiveness in detecting defects, classifying damage, and forecasting degradation in sewer systems. However, AI-based methods remain constrained by training-data imbalance, sensitivity to noisy inspection data, limited interpretability, and insufficient integration with established maintenance standards, resulting in outputs hardly amenable to translation into consistent, stepwise repair procedures of sewer systems. Consequently, despite the importance of reliable decision-making in prescriptive maintenance, traditional decision-making approaches often fall short of effectively and efficiently interpreting heterogeneous and

multimodal inspection data into actionable stepwise repair procedures.

To improve decision-making in sewer system maintenance, this paper introduces a prescriptive maintenance (RxM) framework, in which a pre-trained large language model (LLM) is adapted to the domain of sewer systems maintenance. In particular, the LLM is adapted to the domain of sewer systems maintenance using adapter-based fine-tuning techniques, which involves training an adapter module using a dataset consisting of repair and rehabilitation standards, subsequently integrated into the pretrained LLM. Thereupon, the LLM is capable of interpreting heterogeneous, multimodal inspection data and recommend detailed, stepwise repair procedures, adhering to the RxM paradigm. Contrary to approaches limited to prompt engineering, this study performs domain-specific fine-tuning of the Mistral-7B-Instruct-v0.2 LLM using the low-rank adaptation (LoRA) process, thereby, embedding codified normative knowledge, stemming from sewer systems maintenance repair and rehabilitation standards, into the internal representations of the LLM. The remainder of this paper is structured as follows: First, the design of the RxM-LLM framework is illuminated. Then, the implementation of the of the RxM-LLM framework is presented, followed by a validation test using a dataset not used during fine-tuning the LLM. Next, the results of the validation test are presented and discussed. Finally, the summary and conclusions as well as an outlook on potential future research directions are provided.

Design of the RxM-LLM framework

The rationale behind using LLMs for RxM of sewer systems lies in the capabilities of LLMs to self-learn complex relationship within heterogeneous and multimodal inspection data, as well as procedures mentioned in repair and rehabilitation standards. In this section, the design of the RxM-LLM framework is presented, comprising two phases, (i) preparing the fine-tuning dataset, and (ii) fine-tuning the LLM. Each phase comprises several steps, flowcharted in Figure 1.

Phase 1: Preparing the fine-tuning dataset

1. In the first step, repair and rehabilitation standards related to sewer systems maintenance are selected. Standards providing guidelines associated with inspection, repair, rehabilitation, and operational procedures for sewer systems are considered. The purpose of this step is to identify codified normative documents with technical content that can be used to form the foundation of the fine-tuning dataset.
2. In the second "preprocessing" step, standards, typically available in document formats, such as portable document format (PDF) files, that are not directly interpretable by machines are converted into a machine-readable dataset $D_{mr} = \{d_1, d_2, \ldots, d_i\}$, where d_k denotes the kth standard series part (e.g. DIN EN 1986-4) with $k = 1...i$. Each standard series part d_k is decomposed into page-wise text chunks using context-aware extraction. Specifically, each page j of d_k is represented as a text chunk $c_{k,j}$, forming the set $d_k = \{c_{k,1}, c_{k,2}, \ldots, c_{k,n}\}$, where n denotes the total number of pages in d_k. Furthermore, figures and tables appearing on page j are referenced within the corresponding text chunk $c_{k,j}$, thus preserving contextual integrity and ensuring that D_{mr} is coherent and consistently formatted.

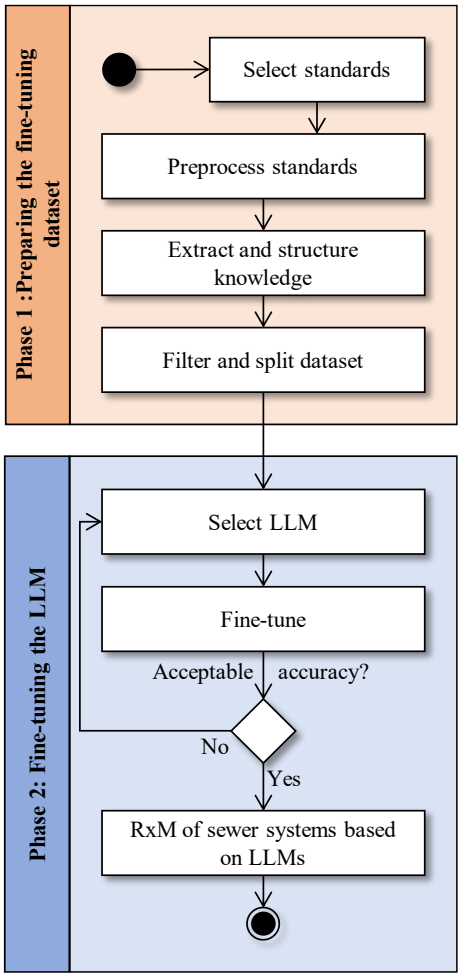

Figure 1: Flowchart of the RxM-LLM framework.

3. In the third "knowledge extraction and structuring" step, a question-answer (Q&A) dataset $D_{Q\&A}$ is generated using a two-stage strategy for fine-tuning the LLM.
   a. In the first stage, a document-level summary S_k is generated for each d_k in D_{mr}. S_k may capture the overarching scope, dominant technical topics, and normative intent of d_k. Furthermore, S_k will serve as a high-level representation of d_k and is not intended to replace the original text in d_k. Instead, S_k is used as contextual guidance to ensure that subsequent processing steps remain aligned with the overall normative context of d_k.
   b. In the second stage, each text chunk $c_{k,j}$, derived from d_k, is processed to generate Q&A pairs according to a domain-specific schema, comprising material type, damage type, damage

cause, damage location, damage severity, and potential maintenance procedures. The domain-specific schema enables a structured generation of $D_{Q\&A}$, ensuring that the Q&A pairs are context-aware and aligned with the requirements for RxM of sewer systems.

4. In the fourth step "filter and split dataset", $D_{Q\&A}$ is filtered to identify and remove similar (duplicate) entries, yielding a "filtered" Q&A dataset ($\tilde{D}_{Q\&A}$) with no redundant Q&A pairs, thereby improving the dataset diversity during fine-tuning. Next, the $\tilde{D}_{Q\&A}$ is split into a training dataset $\tilde{D}_{Q\&A(training)}$, a validation dataset $\tilde{D}_{Q\&A(validation)}$ (to avoid overfitting issues while fine-tuning the LLM), and a testing dataset $\tilde{D}_{Q\&A(testing)}$ (to eventually test the training performance with input data previously unused).

Phase 2: Fine-tuning the LLM

1. In the first step of the phase 2, candidate LLMs are selected for fine-tuning and adapting to the domain of sewer systems RxM. In general, LLMs, under the umbrella of AI systems, are trained on "big" datasets consisting of text from sources such as books, journals, and web pages, assisting the LLMs to comprehensively extract linguistic patterns, semantics, and grammar structures. Thus, LLMs are capable of analyzing, comprehending, and producing human-like language through advanced deep learning techniques, rendering LLMs well-suited for RxM applications. The candidate LLMs are assessed according to criteria, including, (i) parameter scale, relative to available computational resources, (ii) support for instruction tuning and parameter-efficient fine-tuning methods, (iii) model openness and reproducibility, and (iv) compatibility with structured Q&A generation. Then, based on the aforementioned criteria, a single LLM is selected for subsequent fine-tuning and adaptation in the next step.
2. In the second step, the LLM is fine-tuned using the $\tilde{D}_{Q\&A}$ dataset. During training, a large number of LLM parameters (sometimes in the order of billions) for predicting the next word in a sequence are adjusted, gradually learning to produce accurate, context-aware outputs. As a result, training a new LLM for sewer system maintenance would be time-consuming, and fine-tuning, i.e. retraining an already trained LLM, is employed as an alternative, essentially adapting the model to the domain of sewer systems maintenance.

3. In the final step, the accuracy of the fine-tuned LLM is checked using cross-entropy loss and mean "token" accuracy. Each token expresses the smallest unit of text processed by the LLM, obtained through sub-word tokenization, and may represent a complete word, a word fragment, a punctuation mark, or a special symbol. On the one hand, the cross-entropy loss represents the prediction error by measuring the divergence between the distribution of tokens predicted by the LLM and the ground-truth distribution, derived from the training dataset. Fine-tuning entails minimizing the cross-entropy loss between the probabilities of tokens predicted by the LLM and the reference tokens, provided by the ground truth. Low loss values indicate that the distribution of tokens predicted by the LLM closely matches the ground-truth distribution. On the other hand, the mean token accuracy serves as the principal metric for assessing fine-tuning performance, expressing the fraction of tokens predicted correctly out of all tokens in each "mini-batch" (subset of the batch, i.e. training data, processed by the LLM in a single training iteration). The mean token accuracy metric provides a granular indication of the sequence-level ability of the LLM to reproduce linguistic patterns. High mean token accuracy indicates that the LLM is capable of generating outputs closely aligned with realistic sewer systems maintenance procedures.

The combination of the two phases results in actionable information, facilitating real-time decision making in sewer system maintenance. In what follows, the implementation of the RxM-LLM framework is presented.

Implementation of the RxM-LLM framework

The implementation is presented in accordance with the phases of the RxM-LLM framework, previously described, i.e. "preparing the fine-tuning dataset" and "fine-tuning the LLM". In this context, standards on sewer systems repair and rehabilitation, issued by the German Institute for Standardization (Deutsches Institut für Normung, DIN) and harmonized as European standards (Europäische Normen, EN), as well as standards issued by the German Association for Water, Wastewater and Waste (Deutsche Vereinigung für Wasserwirtschaft, Abwasser und Abfall, DWA) are incorporated into the implementation. Furthermore, the programming language Python is employed for implementing both phases.

Phase 1: Preparing the fine-tuning dataset

Figure 2 illustrates the standard series, selected in step 1, used in this study. The parts from the standards series selected, specifically 33 parts, are acquired through the databases "DWA Regelwerk" (Deutsche Vereinigung für Wasserwirtschaft, Abwasser und Abfall (DWA), n.d.) and the standards database "Nautos" (Nautos, n.d.) as PDF files. The standards include:

- The DIN EN 13508 series, which constitute a Europe-wide-harmonized basis for governing inspection, assessment, and documentation of sewer and drainage systems (DIN EN 13508),
- The DIN EN 1986 series, which regulates the planning, design, construction, operation, and maintenance of drainage systems located on private properties, ensuring alignment between private and municipal sewer systems (DIN EN 1986),
- The DWA-M 143 series, which defines technical procedures for inspecting, assessing, and rehabilitating sewer systems (DWA-M 143),

- The DWA-M 144 series, which specifies technical requirements, procedures, and evaluation principles for structural condition assessment of sewer pipelines and manholes, providing a uniform basis for damage classification and maintenance planning (DWA-M 144), and
- The DWA-M 149 series, which provides methods and technical criteria for hydrological, hydraulic, and performance-based assessment of sewer systems, supporting reliable network analysis, monitoring, and operational planning (DWA-M 149).

Data preprocessing (step 2) for converting the PDF files into the machine-readable dataset $D_{mr} = \{d_1, d_2, \ldots, d_{33}\}$ is achieved via a Python preprocessing pipeline. Within the pipeline, textual content contained in the PDF files is extracted into a textual corpus, using optical character recognition (OCR). The textual corpus is then segmented into page-wise text chunks, such that each page j of the standard part d_k corresponds to one text chunk $c_{k,j}$. In parallel, figures contained in the PDF files are exported as separate portable network graphics (PNG) files with automatically assigned captions, and tables are reconstructed as spreadsheets. Figures and tables identified on page j are referenced within the corresponding $c_{k,j}$ to preserve contextual integrity between textual content and visual or tabular information.

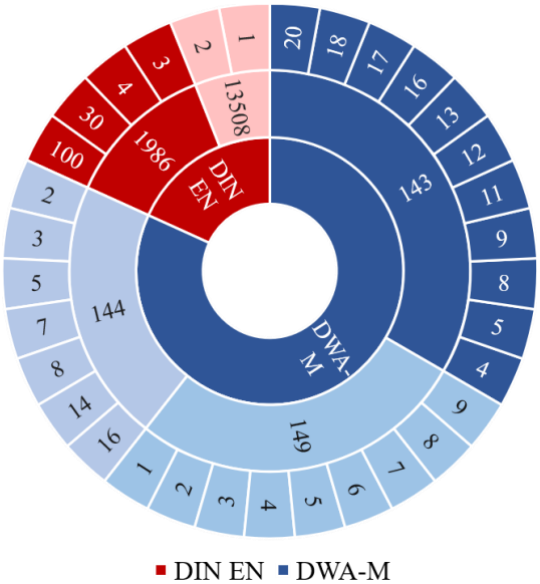

Figure 2: Standards series selected for the implementation of the RxM-LLM framework.

Knowledge extraction and structuring (step 3) for transforming D_{mr} into $D_{Q\&A}$ is accomplished as follows: First, a generation prompt based on Chat GPT-4o-mini LLM is used to produce document-level summaries $S = \{S_1, S_2, \ldots, S_{33}\}$ of D_{mr}, where the summary S_k corresponds to the kth standard part. Next, for standard part d_k, a dedicated generation prompt based on GPT-4o-mini (33 generation prompts in total) is used for generating Q&A pairs using the page-wise text chunks c_{jk}. The GPT-4o-mini generation prompts are constrained by the domain-specific schema, defined in the second stage of step 3, as well as by the document-level summaries $S = \{S_1, S_2, \ldots, S_{33}\}$. As a result, a total of 9,509 Q&A pairs are generated for $D_{Q\&A}$. Figure 3 presents a breakdown of the total Q&A pairs generated from each standard series using the GPT-4o-mini generation prompts.

In the final step of the first phase, filtering and splitting, $D_{Q\&A}$ is filtered to identify and remove duplicate Q&A pairs. Following user review and a cosine-similarity filtering, a total of 476 Q&A pairs are removed. As a result, $\tilde{D}_{Q\&A}$ comprises 9,033 Q&A pairs, which are used for fine-tuning the adapter in the next step. Finally, $\tilde{D}_{Q\&A}$ is split into 80% for training ($\tilde{D}_{Q\&A,training}$) (7,226), 15% for validation ($\tilde{D}_{Q\&A,validation}$) (1,355), and 5% for testing ($\tilde{D}_{Q\&A,testing}$) (452). From $\tilde{D}_{Q\&A,testing}$ a total of 200 Q&A pairs are held-out (not used to evaluate the fine-tuning process) and used later in the validation section. Thus, $\tilde{D}_{Q\&A,testing}$ comprises 252 Q&A pairs.

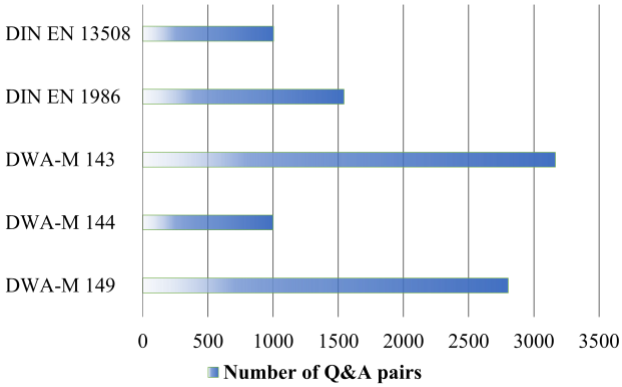

Figure 3: Number of Q&A pairs generated per standard series.

Phase 2: Fine-tuning the LLM

In the LLM selection step, which constitutes the first step of phase 2, two candidate LLMs are initially considered, namely DeepSeek-VL2 and Mistral-7B-Instruct-v0.2 because of multimodal processing and instruction-based text generation, respectively. DeepSeek-VL2 is a multimodal-vision LLM, considered due to the ability of the model to process visual inputs, such as CCTV data, figures from standards, and textual inspection reports. Mistral-7B-Instruct-v0.2 is an instruction-tuned LLM, designed for instruction following and structured text generation. Based on the criteria defined in step 1 of phase 2, the following rationale governs the selection of the LLM: While DeepSeek-VL2 provides a native multimodal processing, the parameter scale and hardware requirements needed for DeepSeek-VL2 exceed the available computational resources. By contrast, Mistral-7B-Instruct-v0.2 supports LoRA through open-source frameworks and enables efficient fine-tuning through libraries such as Hugging Face Transformers, supervised fine-tuning frameworks, and bitsandbytes, under constrained hardware conditions. As a result, the Mistral-7B-Instruct-v0.2 model is selected.

Fine-tuning (step 2 of phase 2) of the Mistral model is achieved via parameter-efficient LoRA. The Fine-tuning is conducted on a single NVIDIA RTX 4090 GPU. The baseline model, i.e. Mistral-7B-Instruct-v0.2, is loaded

using 4-bit NF4 with double quantization, while computations are carried out in bfloat16 to reduce memory consumption. Optimization is performed using the paged AdamW optimizer in 8-bit mode with a learning rate of $2 \cdot 10^{-4}$ and a linear learning-rate schedule. A warm-up phase covering 3% of the total training steps and a weight decay of 0.01 are applied. Training of the adapter is conducted using gradient accumulation to obtain an effective batch size of 32 token sequences, based on a per-device mini-batch size of four token sequences. Input sequences are packed to a maximum length of 2,048 tokens. The training process is configured for a maximum of three epochs, with gradient checkpointing enabled to reduce memory consumption. Moreover, early stop is applied once validation loss (from applying the $\tilde{D}_{Q\&A(validation)}$ dataset) fails to improve two consecutive times. As shown in Figure 4, the fine-tuning process converges to a stable state, with the validation cross-entropy loss stabilizing between 0.32 and 0.34 and the mean token accuracy reaching approximately 88%. The results of the fine-tuning indicate that a consistent and stable adaptation of the Mistral model to the domain-specific task of sewer systems maintenance.

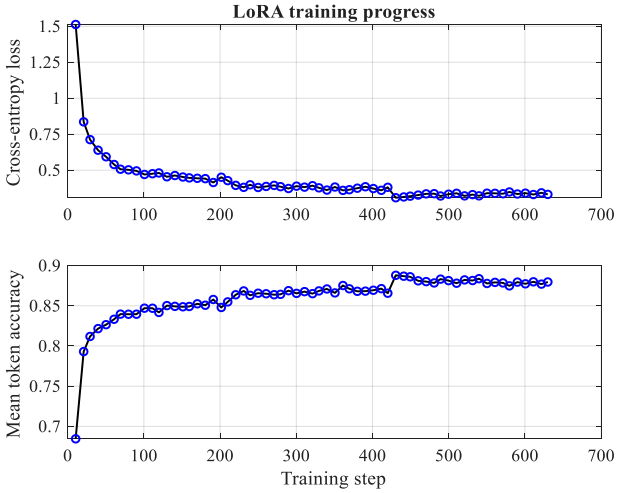

Figure 4. Performance of the LLM fine-tuning, in terms of cross-entropy loss and mean token accuracy.

In the final step, the dataset $\tilde{D}_{Q\&A(testing)}$ is used upon completing training to verify the accuracy of the fine-tuning process of the "adapted" Mistral model, based on the cross-entropy loss and the mean token accuracy, showcasing that 91.82% of the tokens have been correctly predicted. In the following section, the adapted Mistral model, i.e., the Mistral model equipped with the LoRA adapter, is validated and compared against a baseline Mistral model (Mistral-7B-Instruct-v0.2) without adapters.

Validation test

In this section, the RxM-LLM framework is validated by assessing the capabilities of the adapted Mistral model, developed in the implementation section, to interpret heterogeneous, multimodal inspection data, previously unseen, and generate detailed stepwise repair procedures of sewer systems maintenance. In the validation test, a total of 200 Q&A pairs are selected from a held-out dataset not used during fine-tuning. The Q&A pairs cover distinct damage scenarios, damage locations, and repair severity levels. Furthermore, answers generated by the adapted Mistral model are compared with those produced by a baseline Mistral model without adapters, thereby enabling an assessment of how well the adapted Mistral model fits to the domain of sewer systems maintenance.

Both the adapted Mistral model and the baseline Mistral model are evaluated using a domain-specific scoring rubric, which serves as the criterion for assessing the suitability of the models for sewer systems RxM. The scoring rubric is designed to capture requirements of sewer systems maintenance workflows and comprises the following criteria: (i) Structural clarity of responses, assessing whether answers are presented in stepwise and operationally executable formats; (ii) conformity with standards, evaluating explicit references to relevant repair and rehabilitation standards series; (iii) material and damage specificity, assessing the differentiation between pipeline materials (e.g., concrete, vitrified clay, polyvinyl chloride, and glass reinforced plastic) and common damage types (e.g., corrosion, root intrusion, and infiltration); (iv) actionability, evaluating the inclusion of repair and rehabilitation measures, such as CCTV inspection, high-pressure cleaning, injection grouting, short-liner techniques, or cured-in-place pipe lining; (v) consideration of safety and operational constraints, including confined-space entry, bypass pumping, and gas monitoring; (vi) verification and quality assurance measures, such as leak testing, deflection testing, post-rehabilitation CCTV inspection, or as-built documentation; (vii) numerical specificity, assessing the presence of quantitative information included in the repair and rehabilitation standards, such as tolerances or permissible deformation limits; and (viii) a hallucination penalty, applied to answers introducing non-domain-specific or implausible repair and rehabilitation procedures, such as irrelevant inspection technologies or incoherent procedural fragments. The scoring rubric quantifies the performance of each model on a scale from 0 to 10. The results of the validation test are presented and discussed in the following section.

Results and discussion

The quantitative performance of the both models for the 200 Q&A pairs is summarized in Table 1. The evaluation scores are computed using a LLL acting as a judge (LLM-as-a-judge), specifically GPT-5o, which assesses the generated responses based on the predefined rubric criteria introduced in the previous section. The baseline Mistral-7B-Instruct-v0.2 model exhibits an average score of 4.8/10 (±1.2), reflecting frequent fragmentation and limited actionability despite occasional references to standards. Meanwhile, the adapted Mistral model has achieved a higher overall performance with an average score of 7.6/10 (±1.0). The adapted Mistral model demonstrates a strong domain specificity and structural clarity, with correct material and damage references present in 71% of responses.

Table 1: Performance of the adapted Mistral model as well as the baseline Mistral model for the 200 Q&A pairs

Model	Score (1-10)	Standard deviation
Baseline Mistral model	4.8	±1.2
Adapted Mistral model	7.6	±1.0

In addition, more than 65% of the outputs generated by the adapted Mistral model, included at least three distinct repair and rehabilitation measures. A detailed breakdown of the performance of the two models across the individual evaluation criteria, mentioned above, is illustrated in Figure 5.

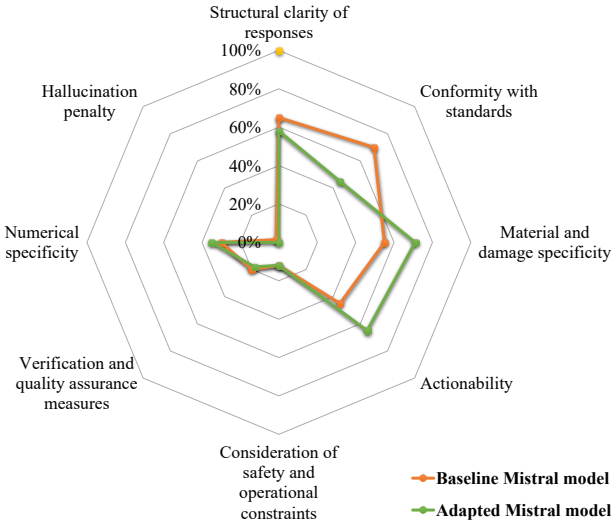

Figure 5. Performance of the two models, based on individual criteria.

Finally, to qualitatively illustrate differences between the baseline Mistral model and the adapted Mistral model, an exemplary prescriptive maintenance query is evaluated across both models. The example addresses the rehabilitation of radial cracks in vitrified clay pipes using short glass-fiber liners, representing a typical maintenance task that requires material awareness, damage-specific repair selection, and operational sequencing. The responses generated by both models are shown in Figure 6.

The baseline Mistral model demonstrates general instructional capability but lacks the technical insight required for RxM of sewer systems. The responses generated by the baseline Mistral model remain abstract and primarily describe general principles rather than actionable procedures. In addition, in outputs generated by the baseline Mistral model, damage-repair coupling is weak, and outputs frequently lack material-specific adaptation and operational details. Furthermore, stepwise repair procedures execution is incomplete, and references to safety measures and quality assurance are often omitted. Finally, the baseline Mistral model provides a superficial overview of repair and rehabilitation concepts without sufficient procedural specificity, rendering the output unsuitable for real-world RxM applications of sewer systems.

The adapted Mistral model shows a clear improvement over the baseline Mistral model, driven by damage-repair mappings introduced through structured fine-tuning. The outputs generated by the adapted Mistral model demonstrate strong alignment with technical procedures and high domain awareness. Furthermore, the adapted Mistral model generates detailed, stepwise repair and rehabilitation procedures, and consistently accounts for sewer pipes material, defect types, and conditions severity. In addition, the adapted Mistral model produces outputs resembling technical repair and rehabilitation reports rather than generic advisory text. In addition, repair and rehabilitation techniques such as cured-in-place pipe lining, short-liner installation, robotic sealing, injection grouting, packer-based repairs, and reinstatement are frequently and appropriately referenced. The adapted Mistral model exhibits accurate matching between damage mechanisms and repair methods, indicating strong alignment with sewer systems repair and rehabilitation practices.

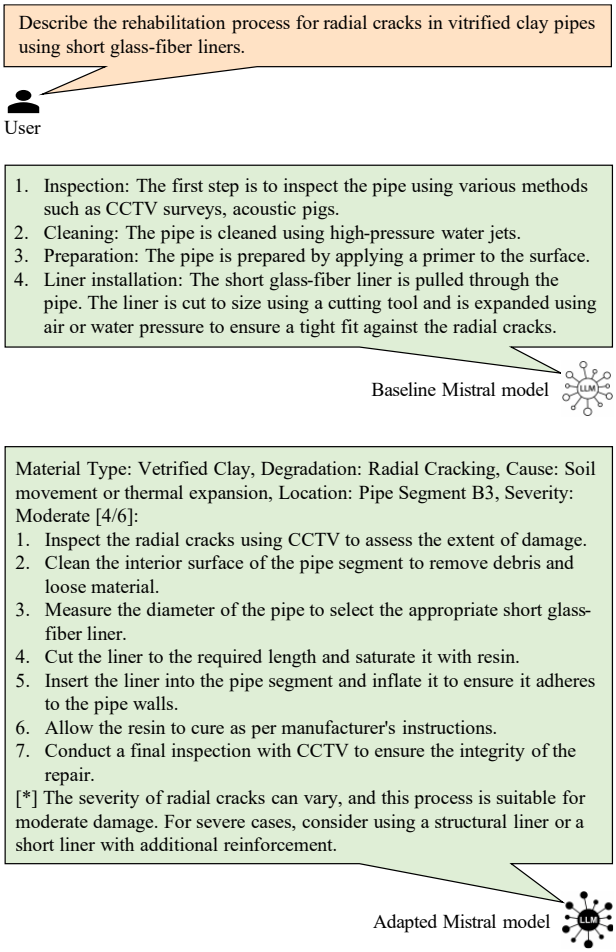

Figure 6: Example conversation of a user with the baseline Mistral model and the adapted Mistral model.

Summary and conclusions

Sewer systems constitute urban infrastructure critical for public health, environmental protection, and flood prevention. Sewer systems maintenance is vital to ensure long-lasting, healthy, and functional infrastructure.

However, decision-making in sewer systems maintenance has failed to effectively interpret heterogeneous and multimodal inspection data into actionable maintenance strategies. This paper has presented a prescriptive maintenance framework, in which, a pre-trained large language model has been adapted to the domain of sewer systems maintenance. The RxM-LLM framework comprises two phases, (i) preparing the fine-tuning dataset, and (ii) fine-tuning the LLM, and it has been implemented based on sewer systems standards defined under the DIN EN and DWA standards. In the implementation of the RxM-LLM framework, a generation prompt based on the ChatGPT-4o-mini model has been employed to generate document-level summaries for each standard. Thereupon, the summaries, together with a domain-specific schema, have been used to constrain downstream generation prompts for producing structured Q&A pairs. The dataset has served as an input for low-rank adaptation fine-tuning of the Mistral-7B-Instruct-v0.2 model. In the validation test, capabilities of the adapted Mistral model in interpreting heterogeneous, multimodal inspection data, and generate detailed stepwise repair procedures of sewer systems maintenance have been evaluated and compared to a baseline Mistral model. The validation test results has shown that the adapted Mistral model outperformed the baseline Mistral model. The adapted Mistral model has demonstrated enhanced structural clarity, consistently generating material-aware, damage-specific, and actionable repair and rehabilitation procedures. The results have demonstrated that adapter-based fine-tuned LLMs are capable of correctly interpreting heterogeneous and multimodal inspection data and recommend stepwise repair procedures, thus supporting decision-making in sewer systems maintenance. Future work may involve further developing the RxM-LLM framework to improve uncertainty handling and additional validation tests using real-world sewer systems inspection data.

FAST-ASSET: A REAL TIME SCAN-TO-3D POINT CLOUD BIM-READY ASSET GENERATION METHOD FOR SMALL MEP ELEMENTS

Urueña, Asier[1]; Eskudero, Ibon[1]; Sagasti, Diego[1]; and Noyé, Sarah[1]
[1]FUNDACION TECNALIA RESEARCH & INNOVATION, Spain

Abstract

Building Information Modeling (BIM) requires timely as-is updates, but existing scan-to-BIM pipelines based on laser scanning or photogrammetry demand specialised hardware and offline processing, limiting frequent small-asset updates in digital-twin maintenance. This paper introduces Fast-Asset, a real-time on-site framework integrating mixed-reality capture, learning-based detection, and incremental 3D reconstruction to generate BIM-ready, pre-segmented point clouds of small MEP assets in a single walkthrough. Instant visual feedback enables in-situ validation and re-capture. Experiments demonstrate a 3-to-10× reduction in capture-to-model time versus laser scanning and photogrammetry, with comparable surface roughness and low background contamination, collapsing multi-stage offline processes into a single field operation.

Introduction

Building Information Modeling (BIM) has become the digital backbone of the construction value-chain, linking design, construction, and facility-management activities (Yilmaz et al., 2023). Although owners increasingly rely on BIM for digital-twin services such as life-cycle assessment, operation, inspection, and predictive maintenance (Boje et al., 2023), most legacy models only reflect the as-designed state. Reality inevitably diverges from design during construction, refurbishments and operation, so decision-makers need rapid, low-cost updates of the as-built geometry and semantics (Wijeratne et al., 2023). Within the digital-twin lifecycle, keeping the virtual replica synchronised with the physical asset is essential for reliable monitoring and maintenance. Yet the cost of re-scanning makes frequent synchronisation impractical for small components. By enabling decentralised, operator-driven model updates, frameworks such as the one proposed in this paper can reduce dependency on specialist surveying teams and shorten the governance cycle for BIM lifecycle management.

Obtaining such updates typically requires expensive static laser scanners or high-end LiDAR rigs, specialist crews, and a multi-day offline processing chain (cleaning, registration, segmentation and modelling). When only a few small industrial assets (valves, pumps, switch-gear, etc.) need to be captured, the cost and latency of conventional scan-to-BIM workflows become prohibitive.

Research over the last decade has gradually shifted from heavy terrestrial laser scanning toward lighter, hybrid capture solutions and from fully manual pipelines to increasingly automated ones.

Scan-to-BIM automation. Automated pipelines that generate semantically labelled point clouds from large-scale scans have reached centimetre-level accuracy for transportation assets (Ding et al., 2024). For construction, guides exist for the integration of such scans into BIM. However, these approaches still rely on bulky LiDAR devices and require offline processing on workstations or cloud servers.

Point-cloud generation and completion. Early efforts focused on reconstructing dense surfaces from laser data. Recent work targets the completion of sparse, noisy data captured with consumer-grade depth sensors. Deep generative models can hallucinate missing geometry, yet they demand offline GPU-based training and inference that is unsuitable for field deployment (Zhuang et al., 2024).

Small-object capture. The literature distinguishes between detecting small assets and generating high-fidelity point clouds for them. Abreu et al. (2023) review scan-to-BIM pipelines and conclude that procedural modelling is essential for objects below 0.1 m. Building on this insight, Pan et al. (2022) combine terrestrial LiDAR with AI-guided photogrammetry to enrich digital twins with sockets, switches and fire-safety fixtures, achieving sub-15 mm accuracy in under three minutes per room. Chen et al. (2023) further demonstrate depth-completion networks that reconstruct fine steel rebars (≈ 20 mm diameter) from multi-view stereo, highlighting the demand for methods that preserve small-object topology.

Mixed-reality capture. Head-mounted devices equipped with RGB-D sensors (e.g., Microsoft HoloLens 2) provide real-time spatial mapping, on-device inference and intuitive visual feedback (Navares-Vázquez et al., 2023). These platforms enable operators to place semantic tags in situ, reducing segmentation error to 2.4 ± 1.8 cm. Nevertheless, the raw point clouds remain cluttered and three-dimensional object detection is still computationally demanding; most approaches still require a desktop step to export IFC-ready geometry.

Detection and segmentation of tiny objects. Clustering-based methods such as adaptive DBSCAN can improve recall for small targets in low-density point clouds (Duan et al., 2024), but they do not integrate with mixed-reality

capture hardware. Lightweight 2D detectors (YOLO family) have proven effective for real-time proposal generation, yet their translation to 3D segmentation remains an open research question.
Despite these advances, three critical gaps prevent a truly on-site, real-time *as-is* BIM update for small-scale MEP components:

1. **On-device processing.** Existing pipelines either offload point-cloud cleaning and segmentation to a workstation or require GPU clusters, contradicting the goal of a single-walkthrough workflow.
2. **Small-object focus.** Methods that achieve sub-centimetre accuracy for tiny assets generally depend on multi-view acquisition or heavy LiDAR, and they rarely produce asset-level point clouds that are already semantically linked to BIM entities.
3. **Immediate usability.** Current mixed-reality tools improve semantic tagging but still require a post-processing stage to obtain a clean, exportable model, delaying the availability of up-to-date information at the construction site.

These limitations hinder the adoption of scan-to-BIM technology in time- and cost-sensitive contexts where maintaining up-to-date digital twins is critical for operational decisions and maintenance planning.
To address those limitations, this paper introduces Fast-Asset, a modular, real-time framework for generating clean, segmented 3D point clouds of small assets directly on site. Fast-Asset integrates four tightly coupled stages:

1. **Live RGB-D capture** that maintains a globally consistent pose while the operator scans the asset.
2. **Lightweight 2D detection** to produce per-frame object masks and class predictions.
3. **Incremental point-cloud fusion**, where masked depth data are merged into clean, class-labelled point clouds whose centroids are verified in situ.
4. **Instant export** of each segmented cloud together with metadata (type, instance ID, acquisition time) ready to be converted to an IFC-compliant schema.

The contribution of the Fast-Asset framework is that the operator receives instant visual feedback on every capture and can re-scan if necessary, reducing revisits and manual post-processing. Because every asset is captured, validated and geo-referenced during a single walkthrough, facility managers can import the generated model snippets directly into the master BIM and obtain an *as-is* representation without manual cropping, registration or annotation. The paper evaluates Fast-Asset against photogrammetric and laser-scanned baselines with respect to both capture-to-model time and geometric accuracy, using intrinsic surface-quality indicators to benchmark lightweight scan-to-BIM systems. By collapsing a multi-day laser-scan and modelling loop into a single on-site operation, Fast-Asset extends recent small-object enrichment approaches such as (Pan et al., 2022) and learning-based completion pipelines such as Chen et al. (2023).

Methodology

General approach

Fast-Asset is a modular, real-time scan-to-asset framework whose pipeline (Figure 1) divides the process into independent yet connected phases: capture, alignment, detection, reconstruction and cleaning. Each block can be updated or swapped without redesigning the rest, ensuring continued relevance as sensors, algorithms or standards evolve.
Unlike laser scanning or deep-learning reconstructions that produce dense scene-wide point clouds requiring costly post-processing, Fast-Asset fuses RGB and depth images to combine scanning and segmentation in a single, lightweight step executable in real time, avoiding the computational burden of techniques such as NeRF or Gaussian splatting and the cost of high-precision hardware.

Framework phases

Built environment capture

The capture phase acquires aligned RGB and depth images to build an RGBD representation of the target asset. While laser scanners provide high accuracy, they are slow and expensive; standalone RGB cameras are affordable but lack native depth. Fast-Asset proposes a device-based capture framework with a built-in depth sensor that delivers pre-aligned RGBD frames, although it could be replaced by any source of RGBD imagery, including monocular depth estimation.

2D-3D alignment

Fast-Asset relies on sensor fusion from a head-mounted device with factory-calibrated RGB and depth sensors, yielding pre-aligned RGB-D frames and eliminating costly software-based 2D-3D alignment required in prior work. Given the depth camera intrinsics $\mathbf{K}_d$ and the extrinsic transform $[\mathbf{R} \mid \mathbf{t}]_{d\to\mathrm{rgb}}$, each depth pixel (u_d, v_d) with depth d is first back-projected into 3D in the depth sensor frame and then mapped to the RGB image plane via the RGB intrinsics $\mathbf{K}_{\mathrm{rgb}}$:

$$\mathbf{p}_d = d\,\mathbf{K}_d^{-1}\begin{bmatrix} u_d \\ v_d \\ 1 \end{bmatrix}, \quad \mathbf{p}_{\mathrm{rgb}} = \mathbf{R}\,\mathbf{p}_d + \mathbf{t} \tag{1}$$

IMU measurements compensate for head motion and maintain temporal synchronisation, so each RGB-D frame remains geometrically consistent for subsequent reconstruction (Dibene and Dunn, 2022).

Asset identification

The proposed method relies on 2D deep-learning detectors to recognise assets on RGB images rather than on 3D point clouds, providing three advantages: (i) lighter computation enabling real-time segmentation, (ii) faster and

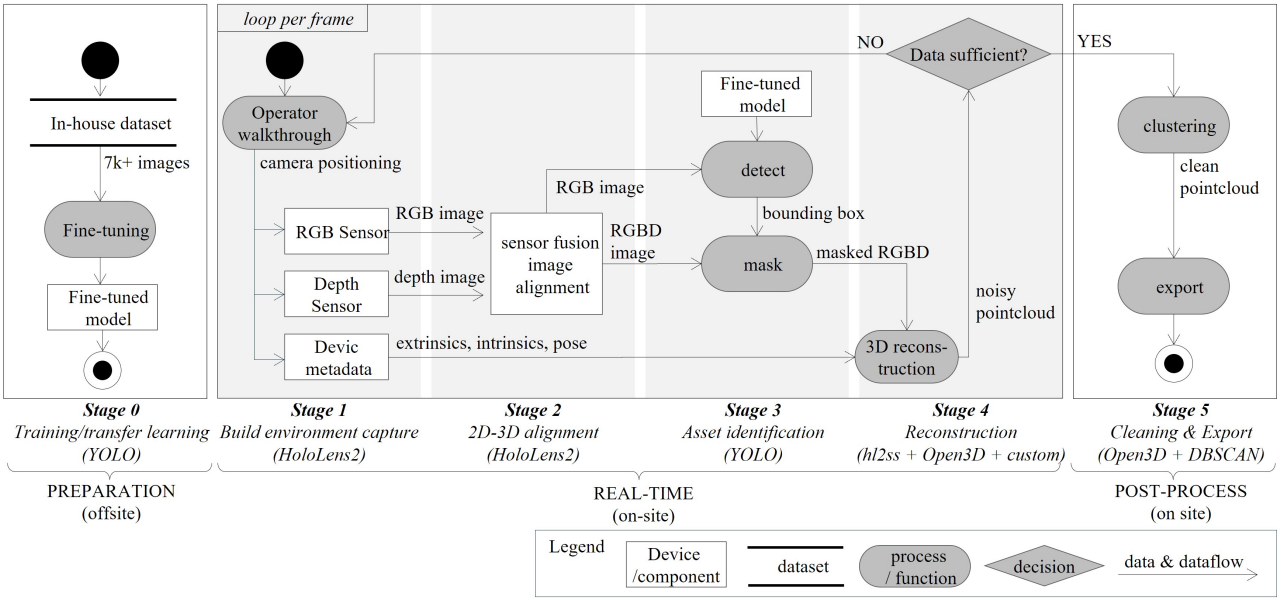

Figure 1: Framework overview showing needed devices/elements and needed tasks for each stage

cheaper dataset creation thanks to 2D image annotation labeling, and (iii) reuse of existing image-based models via transfer learning. By leveraging pre-trained weights from foundation models, the system can be adapted to new asset classes with minimal retraining effort.

Reconstruction

The system operates on a temporal sequence of frames $\{(\mathbf{I}_t, \mathbf{D}_t, \mathbf{T}_t, \mathbf{M}_t)\}_{t=1}^{T}$, where $\mathbf{I}_t$ is the RGB image, $\mathbf{D}_t$ the depth map, $\mathbf{T}_t \in SE(3)$ the camera pose and $\mathbf{M}_t$ the binary detection mask. For each masked pixel (u, v) with $\mathbf{M}_t(u, v) = 1$ and depth $d = \mathbf{D}_t(u, v) > 0$, a 3D point in the global frame is obtained as:

$$\mathbf{p}^w = \mathbf{T}_t \, d \, \mathbf{K}^{-1} \begin{bmatrix} u \\ v \\ 1 \end{bmatrix} \tag{2}$$

The fused point cloud is the union $\mathscr{P} = \bigcup_t \{\mathbf{p}_{t,i}^w\}$, aggregating partial views from multiple viewpoints and progressively densifying the asset representation. The method merges per-frame contributions without explicit overlap validation, deferring class-based filtering to the cleaning phase.

Cleaning

A dedicated cleaning module eliminates noise, artefacts and background geometry. In the current implementation, DBSCAN (Ester et al., 1996) clusters the fused cloud by defining a point $\mathbf{p}$ as a *core point* when its ε-neighbourhood $N_\varepsilon(\mathbf{p}) = \{\mathbf{q} \in \mathscr{P} : \|\mathbf{p} - \mathbf{q}\| \leq \varepsilon\}$ contains at least *MinPts* neighbours. Mutually density-reachable core points are grouped into clusters and only the largest cluster is retained as the final asset representation, discarding isolated noise points and spurious blobs. The parameters ε and *MinPts* are set proportionally to the median nearest-neighbour distance of the cloud, ensuring robustness across varying scan densities. The module can be adapted to specific asset types or detection models with varying false-positive rates.

Taken together, these phases provide a complete specification of the Fast-Asset framework, from data capture to BIM-ready point-cloud output. The different phases could be updated with improved technologies without altering the framework.

Implementation

Overview

The implementation performed couples live RGB-D capture from a Microsoft HoloLens 2, a YOLOv7-based detector fine-tuned for switches and outlets, and a Python back-end that performs incremental point-cloud fusion and clustering with Open3D. As the operator walks through the room, detections are streamed, masked depth is converted to 3D points and fused into a single, segmented point cloud for each target object. At the end of a short walkthrough, the operator receives a cleaned point cloud per asset, exported as `.pcd` for further BIM integration. The four main stages of this workflow (training, capture, streaming+detection, and reconstruction+cleaning) are summarised in Figure 2.

Hardware and capture setup

All experiments were run using a mobile mixed-reality device and a standard workstation. The processing machine was a Dell Precision-class laptop with an Intel Core i7 CPU, 32 GB RAM, SSD storage and a mid-range NVIDIA GPU. These specifications represent a realistic configuration for on-site or near-site processing in construction projects.

Microsoft HoloLens 2 was used as the capture device. It integrates an RGB camera and a long-range depth sensor with factory calibration, providing aligned RGB-D frames

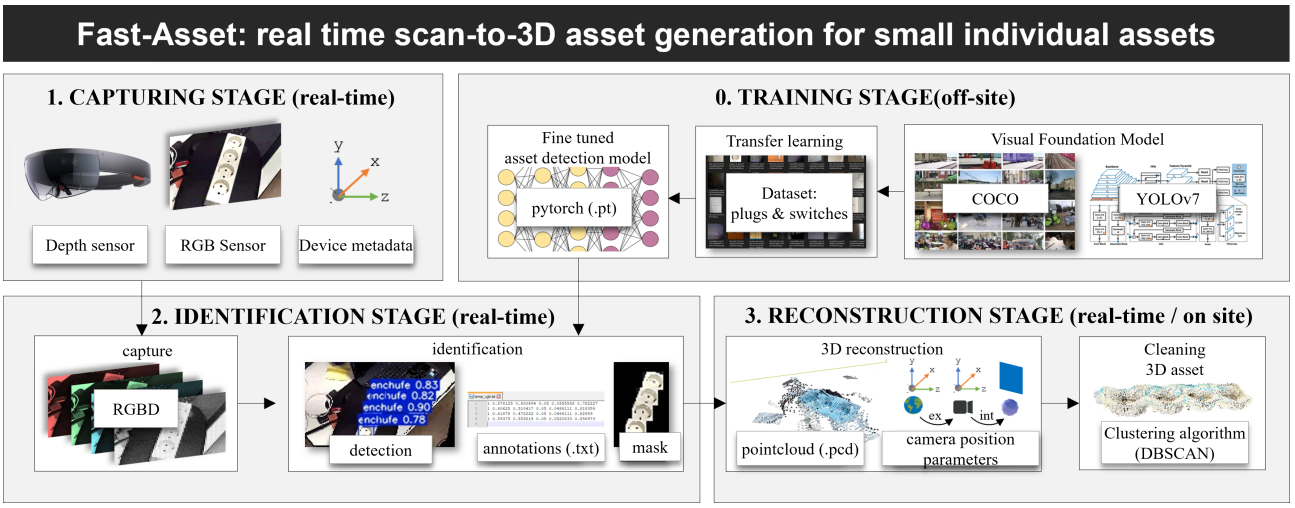

Figure 2: Implemented architecture for streaming detection and point-cloud segmentation

in real time as the user moves. Only the front RGB camera and the long-throw depth sensor were used, while other sensors (IMU, eye tracking, etc.) were leveraged implicitly by the HoloLens runtime for pose estimation but did not require explicit handling in our code. The device was connected to the laptop via WiFi in a shared local network, streaming RGB, depth and pose information through the `hl2ss` library (Dibene and Dunn, 2022). This configuration mirrors the intended deployment context of Fast-Asset, in which an operator walks through a facility with a head-mounted device and offloads the heavier processing to a nearby computer.

Software stack

The implementation was developed in Python 3.10. The HoloLens sensor streams were accessed through the open-source `hl2ss` project, which exposes RGB and depth frames together with camera intrinsics and extrinsics in a client–server setup. YOLOv7 was selected as the object-detection backbone because it combines real-time performance with good accuracy on embedded and edge devices. The publicly available COCO-pretrained weights (Lin et al., 2015) were used as a starting point and then fine-tuned via transfer learning for the target classes (outlets and switches). Open3D (Zhou et al., 2018) was used as the 3D processing back-end, providing utilities for RGB-D handling, point-cloud generation, incremental fusion and visualization. For point-cloud cleaning, we relied on the DBSCAN clustering algorithm (Ester et al., 1996) as implemented in Open3D, retaining only the densest cluster to discard background noise and stray points.
The three-component stack (YOLOv7, `hl2ss`, Open3D) keeps external dependencies minimal, making the implementation straightforward to deploy on different machines or to adapt to alternative detectors and capture devices.

Dataset and transfer learning

The detector focuses on two MEP-related classes: power outlets and light switches. A custom dataset was assembled to reflect realistic indoor conditions. First, 568 images of outlets and switches were captured by the research team in different environments (offices, corridors and homes), covering a variety of background textures, lighting conditions and mounting configurations.
To increase robustness and reduce annotation effort, an additional outlet-focused dataset was imported from the Roboflow platform. This contributed 2 263 base images plus augmented variants (rotations), resulting in a total of 6 789 external samples. Combined with the in-house images, the final dataset comprised 7 329 labelled images, of which 20 % were held out for validation. An example of the annotation format is illustrated in Figure 3, where each bounding box is stored as a class index and normalised coordinates in a YOLO-style text file.
Transfer learning on the combined dataset improved outlet detection recall from 64 % to 92 %, while switch detection remained above 80 % (Table 1). The detector also achieved mAP@0.5 = 0.902 (AP@0.5: 0.841 for switches, 0.962 for outlets). There were no inter-class false detections; only the background generated false positives or negatives. These values were considered sufficient to support real-time mask generation in the target use case.

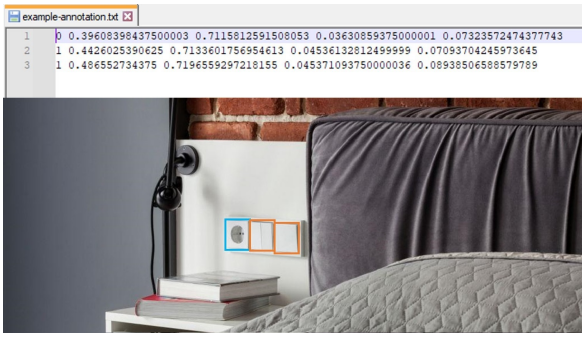

Figure 3: Example of annotations of one of the photographs, where three objects are detected and each line records the class index followed by normalised bounding-box coordinates in $[0, 1]$

Table 1: Normalized confusion matrix (Predicted vs. True).

		True		
		switch	power outlet	background FP
Predicted	switch	0.83	–	0.50
	power outlet	–	0.92	0.50
	background FN	0.17	0.08	–

Normalised per ground-truth class confusion–matrix values. FP false positives, FN false negatives. Computed at a fixed operating point (confidence ≥ 0.4, match IoU ≥ 0.5 after NMS) to reflect the real-time deployment setting and to balance false positives and missed detections while retaining the standard IoU$= 0.5$ matching criterion for a fair, interpretable per-class recall comparison.

Online processing pipeline

The end-to-end implementation follows the methodological stages described earlier but focuses on a practical, streaming-oriented design. For each RGB-D frame delivered by `hl2ss`, the following steps are executed:

1. **Capture and pre-processing.** The client receives an RGB image, a depth map and the current camera pose from the HoloLens 2. Basic consistency checks (resolution, timestamp) are performed, but no heavy pre-processing is required because the device already delivers aligned RGB and depth.
2. **2D detection.** The RGB frame is passed through the YOLOv7 model, which returns bounding boxes, class labels and confidence scores for each detected outlet or switch. Detections below a confidence threshold are discarded to reduce false positives.
3. **Masking and RGB-D construction.** For each retained bounding box, a binary mask is created and applied to the RGB and depth images, zeroing out background pixels. The resulting masked RGB-D frame isolates the candidate asset region while preserving depth information for the visible surfaces.
4. **Point-cloud generation and fusion.** For reconstruction, the masked RGB-D data, together with the camera intrinsics and pose, are back-projected into 3D following Equation 2 and merged into a single global point cloud using Open3D. Multiple viewpoints gradually densify the representation.
5. **Real-time visualization.** An optional Open3D visualizer displays the aggregated point cloud and updates it as new frames arrive. This provides visual feedback so the operator can decide whether additional passes are required to fill occlusions or refine details.

This streaming loop runs continuously while the user scans the environment. Since detection and fusion are relatively lightweight, they can keep up with the HoloLens frame rate on the chosen hardware, enabling an interactive experience: the operator sees both 2D detections and a growing 3D reconstruction within seconds. The timing and resolution metrics obtained from this implementation are later summarised and compared with laser scanning and photogrammetry.

Cleaning and export

Raw fused point clouds inevitably contain residual noise from imperfect detections, depth artefacts and background geometry that slipped through the masks. To obtain a compact, BIM-ready representation, a final cleaning step is applied to each asset-level cloud. In our implementation, DBSCAN clustering is used to segment the cloud into dense regions and outliers. Only the largest, most coherent cluster is retained as the final asset representation, removing isolated points and small spurious blobs around the target object.

The cleaned point cloud is then exported as a `.pcd` file together with basic metadata such as the detected class, a unique instance identifier and the acquisition timestamp. This format can be consumed directly by downstream tools for meshing, parametric fitting or IFC element creation, for instance, by fitting a bounding geometry to the cloud, assigning an `IfcBuildingElementProxy` type and writing the result via IfcOpenShell. In parallel, the implementation logs timing information for the main stages (detection, fusion, cleaning) and the total number of points, enabling quantitative comparison with alternative workflows.

This implementation demonstrates the Fast-Asset concept in practice: small MEP assets can be detected, reconstructed and exported as clean point clouds within a single, short walkthrough, without requiring heavy post-processing or specialised scanning equipment.

Results and discussion

The proposed Fast-Asset workflow was compared against two widely used scan-to-point-cloud baselines, terrestrial laser scanning and photogrammetry, on two representative objects: a power strip, chosen as a typical MEP component that is normally absent from image-based models and a computer keyboard, included as a control object for our transfer-learning pipeline since it is a standard category in COCO-trained YOLO detectors (class ID66). Both objects are medium-sized, abundant in indoor environments and share key traits with typical MEP components: small footprint, surface-mounted installation and prismatic geometry with recesses and holes. Their matte materials avoid specular reflections that hinder photogrammetry and their working distance ($< 2\,\mathrm{m}$) lies within the effective

range of HoloLens 2, making them suitable proxies for everyday BIM-relevant assets.

Time and workflow analysis

Table 2 summarises the scan time, generation time, total time and point-cloud resolution for all combinations of method and object. Laser scanning (Leica P40) required 17 min 30 s per object, yielding dense but unsegmented clouds (≈690k and 659k points). Photogrammetry was run from the same HoloLens 2 captures. While it produced highly detailed models (1.1M–3.0M points), processing times ranged from 4 min to over 50 min and the resulting point clouds include extensive background geometry without semantic segmentation. By contrast, Fast-Asset fixed the scan duration to one minute (to simulate realistic short walkthrough) and performed detection, fusion and cleaning online, yielding total times of 4 min 45 s to 6 min 24 s with pre-segmented, asset-level point clouds. Figure 4 qualitatively illustrates these effects. Photogrammetry and laser scanning retain large amounts of background geometry, requiring post-segmentation, whereas Fast-Asset delivers a pre-segmented cloud concentrated on the target asset.

Geometric quality analysis

Geometric quality is evaluated through two complementary lenses: (i) *cross-method distance metrics* between Fast-Asset and photogrammetry, which share identical acquisitions, using photogrammetry as a dense-reconstruction baseline; and (ii) *intrinsic quality indicators* that characterise each method's reconstruction fidelity independently of a reference model. All point clouds were normalised to a unit bounding-box diagonal before analysis.

Table 3 reports four intrinsic quality indicators computed on the normalised point clouds. **Surface roughness** measures the local planarity residual via PCA on k-neighbourhoods; values of 0.001–0.005 across all methods confirm that all three produce geometrically smooth surfaces, with Fast-Asset achieving the lowest roughness for the power strip (0.0011) and comparable values for the keyboard (0.0033 vs. 0.0026–0.0032). **Normal consistency** reflects how uniformly surface normals are oriented among neighbours. Laser scanning yields the most consistent normals (12–17°), as expected from a high-precision sensor, while Fast-Asset shows higher angular variance (21–30°). This gap reflects the lower spatial resolution of the HoloLens 2 depth sensor relative to laser optics—a hardware constraint, not a pipeline limitation; adopting a higher-resolution depth camera would directly reduce this deviation. **Background ratio** quantifies the proportion of points classified as outliers by statistical outlier removal, serving as a proxy for segmentation effectiveness. Fast-Asset achieves the lowest background for the power strip (1.4 % vs. 3.8–4.1 %), confirming that YOLO detection combined with DBSCAN cleaning effectively suppresses irrelevant geometry; for the keyboard, the moderately higher ratio (5.0 %) results from bounding-box over-inclusion in the denser scan and is readily removable via tighter post-filtering. **Density uniformity** (CV of k-NN distances) shows Fast-Asset achieving the best uniformity for the keyboard (CV = 0.14 vs. 0.16–0.23 for the baselines); the elevated CV for the power strip (1.14) reflects fewer contributing viewpoints during the one-minute scan, addressable through longer or guided acquisition. Overall, Fast-Asset is competitive with the baselines on surface smoothness and excels on at least one object per segmentation-related indicator, while the lower normal consistency is a predictable trade-off of real-time portable capture that does not compromise suitability for BIM-level asset documentation.

Cross-method comparison between Fast-Asset and photogrammetry (both acquired from the same HoloLens 2 session) yielded a normalised RMSE of 0.007 (0.7 % of the object diagonal) and a mean point-to-point distance of 0.006 for the power strip after ICP registration. The keyboard comparison produced a higher RMSE (0.167), partly attributable to cluster-extraction difficulty when isolating the object from the dense photogrammetric cloud. The power-strip result, where cluster extraction was more reliable, therefore provides the more representative accuracy estimate and confirms that the real-time pipeline preserves surface geometry comparable to offline reconstruction, with deviations well within typical BIM tolerance thresholds for small MEP elements.

Error propagation and failure modes

The pipeline performance depends on the accuracy of the 2D detection stage: false positives introduce background fragments into the fused cloud, while missed detections cause incomplete coverage. DBSCAN cleaning mitigates part of these errors by discarding small, isolated clusters; however, when a false detection overlaps spatially with the true asset, the spurious geometry is merged into the main cluster and cannot be removed without additional validation. Conversely, systematic under-detection (e.g. due to occlusion or unusual viewpoints) reduces the surface completeness of the reconstruction. The confusion matrix (Table 1) shows that inter-class misclassification is absent in the current model, so error propagation is limited to background false positives and missed detections against background, both of which have bounded impact on the final asset geometry. Future work could mitigate these issues through multi-view detection consistency checks, 3D instance segmentation to produce tighter masks than bounding boxes, and frame-level ICP validation to reject geometrically inconsistent contributions before fusion.

Scalability

In its current form, Fast-Asset processes one asset class per walkthrough, but the architecture supports multi-class parallel detection because YOLOv7 already outputs bounding boxes for all trained classes simultaneously. Extending to multi-asset environments requires maintaining one fused cloud per detected instance and associating new

Table 2: Scanning time, generation time, total time and point-cloud resolution for the three tested methods.

Methods	Scan time	Generation time	Total time	Total points	
Laser scanner	Keyboard	00:03:30	00:14:00	00:17:30	690 309
Photogrammetry[1]	Keyboard	00:01:00	00:03:02	00:04:02	1 147 792

Laser scanner	Power strip	00:03:30	00:14:00	00:17:30	659 489
Photogrammetry[1]	Power strip	00:01:00	00:49:21	00:50:21	2 955 940
Fast-Asset[2]	Power strip	00:01:00	00:03:45	00:04:45	38 852

[1] Photographs were provided from the HoloLens experiment.
[2] For Fast-Asset, the 3D asset is generated in scan-time, which could be reduced. Generation time can be parallelized with sequential scanning tasks.

Figure 4: Resulting model point clouds using photogrammetry, laser scanner and the proposed method

detections with existing instances via spatial proximity in the global frame. Since detection and back-projection are per-frame operations whose cost is independent of the number of accumulated instances, the system scales linearly with the number of frames rather than with the number of assets, making it suitable for room-level deployments with tens of small objects.

Limitations

The current experiments focus on two objects within the optimal range of HoloLens 2. While the keyboard is not itself an MEP component, pairing it with a power strip allowed us to evaluate both transfer learning on a well-represented class and adaptation to a category absent from standard image models, demonstrating the feasibility of extending Fast-Asset to new asset types. Nonetheless, the choice of proxy objects does not fully capture the diversity of installed MEP components. Generalising to larger assets or full rooms will require multi-scale strategies, additional object categories and tests in operational environments. A rigorous comparison of acquisition cost, training effort and on-site ergonomics is also outside the scope of this paper.

Despite these caveats, the results confirm that Fast-Asset substantially reduces the overall scan-to-BIM time, achieving 4-6 min per asset versus 17–50 min for conventional methods, while delivering pre-segmented, geometrically adequate point clouds with integrated real-time feedback, modular architecture and low background contamination.

Conclusion

The proposed Fast-Asset method produces clean, pre-segmented point clouds of small objects with surface roughness comparable to laser scanning and photogrammetry while reducing total capture-to-model time by a factor 3 to 10 and enabling real-time on-site model generation. For low- to medium-resolution, real-time scanning of individual assets, Fast-Asset better matches practical requirements than conventional approaches. Laser scanners are optimised for large environments and lose efficiency at close range, while photogrammetry, although capable of high-resolution output, lacks real-time feedback and requires offsite reconstruction. In contrast, Fast-Asset generates and visualises a segmented model during acquisition and automates subsequent cleaning once sufficient detail is reached. The geometric quality analysis confirms that the method achieves low background contamination and surface roughness on par with established techniques, while the lower normal consistency, attributable to the depth-sensor resolution rather than the pipeline itself, represents an acceptable trade-off for asset-level BIM updates, supporting shorter governance cycles in which

Table 3: Intrinsic geometric quality indicators for all three methods (unit-normalised point clouds).

Method	Object	Roughness[a]	Normal consist.[b]	Background[c]	Density CV[d]
Laser scanner	Keyboard	0.0026	16.8°	3.0 %	0.16

Fast-Asset	Power strip	0.0011	30.0°	1.4 %	1.14

[a] Mean PCA planarity residual (σ): lower values indicate smoother local surfaces.
[b] Mean angular deviation between neighbouring normals: lower values indicate more consistent surface orientation.
[c] Percentage of points classified as outliers by statistical outlier removal (SOR, k=20, α=2).
[d] Coefficient of variation of local k-NN distances: lower values indicate more uniform point density.

non-specialist operators can maintain the digital twin autonomously.

Future work will focus on improving detection robustness and extending applicability. Expanding and refining the dataset, including negative examples, is expected to improve recall and precision. Extending the pipeline to fully multiclass, parallel processing and integrating advanced segmentation models are also planned. Additionally, a full point-cloud-to-IFC conversion workflow, fitting parametric primitives to the cleaned clouds and exporting them via IfcOpenShell, will be developed to close the gap between BIM-ready point clouds and native BIM elements. In-situ visual guidance via headset display and evaluation on wall-mounted MEP fixtures in operational environments are further planned extensions.

Abstract

Digitising existing buildings supports energy-efficient retrofitting and lifecycle analysis, yet many are documented only by legacy drawings with dimensions embedded as textual annotations. Existing methods often rely on heuristic global scaling over metric fidelity. This paper presents a vision-based framework integrating optical character recognition (OCR), OCR-guided denoising, semantic segmentation, and grid-based alignment. The primary contribution is a cross-modal text–geometry alignment strategy that reconstructs a metric reference grid from annotations and links it to building geometry. A second contribution is an Industry Foundation Classes-based evaluation framework. Results demonstrate reliable recovery of absolute dimensions for dimension-aware BIM reconstruction.

Introduction

The building sector accounts for nearly 40% of global energy consumption (El Hafdaoui et al., 2023), highlighting the need to rapidly digitise existing building stock for energy-efficient retrofits, structural analysis, and lifecycle applications. Many advanced architecture, engineering, and construction (AEC) workflows rely on semantically rich and geometrically precise building information models (BIMs) (Schönfelder et al., 2023). However, most existing buildings predate BIM adoption and are documented primarily by legacy two-dimensional (2D) floorplan drawings (Lu and Lee, 2017). These drawings contain critical geometric, semantic, and dimensional information. Consequently, automated 2D-to-BIM reconstruction has become an important research topic (Lim et al., 2018).

Typical 2D-to-BIM pipelines involve floorplan analysis followed by BIM instantiation. While BIM generation can often be handled deterministically once reliable inputs are available, the floorplan analysis stage remains challenging. Many existing methods prioritise topological correctness over engineering-level geometric precision, often relying on heuristic global scaling or normalised coordinates that are insufficient for millimetre-sensitive BIM reconstruction (Wang and Pajarola, 2025).

Achieving engineering-grade precision requires not only detecting walls and openings, but also correctly interpreting dimensional annotations and associating them with the corresponding building geometry. This task is difficult because engineering drawings contain diverse drafting conventions, rotated or occluded texts, and annotation-induced noise (Pizarro et al., 2022).

Existing studies often assume that relative geometry is sufficient or use annotations only for coarse scale estimation, without establishing explicit component-level correspondences between dimension texts and building elements (Lee et al., 2025). Moreover, reconstruction quality is usually assessed with computer-vision-oriented metrics such as intersection over union (IoU), which are insensitive to millimetre-level geometric deviations. As a result, a model may appear visually correct while remaining inadequate for engineering use.

To address these limitations, this paper proposes an automated framework for dimension-aware 2D-to-BIM reconstruction from annotated raster floorplans. Its primary methodological contribution is a cross-modal text–geometry alignment strategy that reconstructs a metric reference grid from dimensional annotations and links it to segmentation-derived architectural geometry at the component level. Its second main contribution is an IFC-based evaluation framework for engineering-level assessment of reconstruction quality at the object and parameter level.

Related work

Research on 2D-to-BIM reconstruction for existing buildings generally follows a two-stage paradigm: (1) automated floorplan analysis, which extracts geometric and semantic information from legacy drawings, and (2) BIM instantiation, which converts these extracted entities into structured, parameterised building components. BIM instantiation is relatively mature and can often be handled deterministically once reliable inputs are available, using commercial platforms, programmatic APIs, or open-standard libraries (Lu et al., 2020). As a result, the main technical divergence among existing 2D-to-BIM approaches lies in floorplan analysis, where drawing format, quality, and interpretation strategy strongly affect reconstruction accuracy and robustness.

The performance of automated floorplan analysis is influenced by drawing format. Vector-based CAD drawings preserve editable information such as layers, blocks, and dimension objects, enabling rule-based or API-driven methods to achieve high-fidelity geometric reconstruction and component classification (Zhao et al., 2021). However, in practical engineering contexts, access to native CAD files is often restricted by software

dependencies, version incompatibilities, or confidentiality constraints (Dixit et al., 2019). As a result, floorplans are more commonly exchanged as raster images, such as scanned PDFs, which irreversibly lose embedded semantics and introduce noise, resolution variability, and drafting inconsistencies. These limitations have driven increasing interest in learning-based methods designed specifically for raster floorplans.

Existing research on raster-based floorplan analysis largely falls into three parallel streams: (1) geometric analysis, which reconstructs architectural structures such as walls and room boundaries; (2) symbolic object detection and recognition, which identifies standardised elements such as doors, windows, and fixtures; and (3) text detection and recognition, which extracts annotations including room names and dimensional values.

In geometric analysis, wall detection is typically treated as the core task and formulated as pixel-level semantic or instance segmentation to generate wall masks (Sun et al., 2025). More recent approaches attempt to directly predict vectorised primitives, such as corners and edges, using end-to-end models that produce machine-readable spatial layouts (Hu et al., 2024). Nevertheless, most geometric methods operate in normalised image coordinates or relative spatial representations, deriving absolute dimensions only through assumed global scale factors or omitting metric information altogether (Su et al., 2023). Although such representations are sufficient for layout understanding or navigation-oriented applications, they fall short of the millimetre-level geometric accuracy required for engineering-grade BIM reconstruction.

In parallel, symbolic object detection leverages general-purpose frameworks, such as YOLO variants, to localise and classify architectural symbols including doors, windows, and sanitary fixtures (Xu et al., 2024; Jamieson et al., 2025). These models typically output class-labelled bounding boxes or segmentation masks, enabling structured interpretation of floorplan content. However, they are often evaluated on simplified or schematic drawings with sparse or intentionally removed textual annotations. As a result, they are not designed to handle the dense and overlapping annotations commonly found in real-world engineering drawings, which limits their applicability to practical 2D-to-BIM scenarios.

In contrast, text-centric methods follow the standard scene text understanding pipeline, detecting text regions followed by character recognition, and have demonstrated success in handling arbitrarily oriented and stylised annotations (Schönfelder et al., 2024). Yet, their integration into geometry-aware reasoning remains limited. Textual annotations are frequently overlaid on or adjacent to walls, and auxiliary lines, such as dimension leaders, can substantially interfere with structural segmentation and geometric inference.

Consequently, most existing pipelines either ignore textual information entirely or use it only for coarse global scaling, without establishing explicit, component-level associations between dimensional annotations and building elements (Pokuciński and Mrozek, 2024). This reveals a critical gap: although geometric, symbolic, and textual analyses have each advanced substantially, they remain largely decoupled in practice. Existing workflows still rely heavily on heuristic assumptions, without explicitly linking dimensional annotations to building geometry or evaluating reconstruction quality at the engineering level. This limitation reduces metric fidelity and constrains the practical applicability of 2D-to-BIM reconstruction for engineering use.

Methodology

Framework overview

The proposed methodology introduces a multi-stage, vision-based framework for the automated analysis of annotated floorplans to achieve geometry-accurate 2D-to-BIM reconstruction. As illustrated in Figure 1, the framework integrates OCR, OCR-guided denoising, semantic segmentation, and geometric alignment to recover component-level dimensional information from legacy raster floorplans.

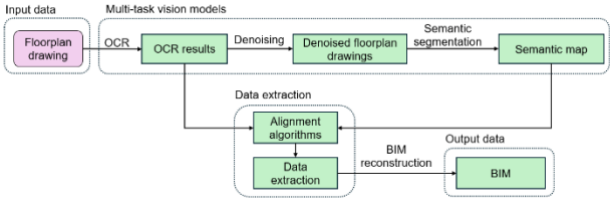

Figure 1: Overall workflow of proposed method

The methodology emphasises the cross-modal integration of heterogeneous visual cues, including textual annotations, auxiliary reference lines, and architectural geometry. This design addresses a critical bottleneck in AEC workflows, namely the lack of robust mechanisms for translating disparate recognition outputs into geometric representations.

The workflow takes raster floorplans as input and does not assume pre-cleaned or simplified documents, as shown in Figure 2(a). Textual and geometric information are processed in parallel and subsequently aligned through a dedicated data extraction and association stage, enabling staged BIM automation with dimensionally grounded component reconstruction.

OCR training and configuration

OCR is applied directly to the input floorplan to detect and recognise textual elements, including dimensional annotations. A two-stage OCR pipeline is employed, consisting of a CRAFT text detector (Baek et al., 2019) and a TPS-STN + CRNN recogniser (Shi et al., 2016) trained with CTC loss.

The OCR model is fine-tuned using 1,000 annotated floorplan images sampled from CubiCasa5k (Kalervo et al., 2019) and CVC-FP (de las Heras et al., 2015), with an 8:1:1 train/validation/test split; ResBIM (Liang et al., 2026) is used exclusively for external validation. Overlapping tiling and print-scan-style augmentations are adopted to handle large drawing canvases and small text

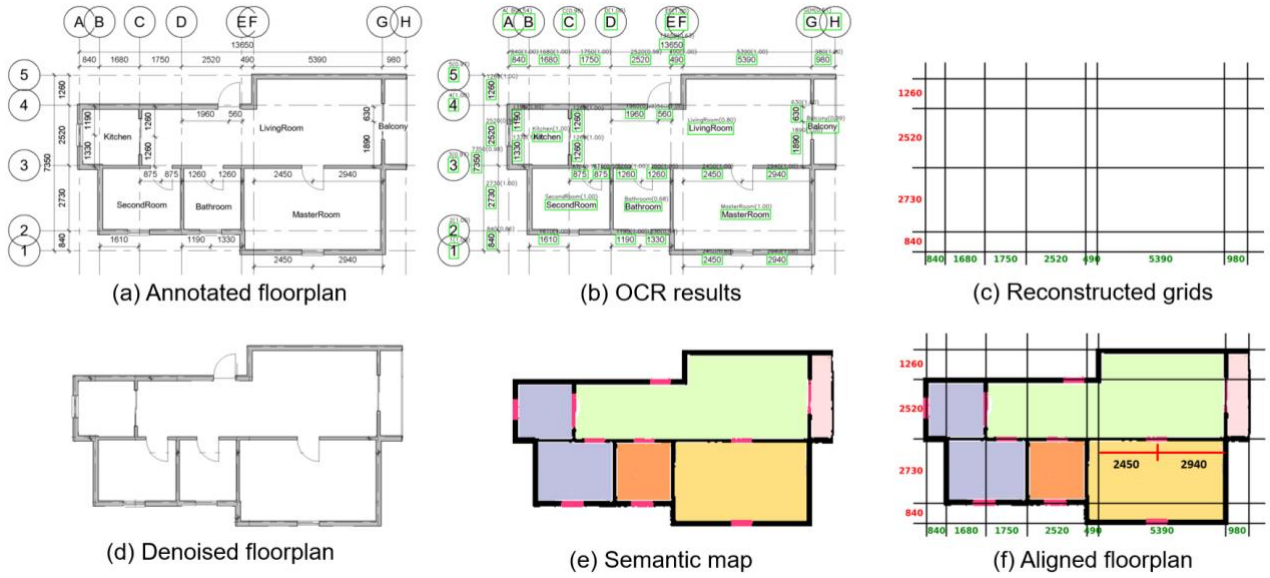

Figure 2: Overall process of multi-stage vision-based framework. instances. Recognised texts are normalised and converted into structured representations, including numeric values, orientations, bounding-box coordinates, and confidence scores. These structured OCR outputs are treated as intermediate dimensional cues and are subsequently used in later cross-modal alignment and geometric reasoning stages.

OCR-guided denoising

Prior to semantic segmentation, an OCR-guided denoising step is applied to suppress annotation-induced artifacts that may interfere with geometric extraction. OCR outputs provide spatial and directional cues that localise regions associated with dimensional annotations. Within these regions, subtraction-based operations are applied to remove annotation lines and leaders that are geometrically aligned with detected text.

To further reduce non-structural artifacts, a thin-line removal procedure is applied to suppress auxiliary reference lines, including grids and leaders, which are typically rendered with thinner strokes than architectural components. Morphological and geometric filtering is used conservatively to preserve wall and opening continuity. The resulting denoised image retains the structural geometry required for segmentation while significantly reducing false positives caused by annotation-related noise, as shown in Figure 2(d).

Semantic segmentation

Semantic segmentation of architectural components is formulated as a multi-task learning problem that jointly models architectural boundaries and interior spatial regions. The adopted U-net encoder-decoder architecture (Ronneberger et al., 2015) employs a shared convolutional encoder and two task-specific decoder branches, enabling efficient feature sharing across related segmentation tasks.

The first decoder branch focuses on boundary segmentation, producing pixel-level masks for structural elements such as walls and openings. The second branch performs region-level semantic segmentation of interior spaces. To enhance structural consistency, boundary features are incorporated into the region prediction process through a boundary-guided attention mechanism at multiple feature scales. This design helps preserve thin geometric elements and enforces spatial alignment between room regions and their enclosing structures. Direction-aware feature aggregation is applied to better capture dominant architectural orientations.

The network is fine-tuned using the R2V (Liu et al., 2017) and R3D (Liu et al., 2015) datasets, which provide pixel-level annotations for both boundaries and regions. Training employs a multi-task, class-balanced loss to mitigate severe data imbalance between large interior regions and thin structural components. Although both tasks are retained during training to leverage shared structural priors, only the boundary-related outputs, specifically wall and opening masks, are propagated to downstream geometric alignment and BIM reconstruction.

In the proposed pipeline, semantic segmentation serves as a geometric sensing module rather than an end objective. Its role is to provide topology-consistent and geometrically reliable structural primitives that can be aligned with OCR-derived dimensional annotations, thereby supporting engineering-grade geometric reconstruction.

Alignment algorithms

The alignment stage aims to establish explicit and metrically consistent correspondences between dimensional annotations extracted by OCR and the architectural geometry obtained from semantic segmentation. Instead of assuming a global scale factor,

the proposed method reconstructs a metric reference grid directly from dimensional annotations embedded in the floorplan drawings. This grid serves as an intermediate geometric representation that bridges raster-level geometry and real-world distances, enabling component-level metric reconstruction.

As illustrated in Algorithm 1, the process begins by analysing OCR outputs, as shown in Figure 2(b), where each detected text instance is represented by its recognised string, bounding box, orientation, and confidence score. High-confidence numeric annotations with consistent orientation are first selected as candidates potentially associated with grid spacing. Drawing-convention-aware spatial heuristics are then applied to identify annotations that likely describe distances between parallel grid lines. Specifically, vertical grid spacings are inferred from horizontally oriented dimension texts whose bounding boxes lie at similar vertical positions, reflecting the common drafting practice in which distances between vertical elements are annotated using horizontal dimension strings placed between the corresponding grid lines.

Candidate annotations are subsequently grouped based on the proximity of their bounding-box coordinates and sorted according to spatial order. Adjacent annotations within each group are interpreted as describing consecutive grid intervals, yielding an ordered set of grid spacings associated with both pixel-domain distances and OCR-derived metric values.

Because OCR outputs may contain recognition errors, a local verification and correction mechanism is introduced prior to global consistency checks. The algorithm estimates a pixel-to-metric conversion ratio by computing the median ratio between OCR-reported distances and their corresponding pixel gaps measured from bounding-box positions or dimension leader extents. Each grid spacing is then re-evaluated by comparing its OCR-derived value with the geometry-inferred distance. When deviations exceed a predefined tolerance, OCR values are locally corrected using geometry-consistent estimates, thereby enforcing metric consistency at the grid-interval level.

After individual grid spacings are verified and corrected, the algorithm detects total grid-length annotations by comparing detected dimension values with cumulative grid lengths. Grid lines are then placed cumulatively according to the corrected distances, forming a globally consistent metric grid in real-world units, as illustrated in Figure 2(c). The semantic map is subsequently scaled along the horizontal and vertical axes to match the grid extent and aligned to the grid coordinate system, as demonstrated in Figures 2(e) and 2(f). Semantic labels for doors, windows, and room regions are transferred to the aligned floorplan, enabling component-level metric interpretation.

The current alignment strategy incorporates several drafting-convention-aware assumptions. It assumes that dimension texts associated with a given grid interval exhibit consistent orientation, preserve relatively regular spatial ordering, and remain sufficiently close to the referenced structural location for local grouping and verification to be meaningful. These assumptions are generally consistent with common engineering drafting practice. However, robustness may decrease for non-standard layouts, such as offset dimension texts, long auxiliary leader lines, overlapping dimension chains, or highly irregular annotation structures.

Algorithm 1: Grid alignment with OCR-guided verification

Input: OCR detections $\mathcal{O} = \{o_i\}_{i=1}^{N}$, $o_i = (s_i, b_i, \theta_i, c_i)$ where s_i is recognized text, $b_i = (x_i, y_i, w_i, h_i)$ is the bounding box, θ_i is text orientation, c_i is confidence; semantic segmentation map $\mathcal{S}$

Output: Metric vertical grid $\mathcal{G}^v$ and grid-aligned geometry

Step 1: Select candidate vertical grid spacings;
Initialize candidate set $\mathcal{C}^v \leftarrow \emptyset$;
foreach $o_i \in \mathcal{O}$ **do**
  if $c_i \geq \tau_c$ *and* $\theta_i = 0$ **then**
    $\mathcal{C}^v \leftarrow \mathcal{C}^v \cup \{o_i\}$; // horizontal text, high confidence

Step 2: Group candidates by vertical alignment;
Partition $\mathcal{C}^v$ into groups $\{\mathcal{C}_k^v\}$ such that $|y_i - y_j| < \tau_y$ for $o_i, o_j \in \mathcal{C}_k^v$; // similar height

Step 3: Extract vertical grid spacings;
Initialize spacing set $\Delta^v \leftarrow \emptyset$;
foreach *group* $\mathcal{C}_k^v$ **do**
  Sort $\mathcal{C}_k^v$ by x coordinate;
  for $j = 1$ **to** $|\mathcal{C}_k^v| - 1$ **do**
    $\delta x_j = |x_{j+1} - x_j|$; // pixel distance between adjacent grid leaders
    $d_j^{ocr} = \mathrm{val}(s_j)$; // OCR-derived spacing value (metric)
    $\Delta^v \leftarrow \Delta^v \cup \{(\delta x_j, d_j^{ocr})\}$; // store pixel gap and OCR distance

Step 4: Verify and correct OCR-derived distances;
Estimate pixel-to-metric ratio $\rho = \mathrm{median}\left(\frac{d_j^{ocr}}{\delta x_j}\right)_{(\delta x_j, d_j^{ocr}) \in \Delta^v}$; // distance per pixel estimated from grid spacings
foreach $(\delta x_j, d_j^{ocr}) \in \Delta^v$ **do**
  $d_j^{px} = \rho \cdot \delta x_j$; // distance inferred from pixel gap
  if $|d_j^{px} - d_j^{ocr}| > \epsilon$ **then**
    $d_j^{ocr} \leftarrow d_j^{px}$; // correct OCR error using geometric consistency

Step 5: Detect total vertical grid length (if available);
Compute cumulative length $L^v = \sum_{(\delta x_j, d_j^{ocr}) \in \Delta^v} d_j^{ocr}$; // sum of verified vertical grid spacings
foreach $o_k \in \mathcal{O}$ **do**
  if $|val(s_k) - L^v| < \epsilon$ **then**
    Mark o_k as total vertical grid length annotation;

Step 6: Construct metric vertical grid and align geometry;
Construct vertical grid $\mathcal{G}^v = \mathrm{cumsum}(\{d_j^{ocr}\}_{(\delta x_j, d_j^{ocr}) \in \Delta^v})$; // metric grid positions
Align semantic segmentation map $\mathcal{S}$ to $\mathcal{G}^v$; // assign coordinates to segmented map

Finally, the aligned geometry and associated semantic information are used to instantiate building elements as IFC entities. The resulting BIM preserves the topological relationships derived from semantic segmentation while incorporating explicit, grid-consistent dimensional information. By using the reconstructed grid as an intermediary between textual annotations and raster geometry, the proposed alignment strategy reliably recovers absolute measurements without relying on heuristic global scaling, thereby providing a robust metric foundation for accurate 2D-to-BIM reconstruction and downstream BIM-based analysis.

Results and discussion

Quantitative results

The quantitative evaluation addresses three complementary aspects: OCR recognition performance, semantic segmentation accuracy, and engineering-level BIM reconstruction quality.

For OCR evaluation, commonly used metrics in computer vision and document analysis include the character error rate, CER, and string similarity measures such as the FuzzyWuzzy ratio. These metrics assess character-level recognition accuracy and are sensitive to minor transcription errors, making them suitable for algorithm

tuning and benchmarking. However, they are not well suited to engineering-oriented reconstruction tasks. In the context of dimensional annotations, even a single-digit error may cause substantial geometric distortion in the reconstructed BIM, making partial string similarity inadequate for downstream evaluation.

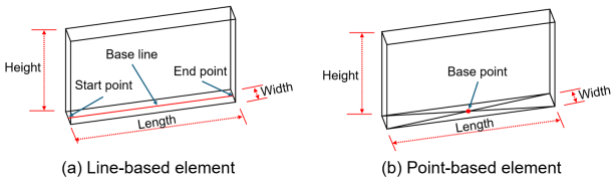
Therefore, a strict OCR accuracy metric is adopted to reflect whether recognised dimension values are directly usable for geometric reconstruction. OCR accuracy is defined as:

$$OCR\ accuracy = \frac{N_{correct}}{N_{GT}} \quad (1)$$

where $N_{correct}$ is the number of correctly recognised dimension annotations and N_{GT} is the total number of ground-truth dimension annotations. A prediction is considered correct only if the numeric value is fully matched. Under this strict criterion, the OCR module achieves an accuracy of 90.2% on the test set and 85.7% on the ResBIM dataset, indicating stable cross-dataset generalisation.

Semantic segmentation performance is evaluated using the IoU metric:

$$IoU = \frac{|A \cap B|}{|A \cup B|} \quad (2)$$



where A and B represent the predicted and ground-truth masks, respectively. The segmentation model achieves an IoU of 92.1% for wall and opening classes, demonstrating reliable extraction of structural geometry from denoised raster floorplans.

IFC-based evaluation

Although OCR accuracy and IoU are standard evaluation metrics in computer vision, they do not directly reflect reconstruction effectiveness at the engineering level, where the geometric correctness of BIM elements is critical. To address this gap, IFC-based evaluation metrics are introduced to assess reconstruction quality at the object and parameter levels.

The ResBIM dataset provides paired annotated floorplans and corresponding reference BIM models, enabling one-to-one comparison between reconstructed and ground-truth elements. Both reconstructed and reference BIMs are converted into IFC format, which provides a platform-independent representation in which each architectural element is encoded as an object with placement and geometric parameters. This object-centric representation enables direct and interpretable element-level comparison. Although this dataset supports rigorous IFC-level comparison, it does not cover the full range of drafting conventions encountered in practice. Therefore, the present evaluation should be interpreted as an initial engineering-level validation under the currently available benchmark setting.

Because the input data consist of 2D floorplans, the evaluation focuses on planar reconstruction accuracy. For walls, the origin location corresponds to the start point of the wall baseline, as shown in Figure 3(a), and the length is defined by the baseline length encoded in the IFC geometry. For doors and windows, the origin is defined by the opening base point, as shown in Figure 3(b), and dimensional parameters are retrieved from the corresponding IFC geometric definitions.

(a) Line-based element (b) Point-based element

Figure 3: Two methods for representing element locations in IFC-based BIM models in the ResBIM dataset

To comprehensively evaluate geometry-accurate 2D-to-BIM reconstruction at the engineering level, three complementary IFC-based metrics are proposed to assess numerical completeness, dimensional correctness, and strict geometric accuracy.

The count error Err_{cnt} measures numerical consistency between reconstructed and ground-truth models.

$$Err_{cnt} = \frac{|N_{pred} - N_{gt}|}{N_{gt}} \quad (3)$$

where N_{pred} and N_{gt} denote the numbers of reconstructed and ground-truth IFC elements, respectively.

The dimension-level precision metric $IFC_{\text{dim_precision}}$ evaluates whether element dimensions are correctly reconstructed, independent of absolute location:

$$IFC_{dim_precision} = \frac{TP_{dim}}{TP_{dim} + FP_{dim}} \quad (4)$$

where TP_{dim} refers to elements whose dimensional parameters are reconstructed within a predefined tolerance, and FP_{dim} corresponds to elements whose dimensions exceed this threshold. This metric evaluates dimensional correctness independently of absolute spatial alignment and is particularly sensitive to OCR and dimension-geometry association errors.

Finally, the strict geometric precision metric $IFC_{precision}$ assesses whether both dimensional parameters and origin locations are simultaneously correct:

$$IFC_{precision} = \frac{TP}{TP + FP} \quad (5)$$

where TP denotes elements whose dimensions and origin locations are simultaneously reconstructed within tolerance, and FP denotes elements failing either criterion. This metric reflects whether reconstructed elements are directly usable for downstream BIM applications without manual correction.

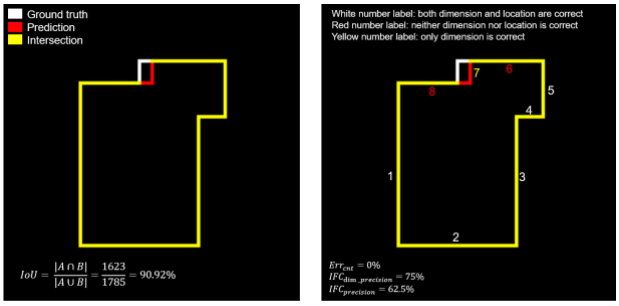
A tolerance of 1 mm is applied to wall dimensions and locations only to absorb minor numerical inconsistencies introduced by IFC export, unit normalisation, and floating-point conversion, rather than to relax geometric evaluation. For openings, a larger tolerance of 20 mm is adopted as a benchmark-specific evaluation threshold. In ResBIM, openings are annotated by centre-point distances rather than explicit physical widths, so opening dimensions and positions must be inferred indirectly from raster geometry and host-wall context before being

converted into IFC opening parameters. This introduces higher annotation and representation uncertainty than for walls, whose baselines and lengths are more directly defined. Because openings are also smaller elements, they are more sensitive to minor segmentation or alignment shifts. The 20 mm threshold therefore accounts for annotation granularity and benchmark-specific uncertainty, rather than implying a looser engineering tolerance.

Experimental results on a randomly selected subset of 200 floorplans from ResBIM are presented in Table 1. The count error Err_{cnt} is 2.45%, indicating high numerical consistency between reconstructed and ground-truth models. At the IFC entity level, the dimension-level precision $IFC_{\text{dim_precision}}$ is 82.4%, and the strict geometric precision $IFC_{precision}$, which requires both correct dimensions and locations, is 71.1%. Notably, in 62 of the 200 floorplan reconstruction tasks, all building components are correctly predicted in both location and dimensional attributes. The average processing time per floorplan is approximately 6.5 minutes.

Table 1: Quantitative evaluation results of the proposed dimension-aware 2D-to-BIM reconstruction framework

Metric	Value
Err_{cnt}	2.5%
$IFC_{\text{dim_precision}}$	82.4%
$IFC_{precision}$	71.1%
Exact dimension match (count)	62/200
Total processing time	21.5 hours



Error analysis and discussion

This study evaluates the proposed vision-based 2D-to-BIM reconstruction framework using both conventional computer vision metrics and the proposed IFC-based evaluation metrics. The OCR module achieves 90.2% accuracy on the in-domain test split and 85.7% on the ResBIM dataset for external validation, while the semantic segmentation model achieves an IoU of 92.1%. These results indicate strong performance when each visual task is evaluated independently using standard computer vision criteria.

However, when the same outputs are assessed using IFC-based reconstruction metrics, a noticeable performance drop is observed. The dimension-level accuracy and strict geometric precision reach only 82.4% and 71.1%, respectively, even after applying the pixel-level correction strategy described in Algorithm 1. This discrepancy reflects a fundamental difference between computer-vision-oriented evaluation and engineering-oriented BIM reconstruction requirements.

Conventional metrics such as OCR accuracy and IoU evaluate predictions in isolation, assessing each text string or pixel region independently. In contrast, BIM reconstruction is inherently relational and connectivity-driven. Walls act as hosts for openings, adjacent walls are expected to connect seamlessly, and local geometric inconsistencies can propagate through topological relationships. As a result, dimensional values extracted by OCR are not independent in the reconstruction context but mutually constraining.

Figure 4 provides a representative qualitative example of this discrepancy. In this case, the predicted wall mask achieves an IoU of 90.92% against the ground truth, and the reconstructed model contains the correct number of wall entities, 8 versus 8. However, only 6 of the 8 wall entities are dimensionally correct, yielding a dimension-level accuracy of 75%, and only 5 of the 8 are correct in both dimension and location, yielding a strict geometric precision of 62.5%. This example illustrates why strong image-level overlap does not necessarily translate into equally high IFC-level correctness.

(a) Pixel-based exterior-wall prediction result and IoU (b) Vectorised exterior-wall and IFC-based metric calculation

Figure 4: Representative exterior-wall example illustrating the difference between conventional computer vision metrics and engineering-oriented IFC metrics.

IFC-based evaluation is stricter because it requires each reconstructed entity to satisfy dimensional correctness, spatial placement, and geometric consistency simultaneously. Therefore, small OCR assignment errors or minor boundary shifts that have little influence on OCR accuracy or IoU may still cause reconstructed IFC entities to be judged incorrect once their baselines, origins, or dimensions exceed the evaluation tolerance. These effects are further amplified during BIM instantiation because local errors do not remain isolated at the image level but propagate through dependent geometric relationships. This explains both the drop from the higher OCR and IoU scores to lower IFC-based metrics and the additional gap between dimension-level precision, 82.4%, and strict geometric precision, 71.1%. In other words, conventional computer vision metrics tend to overestimate reconstruction quality in dimension-sensitive BIM workflows because they do not capture entity-level placement errors and topology-dependent error propagation.

Limitations

Despite its advantages, the proposed pipeline has several limitations. First, the alignment module relies on drafting-convention-aware spatial assumptions, including locally interpretable annotation placement, consistent text orientation, and regular interval ordering. Its robustness may therefore decrease for drawings with highly irregular annotation layouts, overlapping dimension chains, or long auxiliary leader lines that displace dimension texts far

from the referenced geometry. In addition, the alignment algorithm degrades noticeably when OCR accuracy falls below approximately 50%, as may occur in highly cluttered or severely occluded drawings. To maintain computational efficiency, the semantic segmentation model also operates on downsampled inputs, which may amplify geometric distortions in the semantic map and reduce alignment quality.

Second, IFC-based evaluation is constrained by the limited availability of datasets that provide paired floorplans and reference BIM models (Pizarro et al., 2022; Liang et al., 2026). ResBIM enables direct object-level comparison, but relying primarily on a single benchmark limits the diversity of drafting conventions and annotation styles represented in the evaluation. Accordingly, the reported results should be interpreted as benchmark-based evidence rather than a complete demonstration of robustness across all real-world floorplan types.

Third, the current study is limited to planar reconstruction from floorplans and does not recover elevation-related dimensions or richer semantic attributes from multi-view drawings. In addition, although the pipeline automates several reconstruction stages, the present work does not directly quantify labour or time savings through a user study or a comparison against manual or semi-automatic workflows.

Conclusions

This paper presents a multi-stage, vision-based framework for the automated analysis of annotated architectural floorplans to enable dimension-aware 2D-to-BIM reconstruction. The main methodological contribution is the proposed cross-modal text–geometry alignment strategy, which reconstructs a metric reference grid from dimensional annotations and supports component-level metric interpretation. A second key contribution is the IFC-based evaluation framework, which enables direct object-level assessment of reconstruction quality from an engineering perspective.

The results show that conventional computer vision metrics, such as OCR accuracy and segmentation IoU, are insufficient for characterising engineering-level BIM reconstruction quality. Although the proposed workflow supports automated, dimension-aware reconstruction from annotated raster floorplans, the present study remains limited to planar, benchmark-based validation and does not directly quantify labour or time savings through user studies or comparisons with manual or semi-automatic workflows.

Future directions

Several limitations remain and motivate future research. First, the current framework focuses on planar reconstruction from floorplans and does not recover elevation-related dimensions or richer semantic attributes from multi-view drawings. Future work should therefore incorporate additional drawing types, such as elevations and sectional views, to support more complete BIM reconstruction.

Second, the present alignment strategy remains partly rule-based and relies on drafting-convention-aware assumptions. Learning-based alignment methods trained on annotated geometry–text correspondences may improve robustness to OCR errors, irregular annotation layouts, and heterogeneous drawing styles.

Third, the current IFC-level evaluation is constrained by the limited availability of paired floorplan–BIM datasets. Extending the evaluation to more diverse real-world drawings and additional benchmarks will be important for testing generalisability across different drafting conventions and building standards.

Together, these directions support more comprehensive and reliable automation of existing-building digitisation in real-world AEC workflows.

A BIM-INTEGRATED ADAPTIVE SURROGATE FRAMEWORK FOR EFFICIENT UNCERTAINTY QUANTIFICATION IN BUILDING ENERGY SIMULATION

Arash B. Naamrudi[1], Reihaneh Aghamolaei[1]
[1] School of Mechanical & Manufacturing Engineering, Faculty of Engineering and Computing, Dublin City University, Whitehall, Dublin 9, Ireland

Abstract

Uncertainty analysis is critical for reliable building energy predictions, yet classical Monte Carlo simulation is computationally prohibitive for detailed physics-based models. This study proposes a BIM-integrated adaptive surrogate uncertainty analysis framework combining adaptive sampling with sparse Polynomial Chaos Expansion to efficiently propagate uncertainty and perform global sensitivity analysis. The approach is demonstrated on four Irish residential archetypes with uncertain envelope thermal parameters. The adaptive surrogates achieve stable accuracy (CV-RMSE 0.74–2.05 kWh/m² for annual EUI) while reducing computational cost by around 99% compared to Monte Carlo simulation, enabling scalable and interpretable decision support for building design and retrofit.

Introduction

Buildings are a significant contributor to global energy use and carbon emissions, accounting for about 34–37% of total energy consumption worldwide (United Nations Environment Programme, 2024). In the European Union, residential buildings consume nearly 40% of total energy and are responsible for roughly 33% of energy-related greenhouse gas emissions, largely due to an ageing and inefficient building stock with low renovation rates (Energy Performance of Buildings Directive, 2025). Improving the energy performance of existing buildings is therefore critical to reducing energy demand and achieving a fully decarbonised building stock by 2050 (Energy Performance of Buildings Directive, 2025). In response, energy standards such as ASHRAE Standard 90.1 (ASHRAE Standard, 2022) and the International Energy Conservation Code (IECC) (International Code Council (ICC), 2021) have progressively tightened efficiency requirements, increasing the need for accurate yet computationally efficient Building Energy Models (BEMs) to support compliance, retrofit evaluation, and design optimisation (ElSayed, Shultz and Kurtz, 2025). BEM is a computational simulation approach used to predict the energy performance of buildings under defined operating conditions. The typical inputs to a BEM can be broadly categorised into five groups, including geometric and spatial parameters, envelope thermal properties, occupancy and internal load schedules, HVAC system parameters and boundary conditions. The primary outputs of interest in building energy analysis include the annual and monthly Energy Use Intensity (EUI, in kWh/m²), total heating and cooling demand (kWh), peak load (kW), and thermal comfort indicators.

Building Information Modelling (BIM) has increasingly been integrated with BEM to improve data consistency and automation in energy analysis (Heydari and Heravi, 2023). BIM provides a structured, data-rich representation of buildings, incorporating geometry alongside material properties and performance attributes (Shadram *et al.*, 2016; Wang *et al.*, 2022), which can be translated into energy simulations (Arbulu, Oregi and Etxepare, 2024; Forth and Borrmann, 2024). Within BIM-based energy modelling workflows, building performance is most commonly evaluated using deterministic simulation approaches, in which all model inputs are assigned fixed, single-point values (Alwan *et al.*, 2021; Heydari and Heravi, 2023). These values are typically derived from design specifications, standards, or nominal assumptions, implicitly assuming that building components behave exactly as prescribed and that variability arising from construction quality, ageing, occupant behaviour, and environmental conditions is negligible (Liu *et al.*, 2022; Prataviera *et al.*, 2022). While deterministic BIM-based simulations provide a streamlined pathway from design data to energy performance prediction, they are inherently limited by their reliance on single-point input assumptions, which obscure the effects of uncertainty and variability in building parameters.

To address this limitation and consider variability and uncertainty in building parameters, uncertainty-aware modelling frameworks have been developed that explicitly represent uncertain inputs using probabilistic or stochastic descriptions and propagate their effects through building energy models. Within this context, Forward Uncertainty Analysis (FUA) defines the analytical task of quantifying how uncertainty in model inputs translates into uncertainty in energy performance outputs.

FUA can be implemented using a range of numerical and surrogate-based techniques, including Monte Carlo simulation, Latin Hypercube sampling, and surrogate models such as Polynomial Chaos Expansion or Gaussian process regression. Yet, existing approaches face significant computational constraints since they require a high number of simulations over fixed and predefined samples. For example, Monte Carlo Simulation (MCS), the conventional benchmark for FUA, propagates

uncertainties through repeated random sampling (Liu *et al.*, 2020; Chadly *et al.*, 2023; Prilliman *et al.*, 2023). Although theoretically robust, MCS converges slowly, with accuracy improving only with the inverse square root of sample size, often requiring thousands of simulations (Zhao, Lee and Augenbroe, 2016). Given the high computational cost of individual BEM evaluations, this renders MCS impractical for many real-world applications.

To improve the efficiency MCS, static sampling strategies such as Latin Hypercube Sampling (LHS) have been proposed. LHS can reduce the required number of simulations by approximately 50% compared to MCS for similar accuracy (Tian *et al.*, 2020; Koniorczyk *et al.*, 2022). However, LHS allocates samples uniformly across the input domain, irrespective of model sensitivity or non-linearity, leading to inefficient use of computational resources in complex regions of the input space. Adaptive sampling strategies address this limitation by sequentially selecting new samples based on output variance, achieving reported simulation reductions of 25–68% relative to static designs (Yu *et al.*, 2025). Despite these gains, adaptive sampling becomes challenging when applied to high-fidelity BEMs with multiple outputs and temporal resolutions, where the dimensionality of objectives significantly increases computational burden.

Surrogate modelling offers a pathway to overcoming these computational barriers by approximating expensive BEM simulations with inexpensive metamodels trained on limited high-fidelity data (Zhao, Lee and Augenbroe, 2016; Sood *et al.*, 2025). Among surrogate approaches, Polynomial Chaos Expansion (PCE) is particularly attractive due to its explicit polynomial representation of input–output relationships, enabling analytical computation of statistical moments and Sobol' sensitivity indices directly from model coefficients (Tian, 2024). This analytical structure provides both uncertainty and sensitivity information within a single framework and enhances interpretability through direct examination of polynomial terms. However, classical PCE suffers from the curse of dimensionality, as the number of basis terms grows combinatorially with input dimension and polynomial order, making it impractical for building models with moderate to high numbers of uncertain parameters (Thapa, Mulani and Walters, 2020).

To address this challenge, adaptive PCE methods have been developed that iteratively refine the polynomial basis by retaining only influential terms and pruning negligible contributions, reducing required simulations by 40–60% compared to full-order PCE (Cheng and Lu, 2018; Thapa *et al.*, 2024). When combined with sequential sampling strategies, adaptive PCE further improves efficiency by allowing both the surrogate structure and training data to evolve based on observed model behaviour (Thapa, Mulani and Walters, 2020). Despite these advances, adaptive PCE has not been systematically integrated into BIM-based BEM workflows, particularly for simultaneous multi-output and multi-timescale analysis.

The literature, therefore, reveals three critical gaps. First, no existing framework unifies adaptive sampling and adaptive PCE within automated BIM-to-BEM workflows, with current approaches relying on either computationally expensive Monte Carlo methods or static surrogate training designs. Second, most uncertainty and sensitivity studies focus on single outputs and single temporal scales, failing to capture how parameter importance varies across different performance metrics and timescales, a limitation that can misinform retrofit decisions. Third, the scalability of adaptive PCE for multi-output, multi-timescale building energy analysis remains largely unvalidated. Addressing these gaps, this study proposes a unified BIM–BEM framework that integrates adaptive sampling with adaptive PCE to efficiently quantify uncertainty and sensitivity across multiple outputs and temporal resolutions and benchmarks its performance against Monte Carlo simulation.

Methodology

BIM-based BEM Transformation

The proposed framework (Figure 1) integrates BIM-based building modelling with adaptive surrogate-assisted uncertainty and sensitivity analysis. A BEM is first derived from a BIM representation, focusing on envelope-related parameters, including wall, roof, and window U-values and window solar heat gain coefficient (SHGC). These parameters are treated as uncertain inputs and assigned probability distributions. An adaptive PCE surrogate, coupled with sequential sampling, is then constructed to propagate uncertainties and evaluate their influence on multiple performance metrics. The framework employs a two-level adaptivity strategy, combining variance-based basis refinement with sequential experimental design. At each iteration, surrogate accuracy is improved through targeted basis enrichment and adaptive sampling, while convergence is assessed using distribution-based criteria.

The BIM-based building model was developed by identifying geometric and non-geometric parameters that define the physical and thermal characteristics of the building, including story configuration, ceiling height, openings, construction assemblies, and thermal properties. Parameter values were obtained from literature and established databases to ensure representativeness. Autodesk Revit was selected as the BIM authoring platform due to its parametric data structure, interoperability, and industry adoption. Thermal attributes such as U-values, layer thicknesses, and SHGC were extracted directly using a single-step BIM-to-BEM approach to minimise data loss and improve reliability.

To bridge BIM and energy simulation domains, a transitional energy model was generated in HBJSON format using the Pollination plugin. This intermediate representation preserves geometry, zoning, and aperture definitions while enabling quality control of spatial and thermal data. Aggregating spaces with similar thermal behaviours defined thermal zones. Fenestration elements were mapped directly from Revit window families, and

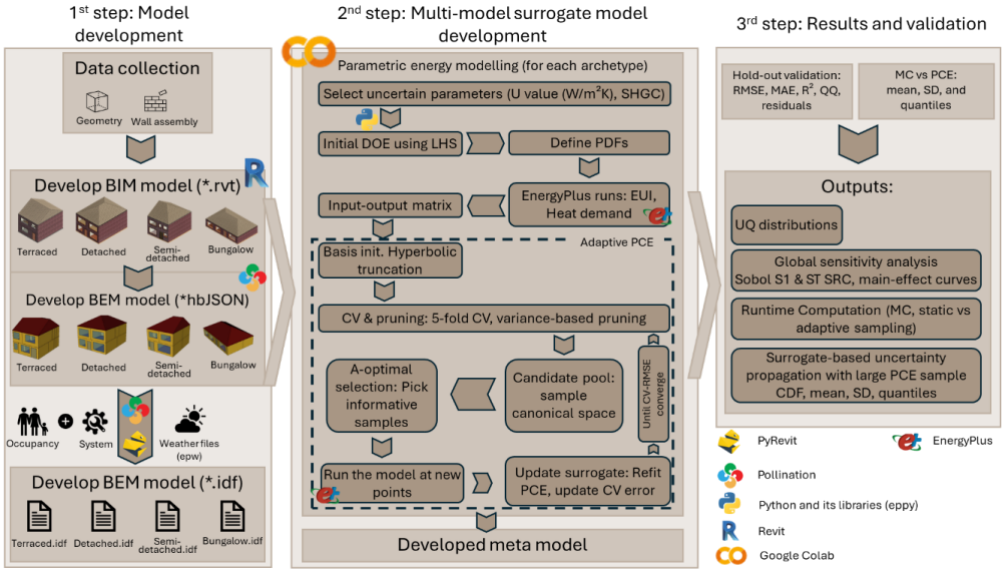

Figure 1. Overarching methodology diagram of the proposed framework.

boundary locations were assigned to wall centrelines to ensure surface alignment and shared interfaces. The transitional model was subsequently validated to correct envelope discontinuities, geometric gaps, and orthogonality issues. Once validated, the model was exported in EnergyPlus IDF format and enriched with material properties, weather data (EPW), occupancy schedules, HVAC parameters, and internal loads, forming the final simulation-ready BEM (Figure 2).

Adaptive Uncertainty Quantification Framework

Uncertainty in envelope parameters was propagated through the BEM using an adaptive PCE framework. Uncertain inputs were modelled as independent normally distributed random variables and transformed into standard normal space to satisfy orthogonality requirements. The building energy response was approximated using a truncated generalised PCE, where multivariate orthogonal basis functions are constructed as tensor products of univariate polynomials. Statistical moments of the output, including mean and variance, were obtained analytically from the PCE coefficients.

When using PCE, the uncertainty is represented through a set of independent random variables $\mathbf{X} = (X_1, \dots, X_d)$, each characterised by a normal probability distribution. In order to allow the construction of a generalised Polynomial Chaos Expansion (gPCE), each variable is transformed to a standardised form $\xi_i = (X_i - \mu_i)/\sigma_i$, such that $\xi_i \sim \mathcal{N}(0,1)$ and μ_i, and σ_i are the mean and standard deviation of the i-th parameter, respectively. The mapping between physical parameters $\mathbf{x}$ and standard normal variables $\boldsymbol{\xi}$ ensures the orthogonality properties required for PCE convergence (Thapa, Mulani and Walters, 2020; Thapa *et al.*, 2024).

In PCE, $u(x(\xi))$, which is a second-order stochastic response with finite variance and dependent on a set of independent random inputs $x = \{x_i\}_{i=1}^{N}$, is represented as a spectral expansion using multivariate orthogonal polynomials $\psi_k(\xi)$ and deterministic PCE coefficients a_k as in Eq 1.

$$u(x(\xi)) \approx \sum_{k=1}^{\infty} a_k \, \Psi_k(\boldsymbol{\xi}) \qquad 1$$

where $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \dots, \alpha_d)$, is a multi-index with non-negative integer components, $a_{\boldsymbol{\alpha}}$ are the PCE coefficients to be determined, $\Psi_{\boldsymbol{\alpha}}(\boldsymbol{\xi})$ are multivariate orthonormal polynomial basis functions. More detailed descriptions and formulas of adaptive PCE are presented in the related literature (Sudret, 2008, 2008; Blatman and Sudret, 2011).

To address the curse of dimensionality, an adaptive PCE formulation (VARPCE) was employed, in which polynomial basis functions are introduced incrementally in small subsets. Variance-based pruning was applied to remove basis terms with negligible contributions while ensuring that the relative loss of total variance remained below a predefined tolerance. Polynomial order selection and overfitting prevention were managed using k-fold cross-validation, with model complexity increased only when cross-validation error showed meaningful improvement.

To validate the adaptive PCE surrogate, a hold-out set of N = 50 direct EnergyPlus simulations, drawn from an independent random seed withheld from the training process, was used as the ground truth. Moreover, the computational efficiency of the adaptive PCE surrogate was benchmarked against direct Monte Carlo simulation using EnergyPlus as the ground truth solver.

Adaptive sampling was integrated with adaptive PCE to efficiently enrich the experimental design. Initial samples were generated using Latin Hypercube Sampling to ensure global coverage of the input space. As the active basis evolved, additional samples were selected using an A-optimal design criterion, which minimises the variance of PCE coefficient estimates and targets regions of high surrogate uncertainty. This strategy balances global exploration with local refinement, reducing redundant simulations and improving surrogate stability (Figure 3). The adaptive sampling procedure is:

1- Generate an initial Latin Hypercube Sample (LHS) of size N_0
2- Evaluate computational model at initial design points
3- For polynomial order $p = 1,2, \dots, p_{\max}$:
   a. Fit PCE using current data
   b. Apply variance-based pruning
   c. Compute cross-validation error
   d. If the CV convergence criterion is met, stop
   e. Otherwise, for $\ell = 1, \dots, L_{\text{adapt}}$ (here $L_{\text{adapt}} = 5$):
      - Generate a candidate set of size N_{cand} via LHS
      - Select n_{new} points (here $n_{\text{new}} = 3$) using the A-optimal criterion
      - Evaluate model at new points
      - Update PCE and check CV convergence

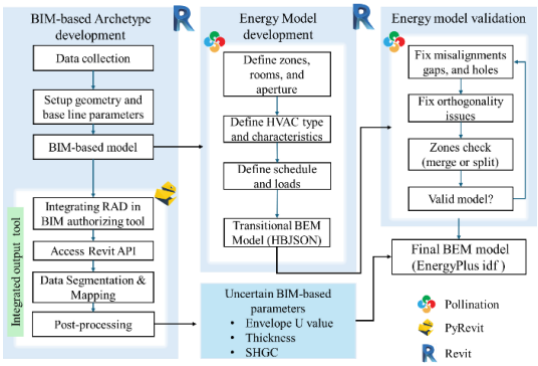

Figure 2. Developing a BIM-based energy-simulation-ready file format.

Sensitivity Analysis

Global sensitivity analysis was performed analytically using the final PCE coefficients. First-order and total-effect Sobol' indices were computed to quantify both main effects and interaction contributions of each uncertain input parameter. Convergence of the adaptive process was primarily assessed using the Kullback–Leibler divergence, which measures stability of output probability distributions across iterations and aligns directly with uncertainty quantification objectives. Secondary validation metrics, including leave-one-out error and the coefficient of determination (Q^2), were used to confirm predictive accuracy. Once the convergence criteria were satisfied, uncertainty and sensitivity results were finalised and benchmarked against Monte Carlo simulation to evaluate computational efficiency and accuracy.

Case study and data preparation

The proposed methodology is applied to four representative Irish residential archetypes: terraced, bungalow, detached, and semi-detached houses. These archetypes are chosen as they have been tested and validated in previous studies (Ali *et al.*, 2024; Sood *et al.*, 2025) and are among the most common archetypes in Ireland. BIM models for each archetype are developed in Revit (Figure 4) to capture both geometric and non-geometric attributes, including floor areas, ceiling heights, fenestration, and thermal envelope properties.

A PyRevit-based workflow is used to directly extract data via the Revit API, enabling a unified, automated, and user-friendly BIM data integration. Envelope-related thermal parameters are treated as uncertain inputs with normal distributions, while deterministic parameters are fixed at literature-based mean values.

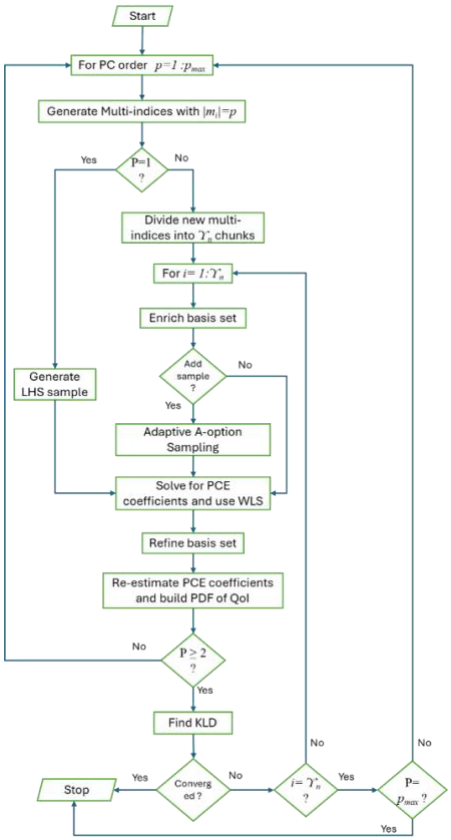

Figure 3. Flowchart of integrating adaptive sampling and adaptive PCE.

The uncertain inputs comprised envelope-related parameters, including U-values of the external walls, roof, and floor, the window U-value, and the solar heat gain coefficient (SHGC), each assigned normal probability distributions as described in the previous Section. Deterministic parameters, such as setpoint temperatures and lighting density, were fixed at mean values derived from the literature (Table 1).

Initial uncertainty propagation was performed using 30 Latin Hypercube samples to generate the training dataset. The adaptive PCE framework was then applied, with polynomial order incrementally increased up to the fourth order. A variance-based pruning strategy was employed to discard basis terms with negligible contribution, while new input samples were iteratively added using an A-optimal sequential design until convergence was achieved. Convergence was determined when the Kullback–Leibler divergence (KLD) between successive output distributions fell below 0.01 and the coefficient of determination (Q^2) exceeded 0.9. The outputs of interest were annual and monthly energy use intensity and annual and monthly heating demand (kWh).

After convergence, global sensitivity analysis was performed using Sobol' indices derived directly from the

final PCE coefficients. Both first-order and total-order Sobol' indices were computed for each uncertain parameter, providing interpretable measures of their individual contributions and interaction effects on the outputs. In the final stage, the computational cost of this method will be compared with that of the classic Monte Carlo.

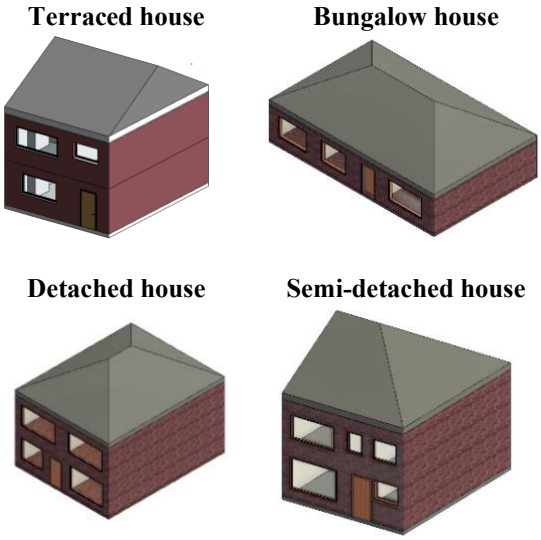

Figure 4. Common archetypes for Irish residential buildings in Revit.

Results and discussion

As shown in Table 2, the convergence history demonstrates that the adaptive sparse PCE model reaches stability very quickly while requiring only a small number of EnergyPlus simulations. At first order with 30 samples, for Bungalow as an example, the meta model contains six terms and already achieves a low Cross-Validation Root Mean Square Error (CV-RMSE) of 2.05 kWh/m², showing that annual EUI is dominated by linear effects, which is typical for U-value perturbations in building envelope analysis. When the adaptive routine adds new samples, the temporary rise in CV-RMSE reflects normal cross-validation variability rather than deteriorating model quality, and the consistent retention of only six terms confirms that higher-order interactions remain negligible.

Table 1. Deterministic parameter values and range of the variables with uncertainty for enriching final energy models (Egan et al.*, 2018; Ali* et al.*, 2024; Sood* et al.*, 2025).*

HVAC and system	Utility energy consumption (kWh/year.m2)			3
	Heating setback (°C)			12
	HVAC efficiency			2.2
	Heating setpoint (°C)			20.5
	DHW (l/m2/day)			2
	Lighting density (W/m2)			5
Internal loads	Occupants (person)			3.5
	Appliance density (W/m2)			11
Envelope	External wall U value (W/m2K)	0.1	1.1	
	Floor U value (W/m2 K)	0.1	1.1	
	Roof U value (W/m2 K)	0.1	0.9	
	Windows U value (W/m2 K)	0.6	4.3	
	SHGC of glass	0.1	0.9	
	Infiltration (ACH at 50 Pa)			1.85

After increasing the polynomial order to two, the meta model for semi-detached retains just 11 terms following pruning, indicating that most quadratic and interaction components do not meaningfully contribute to output variance. This modest growth in active terms aligns with the weak nonlinearities expected from EnergyPlus under small parameter perturbations. Throughout all iterations, the stability of total variance, which remains within the range of approximately 255–284, shows that the model captures the essential variance structure early and preserves it across refinements.

Table 2. Analytical variation of PCE convergence history.

Archetype	Order	No. terms	No. samples	CV-RMSE	Action	Itr.
Semi-detached	1	6	30	1.82	pp	
	1	6	33	2.44		1

*pp: post-prune; Itr: Iteration

The final CV-RMSE of the surrogate model for semi-detached, detached, terraced and bungalow are 0.72, 0.70, 0.82, 0.74 kWh/m² at second order, respectively confirming that the surrogate has reached its optimal balance between accuracy and complexity. Additional samples or higher-order terms do not improve performance, signalling classical convergence in adaptive PCE. Overall, the results show that the relationship between envelope parameters and annual EUI is smooth and predominantly linear, allowing an accurate surrogate to be built using approximately 50 EnergyPlus

simulations for the semi-detached archetype with excellent computational efficiency.

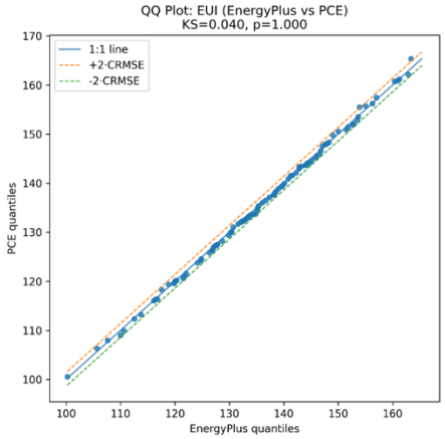

Figure 5. QQ comparison between the semi-detached surrogate predictions and the Energy Plus results.

Figure 5 shows excellent distributional agreement between PCE surrogate predictions and EnergyPlus outputs, with QQ points closely aligned to the 1:1 line across the full EUI range. The KS test (KS = 0.040, p = 1.000) confirms that both distributions are statistically indistinguishable. Nearly all points lie within ±2×CRMSE bounds, indicating small, well-controlled errors that are predominantly random rather than systematic, demonstrating high-fidelity probabilistic emulation by the surrogate.

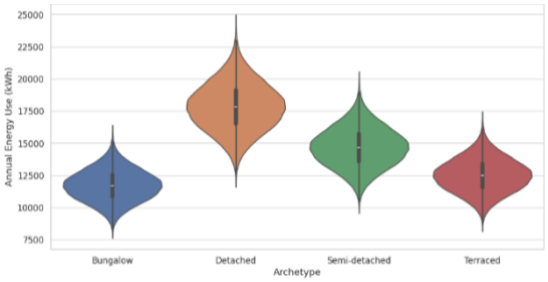

Figure 6. Violin plot of annual energy use for different archetypes.

The violin plot in Figure 6 illustrates the distribution of annual energy use (kWh) across four distinct building archetypes. This illustrates how input uncertainties in envelope U-values and SHGC propagate into annual energy variability. Notably, Detached properties exhibit the highest median annual energy consumption, as well as the broadest distribution, indicating a wider range of energy use within this archetype. Semi-detached properties show a slightly lower median energy use compared to detached, with a similarly wide but slightly less dispersed distribution. Terraced houses consistently demonstrate the lowest median annual energy use, with a comparatively tighter distribution, suggesting more uniform energy consumption patterns. Bungalows, while generally having lower energy use than Detached and Semi-detached, present a distribution that is somewhat wider than Terraced homes but narrower than detached properties. These findings suggest a strong correlation between building archetype (and implicitly, average floor area) and annual energy demand, with larger, standalone properties typically requiring more energy.

The similarity between distributions is because all four archetypes were generated under the same uncertainty space and parameter ranges from identical probabilistic assumptions. As a result, differences in built form alone introduce only second-order effects on annual energy use, leading to overlapping distributions with highly comparable central tendency and spread.

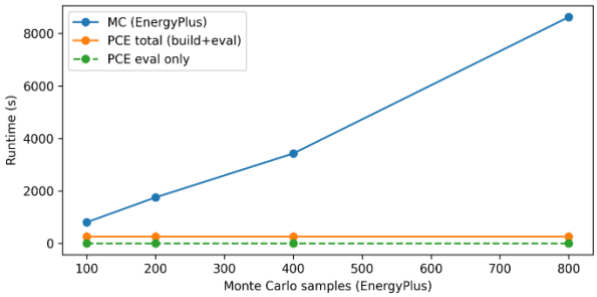

Figure 7. Runtime comparison between direct MCS using EnergyPlus and adaptive PCE surrogate for annual EUI.

Figure 7 compares the computational runtime of direct MCS with that of a PCE surrogate for annual EUI. The MC runtime increases approximately linearly with the number of samples, reflecting the fixed cost of repeated high-fidelity EnergyPlus evaluations and rapidly becoming computationally prohibitive as the number of runs grows. In contrast, the total PCE runtime, comprising surrogate construction and evaluation, remains nearly constant across different numbers of simulations, indicating that the computational cost is dominated by the one-time surrogate construction. Once constructed, the PCE surrogate can be evaluated at negligible cost, enabling large-scale uncertainty propagation and statistical analysis with minimal additional runtime. These results highlight the fundamentally different scaling behaviour of surrogate-based uncertainty quantification and demonstrate the suitability of PCE for applications requiring extensive sampling, repeated analyses, or computationally efficient sensitivity studies. However, the final decision on which method to choose depends on the trade-off between computational budget and required accuracy.

The monthly Sobol' sensitivity analysis shows a strong seasonal pattern in how envelope uncertainties influence energy demand (Table 3). During the heating-dominated months (January–March and September–December), Uwall is the main driver of variability, explaining 47-66% of the monthly energy variance. In contrast, during April–July, Uwin becomes the dominant factor, reflecting the greater role of glazing heat transfer and solar gains in warmer periods. Across all months, first-order and total-order indices are nearly identical (difference < 0.003), indicating that model behaviour is almost entirely additive with minimal interaction effects. This also confirms the strong convergence and stability of the adaptive sparse

PCE surrogate. Overall, the results demonstrate that the dominant envelope parameter changes seasonally, and that the PCE model reliably captures these monthly dynamics for interpreting energy behaviour and guiding retrofit priorities.

Table 3. Top first-order and total Sobol monthly indices.

Month	Top S_1 variable	Top S_1 value	Top S_T variable	Top S_T value
Jan	U_{wall}	0.66	U_{wall}	0.66
Feb	U_{wall}	0.53	U_{wall}	0.53

Dec	U_{wall}	0.58	U_{wall}	0.58

Conclusions

This study introduced a unified BIM–BEM uncertainty framework that integrates adaptive PCE with sequential A-optimal sampling. Unlike conventional BIM-based energy analyses that rely on deterministic simulations or Monte Carlo simulations, the proposed framework embeds uncertainty quantification and global sensitivity analysis directly into the modelling workflow. The results demonstrate that adaptive basis refinement combined with informed sampling is sufficient to capture the dominant variance structure of residential building energy models with high fidelity.

The adaptive sparse PCE surrogate converged using approximately 50 EnergyPlus simulations per archetype, achieving RMSE values below 0.8 kWh/m² and an R^2 exceeding 0.99 for annual EUI. In contrast, a Monte Carlo simulation would require several orders of magnitude more model evaluations to reach comparable distributional accuracy. This confirms that the energy response surface induced by envelope uncertainty is smooth and low-dimensional enough to be efficiently approximated by a variance-pruned polynomial basis, validating the core hypothesis of this study. Additionally, analytical Sobol' indices derived from the final PCE coefficients revealed a clear hierarchy of envelope parameter influence. External wall U-value and window U-value jointly explain the majority of annual EUI variance, while monthly analysis exposes a strong seasonal shift in dominance from opaque envelope components in winter to glazing properties in shoulder and summer months.

Future research should extend the uncertainty space beyond envelope properties to include occupant behaviour, infiltration variability, HVAC details, and system efficiencies, where stronger nonlinearities and interaction effects are expected. It is also valuable to check the effectiveness of LHS vs adaptive sampling and normal PCE vs adaptive PCE. Finally, comparing the results with the measured data could increase the credibility and robustness of the model's validation.

ONTOLOGY-SUPPORTED BRIDGE COMPONENT DESIGN: IMPLEMENTATION OF BRIDGE CAP DESIGN RULES

Tim Noack[1], Han Qian[1], Chongjie Kang[1] and Steffen Marx[1]
[1]TUD Dresden University of Technology, Dresden, Germany

Abstract

The bridge design process is a complex and time-consuming task for bridge engineers. To reduce repetitive tasks, automating the application of guidelines and standards is desirable. Currently, automation attempts are mostly based on table-based calculations. This work proposes a new approach to automated, code-compliant structural design: an exemplary automation process for dimensioning the bridge cap. In this process, an ontology describing bridge components and boundary conditions is created. German road bridge design rules are implemented using the Semantic Web Rule Language (SWRL). The aim is to enable a fully automatic geometric dimensioning of bridge caps based on several boundary conditions.

Introduction

When designing a bridge, the bridge engineer encounters a challenging task. There is a vast number of boundary conditions, requirements and structural mechanics to consider. This leads to long planning and testing phases. Guidelines and standards have been created to support the engineers' decisions and to ensure the quality of bridge design. Their application is often repetitive and laborious because of the many required steps and decisions. Therefore, automating these tasks is desirable. In recent decades, this has primarily been achieved through table-based calculations and, in rare cases, by implementing parts of the standards in programming code (Jeske et al., 2022). Both approaches lack flexibility and are unsuitable for integration into an artificial intelligence-supported bridge design process, which will be essential for a future-proof and efficient bridge engineering sector.

Therefore, a new approach to automated, code-compliant structural design is proposed: an ontology-based bridge cap dimensioning process. Ontologies, as part of the Semantic Web, represent a way to structure semantic knowledge and make it machine-interpretable (Staab and Studer, 2009) and are therefore well suited for representing guidelines and standards. The dimensioning process of a bridge cap was chosen because it is highly standardized in German road guidelines. A bridge engineer needs only a limited set of boundary conditions to determine, without further decision-making, the appropriate bridge-cap type and its dimensions.

In the first step of this work, existing ontologies in the field of bridge engineering and construction guidelines are reviewed. Next, German bridge-engineering guidelines and the process of extracting design rules from them are described. Bridge-cap dimensioning rules are implemented in an ontology using the Semantic Web Rule Language (SWRL) together with existing and newly created ontology structures. The proposed bridge cap dimensioning process is carried out for an exemplary bridge. Finally, the integration of the approach into a Building Information Modeling (BIM)-based process is discussed.

State of the Art

Extensive research on ontologies has been conducted in the broader Architecture, Engineering and Construction (AEC) industry as well as in the more specialized field of bridge engineering. Farghaly et al. (2023) found that between 2000 and 2021, more than 140 journal articles on ontologies, the Semantic Web or Linked Data were published in the AEC sector. They were categorized into ten application fields, such as process, compliance, smart cities and sustainability. Most of the ontologies were developed for managing and interpreting infrastructure or building data. Others aim to create a semantic interoperability between different sets of information. The most established ontologies in this field are the IfcOWL ontology (Beetz et al., 2009) and the Building Topology Ontology (BOT) (Rasmussen et al., 2019, 2020). The purpose of both ontologies is to enable the mapping from Industry Foundation Classes (IFC) to an ontological representation. Thus, with these ontologies, building data from IFC files can be transformed into an ontological database. Since the IFC version 4.3, the standard also includes objects for infrastructure representation, specifically bridge elements and the new basic class IfcBridge (International Organization for Standardization (ISO), 2024). This is why an alignment of new bridge ontologies to the IFC standard or at least to IfcOWL or BOT is recommended.

The objective of this work is to create a new bridge component based on the bridge's boundary conditions and relevant guidelines and standards. Therefore, the ontology application field "compliance" is most important here and requires further investigation. Ontologies in this field have primarily been used for code-compliance evaluation, which is also addressed in this paper. Pauwels et al. (2011, 2017) describe the advantages of mapping building data from IFC-files (explicit building information) into a Se-

mantic Web representation. By using rule languages such as SWRL or N3Logic together with an inference engine, implicit building information can be inferred. For example, the compliance of the building to a specific standard paragraph can be checked automatically. This was used in other research (Salama and El-Gohary, 2013; Jędrzejewska et al., 2026) but only for code-compliance checking, not for deriving a structural design directly from boundary conditions.

In the field of bridge engineering, a similar situation emerges. The application fields of developed ontologies are risk management (Hassan and Le, 2020), Structural Health Monitoring (Li et al., 2021), inspection (Erdene et al., 2020; Liu and El-Gohary, 2022; Zhang et al., 2022), diagnostics (Jäkel et al., 2025), bridge rehabilitation (Wu et al., 2021), and maintenance (Ren et al., 2019; Göbels and Beetz, 2025). These domains involve collecting, managing, and analyzing existing bridge data using various bridge ontologies. Hamdan and Scherer (2020) describe a foundational bridge ontology, the Bridge Topology Ontology (BROT), with several extensions. These ontologies can represent a bridge, its materials, components, and associated damages. BROT is based on BOT and therefore suitable for an integration into a BIM-based process.

Only few research studies have addressed ontologies in the field of bridge design. Aqlan et al. (2025) proposed an ontology for structuring data such as dimensions, structural details, boundary conditions, and images from bridge databases, making it accessible for machine-learning-based bridge design. Zhang et al. (2021) used an ontology for the holistic design of energy piles in a bridge deck deicing system. Although the ontology supports the design of these structures, the described principle is not an automatic design method based on the bridge's boundary conditions. Instead, it performs a database query to select which of 12 predefined design solutions best fits a given condition. Therefore, according to the author, no existing research has addressed automatic bridge-component design or dimensioning based on guideline-derived rules, despite the suitability of Semantic Web technologies for such tasks.

Methodology

Rules from Guidelines and Standards

Standards and guidelines contain information in four main formats: text, formulas, tables, and images (photos, drawings, diagrams). To digitalize and automate the document's content, the information must be interpreted and translated into *if-then* rules, formulas, or algorithms. The interpreted information can then be encoded and integrated into a digital process. The goal is to define boundary conditions as inputs and generate outputs —- such as parameter values or text —- after the process is executed.

This process will be demonstrated in this work using a highly standardized bridge component: the bridge cap. Figure 1 illustrates the regular concrete road slab bridge cross section, including two bridge caps. The caps are a component that generally consists of reinforced concrete and carries the railings, traffic barriers and the foot- or cycleway.

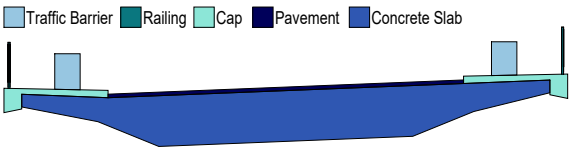

Figure 1: Superstructure cross-section: Main components of a road slab bridge.

In German standards and guidelines, there are several documents defining the design of concrete bridge caps. The RE-ING of the BASt (Bundesanstalt für Straßen- und Verkehrswesen, 2024) is a guideline describing the composition of road bridges. The RiZ-ING, also published by the BASt (Bundesanstalt für Straßen- und Verkehrswesen, 2023) is a collection of road bridge component drawings including twelve types of bridge caps. The Eurocode 2 (CEN/TC 250 Structural Eurocodes et al., 2023) and the DIN 1045 (DIN-Normenausschuss Bauwesen (NABau) et al., 2023) are specifying the concrete mixture and design details such as the concrete cover.

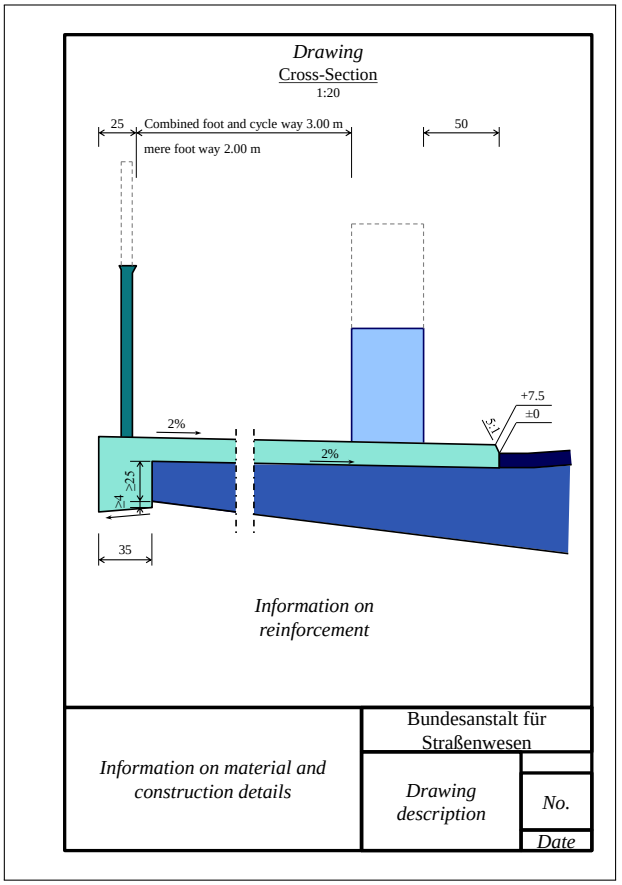

Figure 2: Composition of a RiZ-ING drawing with bridge cap measurements of drawing number "Kap 1 Blatt 3" (Bundesanstalt für Straßen- und Verkehrswesen, 2023)

This work primarily uses the RiZ-ING, since it focuses

on early-stage design where material details and reinforcement configuration are not yet critical. The RiZ-ING drawings are generally A4-pages containing a drawing of the component and its adjacent components. In Figure 2, the composition of such a page is shown. Besides the drawing it contains indicated component dimensions and location as well as additional information in text-form in the drawing and the title block. Each drawing has a title describing the component and a number e.g., "Kap 1 Blatt 3" for the third page of the first cap drawing (Bundesanstalt für Straßen- und Verkehrswesen, 2023). From the information contained in these drawings, rules can be derived that describe the step-by-step dimensioning of bridge caps. These rules can then be used for automated bridge cap dimensioning. Because SWRL is used for implementation, all rules are expressed as *if-then* constructs. Some of these rules are described in the Tables 2, 3 and 4.

The information contained in the RiZ-ING cap drawings can be grouped into three categories:

A) Geometric information on the cap
B) Relational information between the cap and adjacent components
C) Additional information on the cap's purpose, its material and its detailed design

To implement this information into an automated design process, relational and additional information is particularly critical. A minimum requirement would be implementing the rules in object-oriented programming (OOP) to correctly include all the information. OOP would be a good solution for the implementation of rigid *if-then* rules and the process in this work in general. However, OOP is not suitable when rules have to be implemented that are softer or contradicting and need to be weighted against each other. Here, an ontological structure would be appropriate with these rules described in the SPARQL Protocol And RDF Query Language (SPARQL) or the Shapes Constraint Language (SHACL) and applied using a Large Language Model (LLM). Therefore, this work uses ontologies to implement the automated bridge-cap dimensioning process and establish the foundation for future extensions.

Ontology

The ontological structure used in this work is based on the Bridge Topology Ontology (BROT) and the Bridge Component Ontology (BRCOMP) described by Hamdan and Scherer (2020), both of which build upon BOT introduced by Rasmussen et al. (2020). In addition, several *ObjectProperties* of the Relative Location Ontology (RELOC) by Göbels and Beetz (2024) have been incorporated.

Table 1 lists the ontologies used in this work. The Bridge Core Ontology (BCore) and the Bridge Element Design Rule Ontology (BEDRO) were created for this work in the Web Ontology Language (OWL 2) using Protégé (Musen, 2015). BCore extends BROT, BMAT and BRCOMP to represent the bridges, their components and their materials. BCore and BEDRO were created in a bottom-up approach. Thus, the *Classes* and properties

*The publication process for this website is not yet complete at the time of submission of this work.

necessary for the implementation of the RiZ-ING design rules were added to the basic framework of BROT, BMAT and BRCOMP. BCore includes structures for representing boundary conditions relevant to bridge design – the environment where the bridge is to be built. Additionally, it contains *Classes* and *ObjectProperties* describing agents (Persons or Companies) and media files (images, technical documents) that are connected to the specific bridge. These structures are not used in this paper, unlike the *Classes* or *ObjectProperties* displayed in Figure 3.

Here, the *Classes* needed for the dimensioning of the bridge caps are shown. A `Bridge` contains `Components`, such as the `EquipmentComponents` `Cap`, `TrafficBarrier` and `Pavement`. These components are also shown in Figure 1. Their relative locations are represented using the RELOC *ObjectProperties* `meetTop`, `meetBottom`, `meetLeft` and `meetRight`. This allows representing category B information. Newly created *Classes* are `InfrastructureRoute` and its subclasses `FootCycleRoute` and `RoadRoute`. The foot or cycle way can run to the left or to the right of a road. This information belongs to category C.

Several *DataProperties* were added to describe category A information, mainly geometric dimensions: the height of the pavement `PAVh`, the width of the traffic barrier `TRBb` and the cap's geometric parameters shown in Figure 4. All these parameters have the assigned *Datatype* `xsd:decimal`. The `FootCycleWay` has a `xsd:boolean`

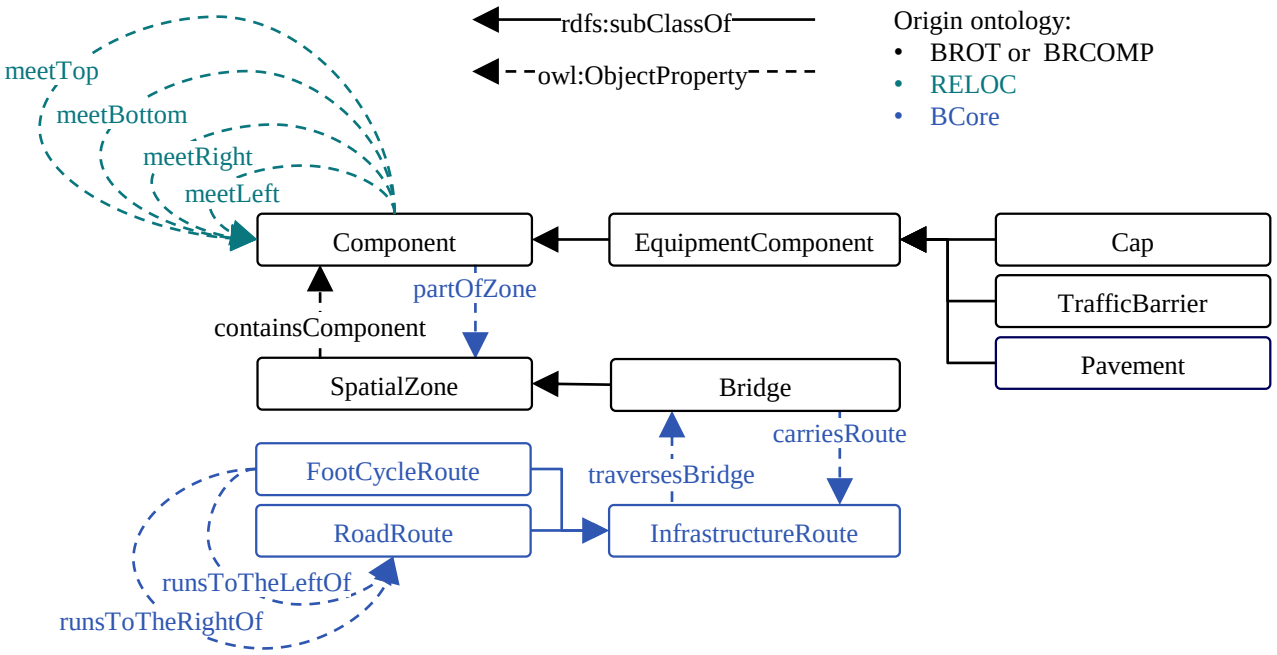

Figure 3: Diagram of Classes *from Hamdan and Scherer (2020) (BROT and BRCOMP, black), with added axioms of BCore (blue) and* ObjectProperties *from Göbels and Beetz (2024) (RELOC, green)*

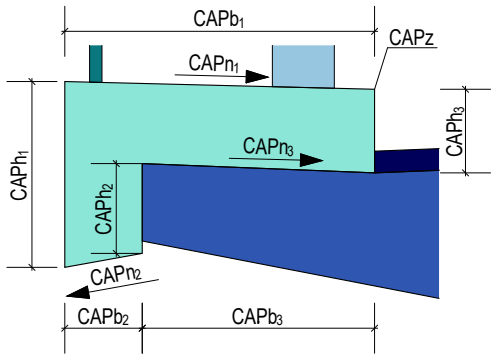

Figure 4: Geometric parameters in a bridge cap cross-section.

property `FootAndCycleWay`, which is `true` if it is a *combined* foot and cycle way. If it is only a foot way, it the value is `false`. The *DataProperty* `Position` of `Component` specifies, where the component is positioned in the bridge superstructure. The value 1 means left (relative to the direction of the route), the value 99 stands for right. If there are more than two components of the same type, they are numbered from left to right starting with 1, where right means always `Position` = 99. There are two more important *DataProperties* of `Cap`: the `CAPType`, indicating which cap design is assigned to the specific cap, and the `CAPCurb`, a `xsd:boolean`-Property describing if the cap has a curb or not. For example, a cap requires a curb if no traffic barrier is located above it, and vice versa.

This rule and other rules have been implemented in an ontology named BEDRO, an extension of BCore containing *if-then* rules extracted from the RiZ-ING guideline (Bundesanstalt für Straßen- und Verkehrswesen, 2023). The rules were first written in natural language before being translated into SWRL (O'Connor et al., 2005).

Three of these rules are contained in the tables below. They depict the cap dimensioning process. First, the boundary conditions of the bridge and the cap have to be checked to decide which type of cap to chose (Table 2). The type of cap refers to the different RiZ-ING drawings. For example, the drawing in Figure 2 dictates the measurements of an outer cap carrying a foot or cycle way and a traffic barrier. Inner caps are just needed if the bridge consists of multiple partial structures.

Table 2: Rule cap type*: description and SWRL-implementation*

If a road traverses a bridge and a combined foot and cycle way runs to the right of it and on the right side of the bridge it contains a cap with a traffic barrier on top, the cap's type is an outer cap with foot and cycle way and traffic barrier ("OuterCap_FCW_TRB")

`RoadRoute(?r) ^FootCycleRoute(?fcw)`
`^runsToTheRightOf(?fcw,?r)`
`^FootAndCycleWay(?fcw,true)`
`^Bridge(?b) ^carriesRoute(?b,?r)`
`^carriesRoute(?b,?fcw)`
`^containsComponent(?b,?c) ^Cap(?c)`
`^Position(?c,99) ^meetBottom(?c,?trb)`
`^TrafficBarrier(?trb)`
`-> CAPType(?c,"OuterCap_FCW_TRB")`

In the second step, the values contained in the RiZ-ING drawing are assigned to the *DataProperties* of the specific cap (Tables 3 and 4). They differ from cap type to cap type and are sometimes dependent on the dimensions of the adjacent components (`Pavement` and `TrafficBarrier`).

Table 3: Rule "Kap 1 Blatt 3" with combined foot- and cycle way*: description and SWRL-implementation*

If a cap has the type "OuterCap_FCW_TRB" (Outer cap with combined foot- and cycle way and traffic barrier) and it lies directly below a traffic barrier, the cap does not need a curb, its dimensions are declared as shown in Figure 2 and the top width is calculated as follows $CAPb_1 = 0.25 + 3.00 + TRBb + 0.5$ (unit: m)
`Cap(?c) ^CAPType(?c,"OuterCap_FCW_TRB")` `^meetBottom(?c,?trb) ^TrafficBarrier(?trb)` `^TRBb(?trb,?trbb)` `^swrlb:add(?b01,0.25,3.00,?trbb,0.50)` `-> CAPb1(?c,?b01) ^CAPb2(?c,0.35)` `^CAPn1(?c,0.02) ^CAPn3(?c,0.02)` `^CAPh2(?c,0.29) ^CAPCurb(?c,false)`

Table 4: Rule cap without curb*: description and SWRL-implementation*

If a bridge contains a pavement and a cap without curb, the cap's height 3 ($CAPh_3$) is 7.5 cm bigger than the pavement's height ($PAVh$), as shown in Figure 2
`Bridge(?b) ^containsComponent(?b,?p)` `^Pavement(?p) ^PAVh(?p,?ph)` `^containsComponent(?b,?c) ^Cap(?c)` `^CAPCurb(?c,false)` `^swrlb:add(?ch3,?ph,0.075)` `-> CAPh3(?c,?ch3)`

The third step is to calculate the rest of the cap's dimensions (see Figure 4) using the following equations (for better readability, the prefix "CAP" has been removed):

$$n_2 \approx 7.5\ \% \tag{1}$$

$$b_3 = b_1 - b_2 \tag{2}$$

$$h_1 = h_2 + h_3 + b_1 n_1 + b_2 n_2 - b_3 n_3 \tag{3}$$

These equations can also be implemented using SWRL and its math built-ins. As soon as all the rules are implemented and are not contradicting, the ontology can be used for an automated bridge cap dimensioning process.

Automated Design Process

Bridge design is typically an iterative process involving repeated refinement of the bridge structure and the components. An exemplary process is shown in Figure 5. It begins with the assessment of the bridge's boundary conditions, followed by a rough design of the superstructure, substructure, and equipment. Then, it is checked if the boundary conditions are met and wether the design meets the requirements related to cost, environmental impact, and aesthetics.

This work proposes automating one part of this process – the equipment planning, specifically the dimensioning of bridge caps. The created ontology with the implemented cap design rules, BEDRO, can be used as follows:

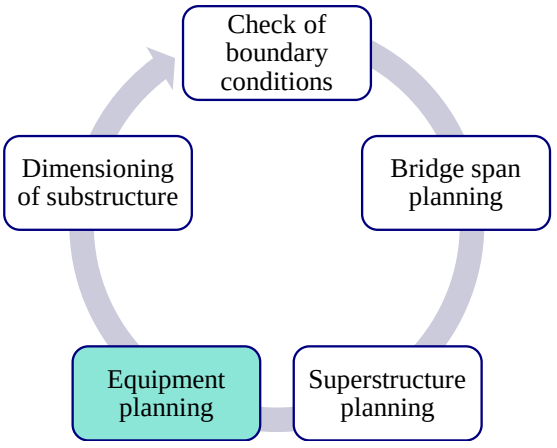

Figure 5: Iterative bridge design process.

1. Create instances of `Bridge`, `RoadRoute` and possibly one or two instances of `FootCycleRoute`.
2. Connect `RoadRoute` and `FootCycleRoute` instances to the `Bridge` via `traversesBridge` and assign either `runsToTheRightOf` or `runsToTheLeftOf` as between the routes.
3. Create an instance of `Pavement`, two instances of `Cap` and possibly instances of `TrafficBarrier`.
4. Assign *DataProperties* values for the components. Each cap and traffic barrier needs a value for its `Position`. The left component is assigned a "1", the right one a "99". As no design rules for `Pavement` or `TrafficBarrier` are implemented yet, their dimensions (e.g., `PAVh`, `TRBb`) must be provided manually.
5. Instantiate `partOfZone` as property of the components and the `Bridge`.
6. Run a SWRL-capable reasoner on the ontology and the dimensions of the bridge cap get automatically assigned values. In Protégé, the reasoner *Pellet* is recommended, as it handles SWRL effectively (O'Connor et al., 2005).

In Table 5, exemplary instances of a bridge and its corresponding routes and equipment components are described as well as their *ObjectProperties* and *DataProperties*. After implementing them in BEDRO and running the *Pellet*-reasoner, new relations and attributes have been created. Figure 6 shows the instance "B1Cap1", which is the left cap of the bridge "B1". The reasoner has inferred two *ObjectProperties*, describing that the cap is directly below the traffic barrier "B1TrB1" and directly left of the bridges pavement "B1Pav1". Also, it has inferred that the type of the cap is "OuterCap_FCW_TRB", following the rule in Table 2. The other inferred values are assigned by executing the other rules described above. "B1Cap99" does not have the same type as "B1Cap1" and hence has other values for its properties.

Since not many bridge engineers are experienced in working with ontologies or Protégé, the process must be made more user-friendly for practical adoption. A graphical user-interface (GUI) may be implemented,

Table 5: Exemplary instances and assigned properties for an automated dimensioning of the bridge caps "B1Cap1" and "B2Cap99"

Class	Instance	ObjectProperty/ DataProperty	Value
`Bridge`	B1		
`Road`	R1	`traversesBridge`	B1
`FootCycleWay`	FC1	`FootAndCycleWay`	true
		`runsToTheLeftOf`	R1
		`traversesBridge`	B1
`Cap`	B1Cap1	`Position`	1
		`partOfZone`	B1
`Cap`	B1Cap99	`Position`	99
		`partOfZone`	B1
`Pavement`	B1Pav	`PAVh`	0.07
		`partOfZone`	B1
`TrafficBarrier`	B1TrB1	`Position`	1
		`TRBb`	0.5
		`partOfZone`	B1

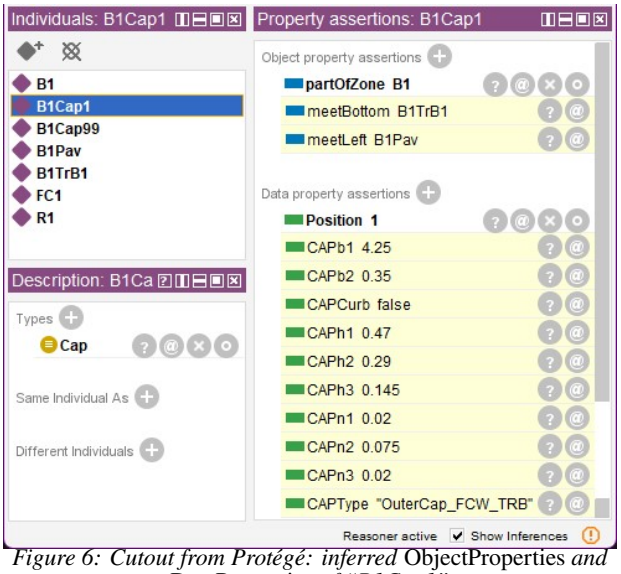

Figure 6: Cutout from Protégé: inferred ObjectProperties *and* DataProperties *of "B1Cap1"*

where the engineer can insert the boundary conditions of the respective bridge. Via an application programming interface (API), the *Classes* and *Properties* are then created, the reasoner is run and the generated cap dimensions are displayed as in Figure 7. Also, an export of these dimensions to a CSV-file would be feasible.

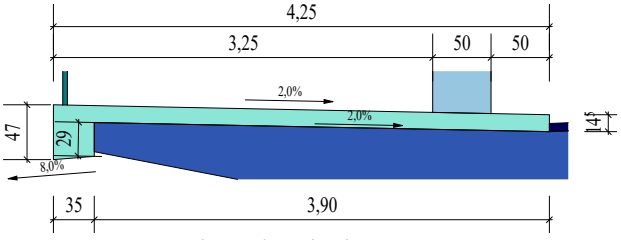

Figure 7: Rule-conform bridge cap cross-section.

A step further would be to implement the whole process into a combined GIS-BIM-approach. Here, it would be possible to extract the relevant boundary conditions from geographical information system (GIS)-data. The boundary conditions are then integrated into the ontology via an API. After the application of the rules using a reasoner, the generated component attributes can be extracted. With this data, a parametric building information model as described by Jeske et al. (2022) is populated, to obtain rule-conform dimensions and material information. This model can be used for further analyses such as quantity or cost estimation, as well as for visualization of the created bridge components.

Discussion

This work proposes a method for implementing design rules from a German guideline, the RiZ-ING, into an ontology. This ontology can be used to automatically generate rule-conform bridge cap dimensions for specific bridge boundary conditions. For that, SWRL rules were derived and can be applied using a reasoner. This process is limited in its user friendliness, applicability and scalability.

As stated before, bridge engineers do not usually work with ontologies and even when they do, many manual steps are still required before the cap dimensions can be generated. A solution could be a GUI, or integration into a GIS-BIM-application. Implementing a GUI or API would be simpler if the entire process were programmed in OOP. No API to the ontology would be needed and *if-then* rules can also be implemented in OOP. SWRL also has limitations: although it can in principle create new instances or properties, most reasoners do not support this functionality. Also, the Open World Assumption of OWL 2 makes it hard to check for non-existent instances (O'Connor et al., 2005).

The integrated rules apply only to new German road bridge caps. Thus, when designing a railway bridge or a French bridge, the ontology cannot be used. Also, the rules from the RiZ-ING the RiZ-ING rules are recommenda-

tions rather than legal requirements i.e., it is possible to deviate from these rules. Fixed *if-then* rules do not allow such deviations which also complicates transferring the approach to other components or another structure. In this case, a highly standardized component is needed, where every dimension can be derived using rules. In the field of bridge design, this condition mainly applies to equipment components e.g., the pavement, railing or traffic barrier. But, possibly, a manual intermediate step is needed here for a complete component design. For an automated design of the whole bridge, generative artificial intelligence is needed, but can be supported by rules implemented in an ontology.

Nevertheless, this exemplary automated dimensioning shows the potential of ontology applications in the construction sector. As stated above, in the AEC sector, ontologies and semantic rules have not yet been used to create new structural designs from the structure's boundary conditions. Especially in the field of bridge engineering, using ontologies for bridge design and guideline implementation is a new topic.

In principle, it is possible to transfer the process to other bridge components if they are as highly standardized as the bridge cap. The implementation of different kinds of rules still needs to be tested. Also, a human in the loop-implementation is imaginable if not every design decision can be automatized. When embedded in a well-adapted application, it could save bridge engineers significant time by avoiding repeatedly dimensioning the bridge cap or other standardized components every time for a new round of design circle (see Figure 5) but just to enter the boundary conditions and to generate the dimensions automatically. With that, they can concentrate on the more important decisions in the substructure and superstructure planning.

Conclusions

Bridge design consists of a vast amount of boundary conditions to consider and of decisions to make. This work proposes a way of automating the dimensioning of highly standardized bridge components, to reduce the engineer's workload. German road bridge guidelines are translated into *if-then*-rules defining the dimensions of the bridge caps for specific boundary conditions. The rules are implemented in an ontology using SWRL. The ontology in combination with a reasoner can be used to automatically generate the cap's dimensions. The process was applied to an exemplary imaginary bridge. The findings of this work are:

1. Information in guidelines and standards is contained in different forms and formats. For an automated design process, the information needs to be translated into *if-then*-rules, which can be transformed into programming code and applied to the respective design task. In this work, the *if-then*-rules were transformed into SWRL-rules.
2. It is possible to generate the bridge cap's dimensions using an ontology, SWRL and a reasoner. For that, the boundary conditions of the bridge and the bridge components need to be created as instances in the ontology. The proposed process can be transferred to other components, as long as they are highly standardized and the content of these standards can be translated into *if-then*-rules.
3. There are several limitations of this process: user friendliness, applicability and expandability. These limitations can be met using different state of the art-technologies such as a GIS-BIM-application, generative AI and newly developed APIs or by creating a well-adapted GUI and manual intermediate steps and intermediate decisions into the bridge design process.

Abstract

Conventional office fit-outs are designed for fixed requirements, which limits their long-term adaptability. This paper introduces a workflow that integrates configurable floor-plan graphs with large language models (LLMs) to enable adaptable office layout exploration. Interior space is represented as a graph that encodes geometry, adjacency, and accessibility, and is parameterised by binary partition decisions. For each candidate configuration, an LLM infers program assignments across multiple scenarios, and solutions are evaluated in a multi-objective combinatorial optimisation. Results show configurations with feasible performance across scenarios, suggesting that LLM-based program assignment can serve as a flexible semantic component that complements quantitative solver-based methods.

Introduction

Offices are constantly evolving. Changes in organisational structures, workforce patterns, and work styles require interiors to adapt. However, this adaptation often comes with a cost: frequent renovations lead to significant environmental impacts, with emissions and waste from repeated fit-out cycles exceeding those of the building itself during its lifetime (Casas Arredondo, 2021; Forsythe and Wilkinson, 2015).

Circular fit-out design has emerged as a response to the environmental consequences of short fit-out lifecycles. In circular construction, adaptability is a core design requirement that increases the ability to accommodate changes in use, environment, and specification throughout time without extensive refurbishment, enabling longer building lifespans and lower embodied greenhouse gas emissions (Watt et al., 2023). Rather than optimising interiors for a single functional state, adaptable fit-outs explicitly account for change over time, by extending the design scope to encompass successive use scenarios within the same spatial system.

Computational generative-design methods offer a promising means to support such adaptability by systematically generating and evaluating alternative spatial configurations under varying requirements. However, most existing generative-design paradigms remain orientated toward single-scenario or fixed specifications. Implicitly assuming stable functional requirements, they optimise layouts for a single, fixed programmatic state. As a result, adaptability is typically treated as an evaluative afterthought rather than a generative principle embedded in the design process itself.

This research addresses the limitation of single-scenario design by decoupling spatial configuration from programmatic assignment. We investigate how floor plan graphs, in which spaces are modelled as nodes and connectivity is encoded as edges, can support large language models (LLMs) in assigning program labels for a given spatial configuration under different scenarios. Multi-objective optimisation is employed to find configurations that maintain acceptable performance across multiple programmatic scenarios.

The hypothesis is threefold. First, separating spatial configuration from programmatic assignment enables the modelling of multifunctionality, in which a single space can accommodate multiple uses. Second, floor plan graphs act as an intermediate representation bridging geometric and semantic interpretation. Third, LLM-based programmatic assignment may provide a flexible semantic labelling step that complements quantitative constraint-based solvers and helps relate underspecified preferences to optimisation objectives.

The proposed workflow supports finding spatial configurations that can accommodate multiple programmatic scenarios (Figure 1). By operationalising adaptability in the workflow, this work provides a method for exploring spatial configurations that remain viable across multiple future use scenarios, supporting longer fit-out lifecycles.

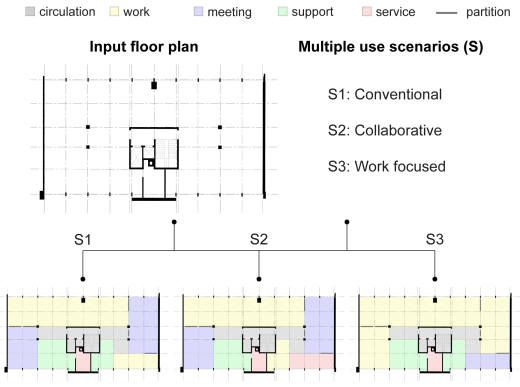

Figure 1: Adaptive layout objective. Given an input floor plan and multiple scenario requirements, we seek layouts that accommodate multiple programs without reconfiguration.

Background

Modelling spatial adaptability in circular fit-out

Adaptability operates on multiple temporal scales, ranging from short-term adjustments such as moving furniture, through medium-term reconfiguration of spatial layouts, to long-term transformations including changes in building use (Schmidt-III and Austin, 2016; Watt et al., 2023). For office interiors, adaptability is primarily situated on a short- to medium-term scale, where frequent organisational and operational changes require interior interventions. To minimise environmental impact, we posit that adaptability at these scales depends on the latent capacity of a spatial layout to support multiple configurations with minimal structural intervention.

The spatial capacity represented by the dimensions of space and the position of durable elements plays a significant role in the definition of the future adaptability (Durmišević, 2018). Graph-based representations offer an opportunity to model such spatial capacity. For example, Pacquée et al. (2025) developed a graph-based method to encode the topology and geometry of a building, allowing comparison between reference projects to assess their potential for future reuse. At the scale of architectural layouts, Herthogs et al. (2019) modelled floor plans as spatial graphs and quantified their capacity for change through measures of topological depth and path redundancy as a proxy of the layout's ability to support multiple programmatic scenarios over time.

Building on this body of work, we adopt spatial graphs not primarily as an evaluative tool to measure adaptability but as a configurable representation to systematically explore alternative layout configurations under varying programmatic scenarios.

Generative design of an adaptable office

Generative spatial layout design has been widely studied in computational design and space-planning research, which commonly distinguishes between knowledge-driven and data-driven approaches (Yan et al., 2025). Knowledge-driven methods generate layouts by explicitly structuring the design through rules, constraints, and objectives. They encompass rule-based systems, heuristic and mathematical optimisation, and reinforcement learning. Architectural intent is explicitly encoded at different stages of the generative process: rule-based methods formalise the design intent through predefined spatial rules and discretization schemes (Sheijani et al., 2024), parametric workflows couple parametric models with multi-objective evolutionary optimisation to explore trade-offs among evaluation criteria (Nagy et al., 2017), and hybrid approaches combine constraint programming with evolutionary search to generate feasible layouts within fixed envelopes (Laignel et al., 2021). More recently, reinforcement learning has been used to incorporate spatial constraints and objectives directly into state, action, and reward formulations (Zhang et al., 2024b). Although considerably effective, these approaches rely on extensive explicit knowledge encoding, and thus face scalability limits for real-world problems that are often open-ended and incomplete.

Data-driven approaches generate spatial layouts by learning patterns from given datasets; for example, they map partial design input such as text prompts, bubble diagrams, or footprint constraints to complete spatial layouts. Data-driven approach includes statistical generative models, deep neural networks, and example-based or case-based generation methods. Representative examples include models based on the generative adversarial network (GAN) such as HouseGAN (Nauata et al., 2020), diffusion-based approaches such as HouseDiffusion (Shabani et al., 2023), and transformer-based models such as MaskPLAN (Zhang et al., 2024a). However, the limited availability of large, high-quality architectural datasets has mostly confined these methods to residential typologies.

Beyond these limitations, most generative-design methods optimise layouts for a single design state, limiting future adaptability. We address this limitation by decoupling spatial configuration from programmatic assignment. This separation allows multiple program interpretations to be inferred from the same spatial configuration in response to different use scenarios.

LLM graph-based spatial reasoning in generative design

Recent advances in LLMs have shown growing capabilities in symbolic and relational tasks, motivating their integration into generative-design workflows for spatial layout problems. Rather than directly generating precise geometry, most approaches use LLMs as high-level semantic or planning components operating over abstract spatial representations, such as graphs, symbolic relations, or procedural descriptions. At the interior scale, LayoutGPT frames layout generation as a compositional planning problem using in-context examples, in which LLMs translate natural language prompts into structured descriptions of objects and their spatial properties in a CSS-like format (Feng et al., 2023). FlairGPT uses LLMs to generate zones, objects, and inter-object constraints, which are organised into a layout constraint graph and solved using standard optimisation algorithms (Littlefair et al., 2025). At the building scale, Text2BIM extends this direction through a multi-agent framework that generates structured procedural instructions for BIM authoring tools (Du et al., 2026). Collectively, these works suggest that LLMs are most effective when applied to high-level semantic and relational tasks, while detailed geometric realisation is delegated to rule-based, procedural, or optimisation-based systems.

Method for graph-based fit-out design explorations

Overview

We propose a generative workflow for an adaptable layout design that integrates spatial-configuration optimisation with scenario-driven programmatic assignment (Figure 2). The workflow starts with two inputs: an input floor

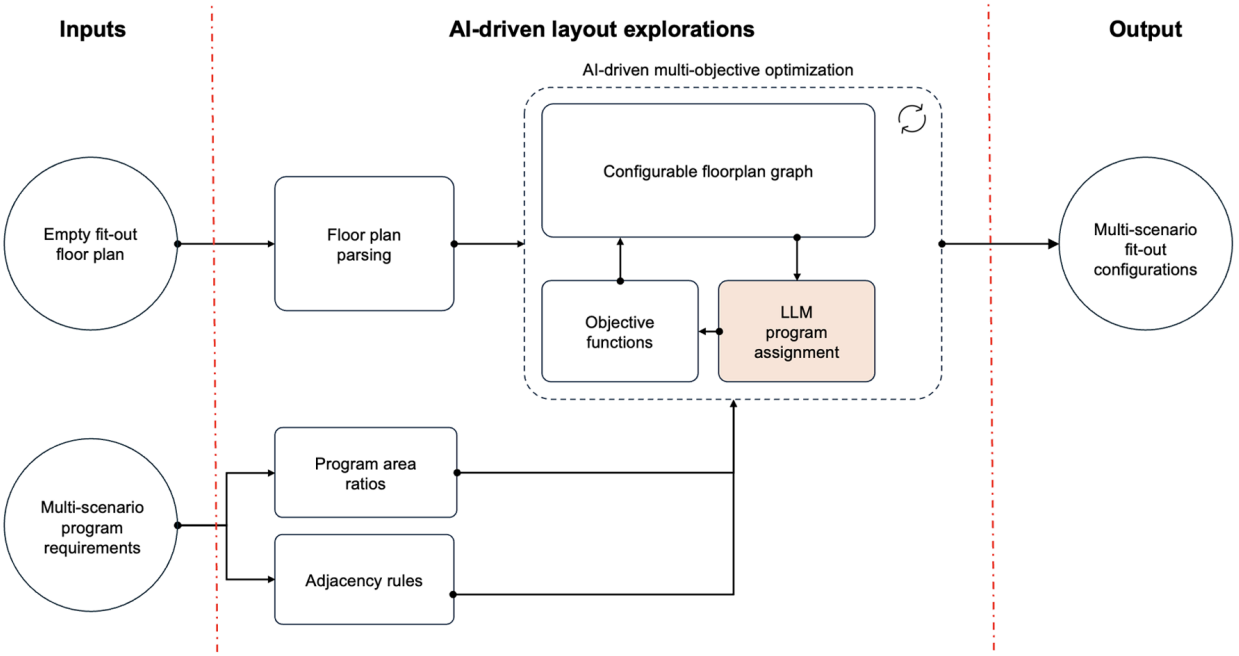

Figure 2: Overview of graph-based fit-out layout explorations with LLM

plan and a set of use scenarios. The floor plan is parsed into a configurable floor plan graph that defines a fixed topological layout independent of the program. The programmatic requirements of each scenario are delegated to an LLM, which assigns zone labels to the floor plan graph according to the area-ratio targets and adjacency rules. A multi-objective evolutionary algorithm optimises the spatial configuration using these criteria, yielding layouts that can accommodate multiple scenarios.

Parsing the input floor plan into a configurable graph

The input floor plan contains geometric information on the existing structure, walls, doors, and windows as well as predefined zones, such as the entrance and the service areas, and an underlying planning grid used to discretise the layout. The parsing module converts this input into a parametric representation by discretising the floor area into cells and introducing binary decision variables, x, that govern the placement of partitions between adjacent cells (Figure 3). From this representation, an intermediate visibility graph is constructed, and strongly connected cells are clustered to produce a configurable floor plan graph, $G_{fp}(x)$. Changing x, the optimisation algorithm explores alternative spatial configurations, each of which is reflected in a corresponding instance of $G_{fp}(x)$. The resulting graph representation then serves as input for the LLM modules to infer programmatic assignments under different use scenarios.

Programmatic requirements for multi-scenario inputs

Programmatic requirements are specified as a set of discrete use scenarios, each of which is translated into two complementary specifications: (1) target program area ratios and (2) adjacency rules between functional zones.

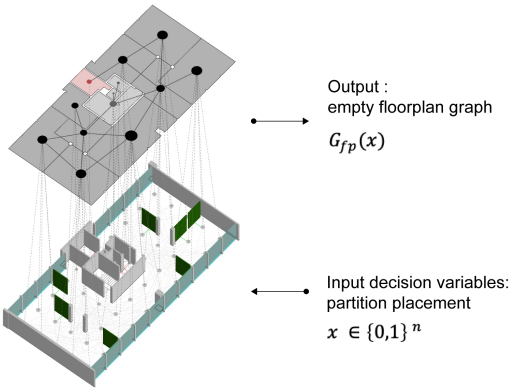

Figure 3: The empty floor plan is parsed into a configurable graph, where binary decision variables defined on the planning grid control the placement of partitions.

This formulation allows multiple future programs to be evaluated against a shared spatial configuration. In this preliminary study, each scenario defines target area ratios for five abstract zone types: Work (W), Meeting (M), Support (Su), Service (Se), and Circulation (C) (Table 1). In parallel, qualitative spatial relationships are encoded as hop-based constraints on the floor plan graph (Table 2). Required adjacencies (R_1) and forbidden adjacencies (F_1) are enforced as hard constraints, defined in terms of graph distance between zones, while preferred proximities (P_2) are modelled as soft objectives that bias solutions toward functional coherence without over-constraining the layout. Circulation is constrained to maintain direct adjacency to all other zone types, ensuring global accessibility across configurations.

For each scenario, s, the programmatic requirements are

represented by a pair (A_s, R_s), where A_s specifies the ratios of the target program area, and R_s specifies the adjacency rules. These scenario specifications serve two functions in the workflow. First, they are translated into a structured prompt context for the LLM, which assigns zone labels to the nodes of the input floor plan graph for each scenario. Second, they parameterise the objective functions used during evolutionary optimisation. Specifically, deviations from A_s and violations of R_s are quantified through scenario-wise evaluations, which are subsequently aggregated across scenarios to assess the adaptability of a given spatial configuration.

Table 1: Program scenarios as target area ratios (sum = 1.0)

Scenario	W	M	Su	Se	C
S1	0.50	0.20	0.10	0.10	0.10
S2	0.40	0.30	0.10	0.10	0.10
S3	0.65	0.10	0.10	0.05	0.10

Table 2: Adjacency and proximity constraints encoded as hop-based relations

From\To	W	M	Su	Se	C
W	–	P_2	P_2	F_1	R_1
M	P_2	–	–	F_1	R_1
Su	–	–	–	P_2	R_1
Se	F_1	F_1	P_2	–	R_1
C	R_1	R_1	R_1	R_1	–

LLM programmatic inference

Given a candidate floor plan graph, G_{fp}, and a scenario-specific program configuration (A_s, R_s), we construct a textual prompt, P_s, consisting of a program block and a rules block. The floor plan graph, G_{fp}, is provided to the LLM as a structured JSON representation encoding global, node, and edge properties, including spatial attributes such as area, perimeter components, bounding boxes, aspect ratios, and interface characteristics between adjacent spaces. The program block derives the total usable area from the node attributes in G_{fp} and specifies the target area for each zone type in A_s, reported in absolute and relative terms. The rules block serialises the adjacency constraints in R_s as hard and soft relations with associated predicates and targets. A structured system instruction and output template guide the LLM to assign zone labels within a predefined schema without modifying the underlying spatial topology. The instruction embeds the scenario context, P_s, together with the list of valid zone types. Outputs that do not conform to the expected schema or label set are discarded, and the original unlabelled floor plan graph is retained for evaluation. Analysis of the reported experiments suggests that such fallback was negligible, occurring in at most 1 of 5000 evaluated rows for the LLM-based setups. The final prompt is formed by concatenating the two blocks (1), and the LLM receives G_{fp} and P_s to assign zone labels, producing an updated graph, G_{fp}^{llm} (2).

$$P_s(G_{fp}, A_s, R_s) = P_{\text{prog}}(G_{fp}, A_s) \parallel P_{\text{rules}}(R_s) \quad (1)$$

$$G_{fp}^{\text{llm}} \leftarrow \text{LLM}(G_{fp}, P_s) \quad (2)$$

Multi-objective optimisation

Optimisation variables are the binary partition decisions, x, defined in the planning grid. For each candidate, x, a floor plan graph, $G_{fp}(x)$, is generated and tested for connectivity. Only connected configurations invoke LLM inference; disconnected graphs are excluded using a hard feasibility constraint.

For each scenario, $s \in S$, the LLM assigns zone labels to $G_{fp}(x)$ using the corresponding program area ratios and adjacency rules, producing a set of inferred graphs, $\{G_{fp}^{\text{llm}}(s)\}$. Then, two objective functions are evaluated and aggregated across scenarios: program-ratio fitness and rule compliance. The fitness of the program ratio measures the deviation between the achieved and target area ratios using the mean absolute error (MAE). Rule compliance evaluates the adherence to required, forbidden, and preferred adjacencies using hop-based scoring, normalised to a score in the range $[0, 100]$. The resulting bi-objective optimisation problem is defined as:

$$f_1(x) = \frac{1}{|S|} \sum_{s \in S} \text{MAE}_{\text{area}}\left(G_{fp}^{\text{llm}}(s), A_s\right), \quad (3)$$

$$f_2(x) = -\frac{1}{|S|} \sum_{s \in S} \text{Score}_{\text{rules}}\left(G_{fp}^{\text{llm}}(s)\right), \quad (4)$$

$$\text{subject to } G_{fp}(x) \in \mathcal{G}_{\text{conn}}. \quad (5)$$

We solve this bi-objective optimisation problem using NSGA-II (Deb et al., 2002). The initial population is sampled as sparse binary vectors to promote diversity in partition configurations. Optimisation terminates after a fixed number of generations or when changes in decision variables and objective values fall below a predefined tolerance.

Case study and discussion

Based on an input office floor plan with a total area of approximately 400 m^2 (Figure 1) and the multi-scenario programmatic specifications in Tables 1 and 2, we conducted a series of experiments to evaluate the proposed workflow using different LLMs and a baseline approach, assessing their performance across optimisation quality, spatial regularity and topological complexity of the resulting layouts.

Experiment setup

LLM-based programmatic inference is executed using a locally hosted Ollama server accessed through the Python `ollama` client, keeping all inference local to the experimental environment. We evaluate three large language

models with increasing capacity: `phi4:14b`, `deepseek-r1:32b`, and `gpt-oss:120b`, where model size (in billions of parameters) provides a rough indication of overall model capability.

To ensure reproducibility, deterministic decoding is used where possible. Greedy decoding (temperature = 0.0) is applied for `phi4:14b` and `deepseek-r1:32b`, producing consistent outputs across runs. For `gpt-oss:120b`, temperature = 0.0 proved unstable in our Ollama setup; therefore, we retain the model's default sampling configuration (temperature = 1.0) and set `thinking=low`, leaving other decoding parameters unchanged.

As a baseline, we implement a constraint-programming model using OR-Tools CP-SAT (Perron et al., 2023). Following established discrete space allocation formulations (Laignel et al., 2021), the solver assigns a single zone label to each node of the floor plan graph using a one-hot encoding while keeping the topology fixed and respecting predefined labels. The objective minimises deviations from target area ratios and penalties for soft spatial preferences, such as proximity and path coherence. Hop-based adjacency rules are converted into weighted penalties. Circulation accessibility is approximated by enforcing connectivity among circulation-labelled nodes using a predecessor-tree formulation.

Optimisation of spatial configuration is performed using NSGA-II implemented in an existing Python package (Blank and Deb, 2020), with a population size of 50 evolved over 100 generations. The initial population is generated through Bernoulli sampling with an open-edge probability of 0.1, biasing the search toward sparse partition configurations in early generations. Results are reported from a single optimisation run per setup with a fixed random seed. For each optimisation run, LLM inference consumed an estimated 49.9 million tokens in total, including 46.0 million input tokens and 3.9 million output tokens.

We evaluate the results in three complementary dimensions. First, optimisation performance is assessed by comparing Pareto fronts across setups using hypervolume (HV) (Fonseca et al., 2006) and inverted generational distance plus (IGD+) (Ishibuchi et al., 2015). Both indicators are computed on normalised objective values, with objectives scaled to $[0, 1]$ across all experiments. For HV, a fixed reference point of $(1.1, 1.1)$ is used to ensure dominance over all feasible solutions. IGD+ is computed with respect to the union of non-dominated solutions obtained across all setups, serving as a common reference set for convergence comparison. These metrics jointly quantify trade-off quality and convergence with respect to program area-ratio fitness and rule compliance. Second, the shape complexity of the generated layouts is evaluated following Brinkhoff et al. (1995). The measure captures the irregularity of the boundaries and the convexity of the shapes of individual rooms, weighted by room area, providing an indicator of spatial regularity and constructibility. Third, the topological complexity of Pareto-optimal floor plan graphs is evaluated using the cyclomatic number (McCabe, 1976), which captures loop redundancy in adjacency and circulation networks and indicates the potential for alternative routing and future adaptability.

Pareto fronts

The comparison of Pareto fronts across different setups is shown in Figure 4 and Table 3. A clear distinction emerges between constraint-based and LLM-based programmatic inference. The CP-SAT baseline consistently achieves higher HV and lower IGD+, reflecting its ability to exploit a fully specified optimisation model under explicitly encoded objectives. In contrast, all LLM-based setups exhibit lower Pareto-front quality, with broader but less extreme fronts, indicating weaker convergence within the defined objective space.

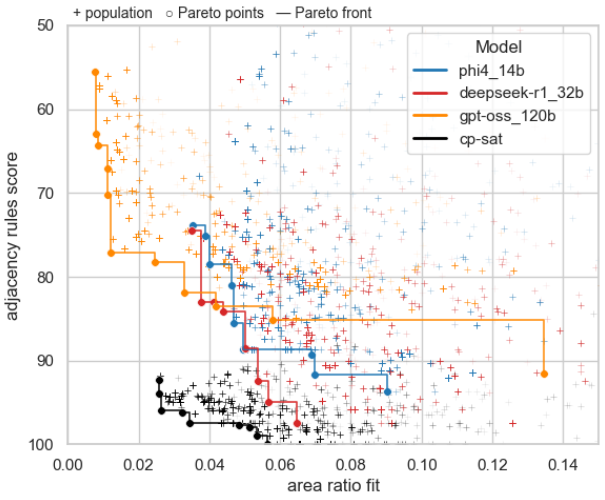

Figure 4: Pareto fronts from the optimisation results

Table 3: Pareto-front quality metrics across setups

Setup	HV ↑	IGD+ ↓
Phi-4	1.051	0.079
DeepSeek-R1	1.092	0.060
GPT-OSS	1.086	0.070
CP-SAT	1.153	0.018

Among the LLM-based configurations, optimisation performance does not consistently improve with larger model size. DeepSeek-R1:32B achieves the highest HV and lowest IGD+ among the LLM variants, suggesting a more balanced trade-off between program area-ratio fitness and adjacency rule compliance. GPT-OSS:120B tends to favour program area-ratio fitness, achieving lower area deviation at the expense of adjacency rule compliance, while Phi-4:14B shows the weakest overall performance across both objectives. Overall, LLM-based programmatic inference remains substantially below the CP-SAT baseline and is better understood as a flexible program-assignment mechanism rather than a replacement for exact optimisation.

These observations point to a hybrid direction for future work, in which hard constraints are handled by classical

solvers while LLMs support more qualitative or underspecified aspects of program assignment.

Floor plan complexity

To further characterise the generated layouts, we use shape complexity and cyclomatic number as proxies for geometric and topological complexity, respectively. Both metrics are evaluated for the Pareto-optimal solutions of each setup, with their distributions shown in Figure 5.

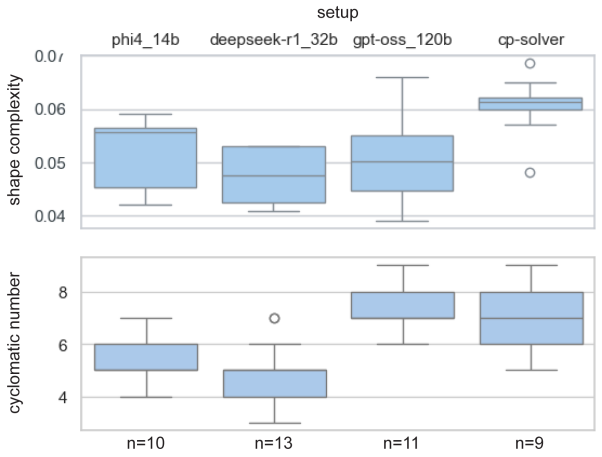

Figure 5: Comparison of room shape and topological complexity of Pareto-optimal floor plan graphs generated by different setups

The results reveal clear differences between the CP-SAT baseline and the LLM-based setups. While the CP-SAT solver identifies Pareto-optimal solutions that more closely satisfy the explicitly defined objectives, it also produces layouts with more irregular room geometries. This indicates a geometric trade-off associated with closely fitting the optimisation objectives.

A separate pattern appears in the topological metrics. The higher distribution of cyclomatic complexity indicates that CP-SAT also explores configurations with more complex adjacency and circulation structures. This is broadly consistent with (Herthogs et al., 2019), who related spatial-graph measures such as topological depth and path redundancy to a layout's capacity for change across programmatic scenarios. From this perspective, higher topological complexity may indicate greater capacity for change across programmatic scenarios, as increased loop redundancy can support alternative spatial relationships.

In contrast, LLM-based setups tend to favour structurally simpler layouts. Phi-4:14B and DeepSeek-R1:32B both produce layouts with simpler room geometries and lower cyclomatic complexity, with DeepSeek-R1:32B showing the strongest reduction in complexity. However, from the perspective of graph-based adaptability, this simplification may also imply lower path redundancy and reduced capacity to accommodate alternative programmatic scenarios. GPT-OSS:120B departs from this pattern, exhibiting higher topological complexity and greater variability in room shape complexity, suggesting that stronger optimisation of program area ratios may again introduce more complex spatial structures.

Multi-scenario layout configurations

Figure 6 presents representative multi-scenario layout configurations obtained from each setup. Each column shows a single spatial configuration evaluated in three scenarios, together with summary metrics on geometric complexity, topological complexity, and objective performance. The qualitative observations are consistent with the quantitative analysis reported earlier.

The CP-SAT baseline is a strong benchmark when program requirements are clearly defined. By directly optimising area ratios and adjacency constraints, it consistently achieves the best objective performance, underscoring the value of explicit formulations: when objectives and constraints can be clearly encoded, exact optimisation is most effective. In contrast, LLM-based setups use floor plan graph features and in-context prompting to assign program labels across scenarios. They do not reliably match CP-SAT's objective values and show variable geometric and topological complexity, but they offer an alternative assignment method when scenario-specific formulations are underspecified or difficult to encode explicitly.

Representative samples from `phi4:14b` and `deepseek-r1:32b` balance objective performance with relatively low topological complexity, with `phi4:14b` showing higher geometric complexity than `deepseek-r1:32b`. `gpt-oss:120b` instead produces layouts with lower geometric complexity but more rooms and connections, increasing topological complexity.

Separating spatial configuration search from programmatic assignment allows adaptable layout exploration, since one configuration can be evaluated across scenarios while optimisation targets layouts that support high-quality assignments. In this setup, explicit constraint solving is effective when program requirements are clearly specified, as in the CP-SAT baseline. LLM-based inference is generally less optimal but provides an alternative when scenario requirements are less fully specified or more difficult to encode explicitly.

Limitations

The proposed workflow is intended as an exploratory prototype and several limitations should be addressed in future work. Although the graph-based representation enables LLM-based programmatic inference, a clear performance gap remains compared to the constraint-based baseline, and embedding LLM inference within the optimisation loop introduces substantial computational overhead. This finding motivates more selective hybrid workflows in which well-defined objectives and hard constraints are handled by solvers, while LLM-based programmatic inference is applied only to a smaller set of promising candidate configurations. In addition, the reported experiments are limited to a single optimisation run on one small office floor plate and a set of simplified programmatic sce-

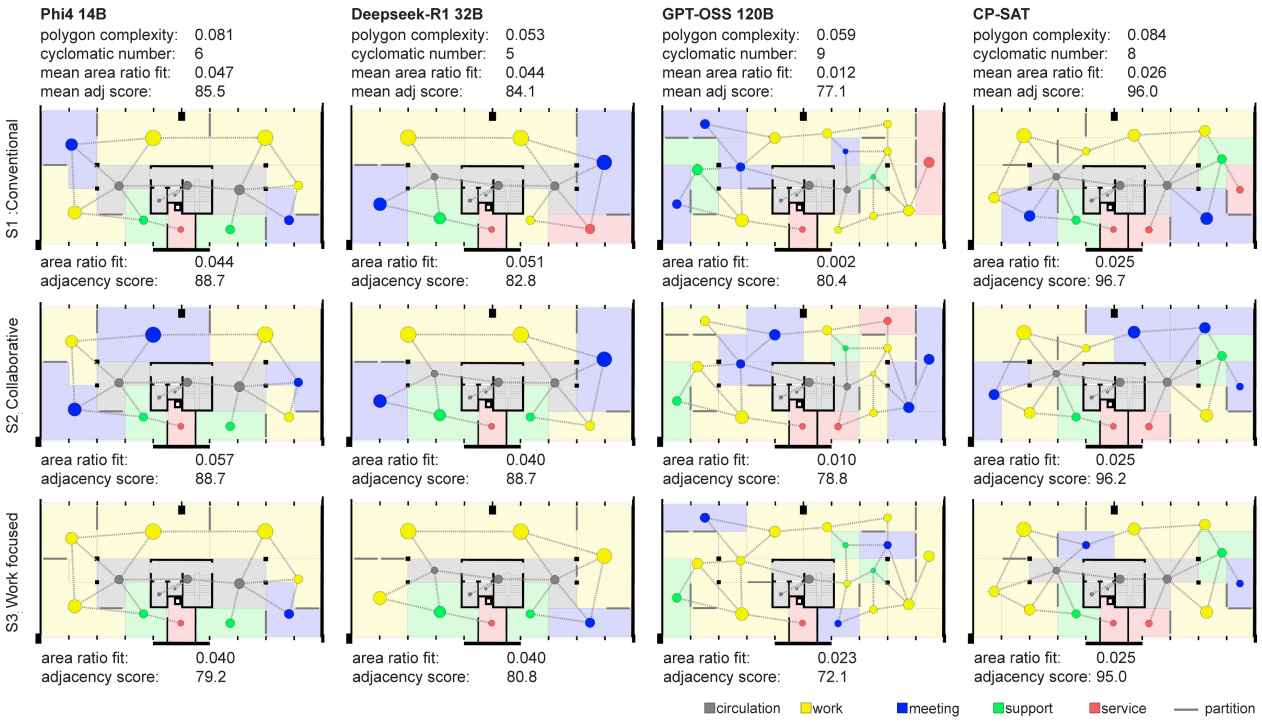

Figure 6: Representative sample of generated multi-scenario floor plans from across setups

narios with only modest structural differences, so the findings should be read as exploratory rather than generalisable. Finally, the evaluation focuses on proxy metrics to assess the feasibility of the results; more comprehensive and practice-orientated measures, including direct indicators of adaptability, circularity, and environmental impact, are required to evaluate the effectiveness of the method in reducing the embodied greenhouse gas emissions associated with office refurbishments.

Conclusion and outlook

This paper presented a graph-based computational workflow for exploring adaptable office fit-out layouts across multiple future use scenarios. By decoupling spatial configuration from programmatic assignment and delegating scenario-specific program assignment to LLMs, the approach supports the systematic exploration of spatial layouts that remain viable across changing requirements. The results show that, while LLM-based programmatic inference does not match the optimisation performance of fully specified constraint-based models, it can generate diverse configurations without requiring exhaustive re-encoding of programmatic constraints for each scenario. This suggests that LLMs are better understood as flexible semantic components within a hybrid optimisation workflow rather than as replacements for exact optimisation.

Looking ahead, the findings point toward more selective hybrid generative-design workflows in which classical optimisation methods enforce hard constraints and quantitative objectives, while LLM-based programmatic inference is applied to a reduced set of promising candidate layouts. Future work should extend the method to larger and more heterogeneous floor plans, richer and more realistic program definitions, and a broader set of evaluation criteria relevant to adaptability, circularity, and environmental impact. Incorporating downstream fit-out feasibility and reuse-related assessments would further support practical application in circular fit-out design.

FEW-SHOT BUILDING ELEMENT DETECTION WITH VISION TRANSFORMERS: IMPROVING ENERGY RETROFIT MATCHING

Tom Slik[1], Raphaël Gueulet[1], Christos Lathourakis[1]
[1]Netherlands Organisation for Applied Scientific Research

Abstract

Traditional computer vision struggles with domain-specific few-shot building element detection in street-view imagery, creating a bottleneck for extracting the building information needed for data-driven retrofit matching. This paper proposes a few-shot framework that combines a pre-trained Vision Transformer with a Random Forest patch classifier and adaptive cropping to address domain shift and limited annotations. With only 21 labeled images per element, the method achieves mean detection accuracy greater than 0.95 across seven elements and enriches building stock data at address level, enabling more accurate matching of retrofit measures.

Introduction

Accelerating energy retrofits is critical for climate neutrality, yet scaling standardized solutions across millions of dwellings remains challenging due to limited address-level data on retrofit feasibility.

Recent innovation projects (e.g., Energiesprong and INFINITE) and research initiatives have demonstrated that accelerating energy retrofit requires a shift from custom, project-based approaches toward standardized or product-based methodologies that enable scalability through industrialization (van Groesen, 2022; Bjelland et al., 2024).

Large-scale renovation studies often rely on building archetypes, where dwellings are typically grouped by construction period and type. An archetype can be associated with renovation measures that correspond to characteristic insulation and energy performance levels—supporting macro-scale renovation planning, scenario analysis, and cost and energy estimations (Uihlein and Eder, 2010; Coffee et al., 2025; Mata et al., 2014). A comprehensive review of archetype-based modeling underlines both their central role in building stock analysis and their methodological limits, encouraging more adaptive, data-driven approaches (Shen and Wang, 2024).

Despite their practicality, archetypes mask substantial intra-class heterogeneity (Rivallain et al., 2020). The feasibility of a retrofit often depends on factors that archetypes overlook. For instance, clustering a Swiss village dataset yielded more precise representative buildings for realistic large-scale retrofit planning (Geyer et al., 2017), while a machine learning classifier predicted renovation measure applicability across New York City's building stock using detailed building attributes (Marasco and Kontokosta, 2016). Such methods exploit fine-grained characteristics—construction details and heating system attributes—beyond archetype averages and open-data limitations.

This creates a knowledge gap: how to predict retrofit applicability at address level without coarse archetype grouping or manual audits, using scalable feature extraction?

In the Dutch housing stock (8M dwellings), we apply a renovation-centered approach to identify dwellings suitable for standardized renovation solutions at scale, minimizing the need for per-building customization.

To predict retrofit applicability for individual addresses, we created datasets combining open data sources (e.g., cadastral records) for detailed building characteristics with supplier-provided training labels—historical records of hundreds to thousands of addresses labeled with binary applicability values for their standardized solutions. Using these supplier-labeled datasets as ground truth and open data characteristics as input features, we trained machine learning classifiers designed to extrapolate retrofit applicability predictions across the entire national housing stock, provided they achieve sufficient performance.

The accuracy of address-level retrofit predictions depends on how well building features capture aspects relevant to renovation applicability. Relying solely on readily available open-data features, such as cadastral information, provided limited precision for many retrofit solutions. Facade and roof components may strongly influence the feasibility of certain renovation measures. Therefore, we employed computer vision methods to extract building features from street-level imagery. These vision-derived features extend the feature set beyond current open-data sources, thereby enabling more precise applicability predictions.

In this research, we developed a scalable computer vision methodology to extract building element features from street-view imagery, addressing critical knowledge gaps in the Dutch housing stock for data-driven retrofit matching. Our objective is to investigate whether the automated detection of building elements, including solar panels, dormers, chimneys, roof windows, ventilation units, removable panels, and balconies, can improve predictions of renovation solution applicability at the address level. This methodology leverages self-supervised Vision Transformers (ViTs) that learn semantic representations without man-

ual annotation, using a patch-based classification approach on dense patch embeddings. We combined this with an adaptive cropping strategy that maximizes relevant patch samples from bounding box annotations, enabling effective few-shot learning with limited labeled data that reflect real-world scenarios where domain-specific building element datasets are scarce.

This study makes two principal contributions to the existing literature. First, we demonstrated a practical computer vision pipeline requiring minimal labeling across the entire workflow: we extracted building element features from street-view imagery and evaluated detection performance per feature. Second, we evaluated whether augmenting building stock databases with these vision-derived features improved the predictive accuracy of retrofit solution applicability models, providing evidence of computer vision's value in data-driven retrofit matching.

Background and Related Work

Automatic detection of building elements from street-view imagery remains a challenging task in computer vision. This section establishes the motivation, technical foundations, and related work for patch-level detection using self-supervised ViTs. We begin by examining existing approaches to collecting building information from street-view imagery and identify gaps where scalable, data-efficient methods are needed. Next, we explore how self-supervised ViTs have emerged as a promising approach and how their dense patch-level representations can capture semantic information almost directly off the shelf. Finally, we survey how recent research leveraged ViTs patch embeddings for detection and classification.

Collecting Building Information from Street-View Imagery and CNN-based Facade Parsing

Several facade datasets were created for building element detection. The ECP dataset contains 104 images, whereas the eTRIMS 8-Class database comprises 60 images (Liu et al., 2017; Korc and Förstner, 2009). The CMP Facade Database is larger, providing 606 images from diverse architectural styles (Tyleček and Šára, 2013). These datasets cover basic facade components such as windows, walls, balconies, doors, shops, sky, chimneys, roofs, and background elements, with CMP introducing finer architectural details across 12 classes including molding, cornice, and pillar. The large-scale ADE20K dataset extends coverage to diverse scene types and includes certain building elements, such as dormers and chimneys (Zhou et al., 2018). However, annotation consistency analysis revealed missing object labels throughout ADE20K, with objects labeled inconsistently across images. Moreover, certain elements crucial for assessing retrofit applicability remain absent from the existing dataset classes. Consequently, relying only on existing datasets restricts the usefulness of facade imagery for extracting detailed domain-specific information relevant to renovation solution matching.

The existing literature approaches facade parsing using classical deep learning architectures. DeepFacade employs FCN-8s with symmetric regularization for pixel-wise segmentation, and more recent work apply encoder-decoder architectures such as Xception-based networks with pyramidal multi-scale fusion (Liu et al., 2020; Chen et al., 2023). These methods rely on CNNs and are usually pretrained on ImageNet, followed by extensive fine-tuning. However, research has demonstrated that transfer learning with CNNs struggles to generalize across datasets (Zhang et al., 2022; Lin et al., 2021; Li et al., 2020). Distribution shifts, whether from imaging conditions, architectural styles, or geographic contexts, often cause performance degradation. This limitation motivated the exploration of more robust, large-scale pretraining approaches that do not depend on supervised label distributions.

Self-Supervised Vision Transformers for Dense Prediction

Self-supervised ViTs have emerged as powerful alternatives to supervised learning, providing versatile and transferable image representations without requiring labeled data. It was demonstrated that self-supervised ViT features contain explicit semantic information about the image structure; its features are sufficiently dense that attention maps directly reveal semantic correspondences and segmentation patterns (Caron et al., 2021). Building on this foundation, DINOv2 was introduced to scale self-supervised pretraining using a dataset of 142 million diverse images, achieving state-of-the-art performance on dense prediction tasks (Oquab et al., 2023). Next, a key innovation addressed artifacts in ViT attention maps, introducing learnable register tokens that eliminate high-norm outliers and produce cleaner, more interpretable feature maps without performance degradation (Darcet et al., 2023). Most recent advances, including DINOv3, have introduced regularization to stabilize dense feature learning at scale, essentially ensuring that patch representations are well-distributed in the embedding space (Siméoni et al., 2025).

In addition, recent studies on pretrained ViTs have investigated the use and refinement of patch-level representations. STEGO performs unsupervised semantic segmentation by clustering DINO features (Hamilton et al., 2022). In contrast, NeCo employs a retraining approach that refines patch embeddings for nearest-neighbor retrieval of semantically similar patches across and within images (Pariza et al., 2024). As illustrated in Figure 2 and 4 in STEGO and NeCo, respectively, individual patch embeddings can serve as queries to identify semantically similar regions without requiring labels. This capability provides a foundation for the data-efficient building element detection method from street-view imagery proposed in this study.

Classification with Patch Embeddings

Self-supervised ViTs produce rich patch-level representations applicable to downstream tasks, although existing methods typically require additional processing or archi-

tectural modifications to extract class-relevant information. Class-Aware Patch Embedding Adaptation was introduced to adapt patch embeddings via learnable class-aware embeddings (Hao et al., 2023), while Class-relevant Patch Embedding Selection was proposed to filter patches by similarity to a single class embedding (Jiang et al., 2024). Both methods aggregate class-relevant patches through global image representations and succeed on image-level few-shot benchmarks (miniImageNet, tiered-ImageNet, CIFAR-FS, and FC-100), where the entire image belongs to one class, and patches collectively support the image classification. However, building element detection requires patch-level classification of multiple elements present simultaneously in different image regions. Global patch selection biases the model toward overall building features rather than fine-grained architectural elements, filtering out local information critical for precise element classification. Moreover, existing few-shot object detection methods require extensive base class training on thousands of annotations before adapting to novel classes contradicting truly annotation-scarce scenarios (Zhang et al., 2023; Bulat et al., 2023), while vision-language alternatives like GroundingDINO require large-scale pretraining on millions of image-text pairs (Liu et al., 2024).

We adopted a simpler approach: direct classification of patch embeddings using standard machine learning classifiers (k-Nearest Neighbors (kNN), Random Forest (RF), Multilayer Perceptron (MLP), and Support Vector Machine (SVM)) applied to DINOv2 embeddings. While the use of kNN with dense ViT representations have been explored, techniques that use more complex non-linear classifiers on patch embeddings for independent patch-level classification remain, to our knowledge, underexplored. By treating each patch as an independent instance for classification, we enable patch-level predictions without requiring global image representation or modifications to the pretrained backbone. This approach provides fine-grained control with a minimal training overhead and achieves reliable detection with only 21 labeled images total per building element.

Methodology

The full pipeline, from street-view image annotation to building element inference, is described in the five steps below. Figure 1 visualizes steps 1 (annotation), 3 (patch embedding extraction), and 4 (classifier training); steps 2 and 5, adaptive cropping and inference on unseen images, are omitted from the figure but described in their respective subsections below.

Step 1: Annotation

Rather than drawing bounding boxes around entire elements, we annotate smaller bounding boxes *within* the elements of interest, providing precise control over the area to be extracted by the ViT, well-suited to its square patch structure. Polygon annotations were also explored in Slik (2025) but yielded lower detection performance,

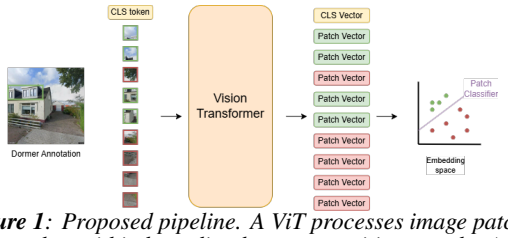

***Figure 1**: Proposed pipeline. A ViT processes image patches, with patches within bounding boxes as positive samples (green) and others as negatives (red), training a classifier per class.*

making axis-aligned bounding boxes the preferred choice. Areas without an element of interest are marked with "negative" bounding boxes. Two examples of this annotation style are shown in Figure 2. For this study we focused on seven building elements: solar panels, dormers, chimneys, roof windows, roof ventilation, removable panels, and balconies. Per element, 21 images with bounding box annotations are used for training, and 100 images carrying only image-level presence labels—50 positive and 50 negative—are used for testing. All 121 images per element depict distinct buildings, ensuring no building appears more than once across the training and test sets of a given element.

(a) Balcony Annotation (b) Solar Panel Annotation

***Figure 2**: Annotations to collect patch embeddings.*

Step 2: Adaptive Cropping

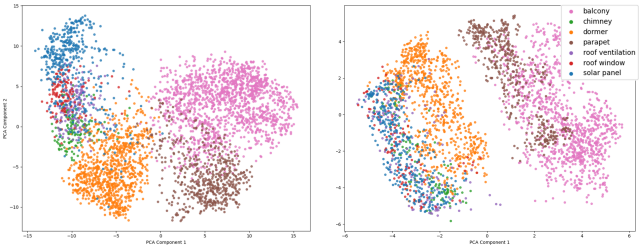
A ViT processes an image as a grid of patches, where each patch is a visual token. Bounding box annotations are often misaligned with this patch grid, reducing the number of usable positive patches. To address this, we apply adaptive cropping: the image is strategically cropped so the annotation aligns with the patch grid, enabling selection of significantly more relevant patches. Patches that partially overlap the bounding box along its right and bottom edges are also included, ensuring coverage when the annotation is smaller than the patch size. Figure 3 illustrates the worst-case scenario without alignment (left) versus the optimized configuration (right), increasing extracted patches from 4 to 12.

As shown in Table 1, the patch yield at least doubles for every element class: chimneys go from 0 to 57 patches, making classification possible where it would otherwise fail entirely.

(a) Without Alignment (b) With Adaptive Cropping

Figure 3*: Adaptive cropping impact on patch selection. Left: misaligned grid extracts 4 patches. Right: adaptive cropping aligns bounding box with patch grid, extracting 12 patches.*

Table 1*: Number of patch embedding collected from example images* ***without*** *and* ***with*** *adaptive cropping.*



Class	**without**	**with**
Solar Panel	103	244
Dormer	234	539
Chimney	0	57
Roof Window	2	69
Roof Ventilation	8	75
Removable Panels	107	530
Balcony	368	867

Step 3: Patch Embedding Extraction

Images used have a resolution of 640×640 pixels before being passed to the ViT, which operates with a fixed patch size of 14×14 pixels, yielding a spatial grid of 45×45 patches per image. The ViT processes each cropped image and produces one embedding vector per patch. The choice of pretrained ViT significantly affects task behavior. We visualized the per-element patch embedding spaces of DINOv2 and DINOv3 models after PCA reduction to two dimensions (Figure 4). DINOv2 embeddings (Figure 4a) exhibit greater class separation, with distinct regions for different building components. In contrast, DINOv3 embeddings (Figure 4b) are more compressed and overlapping reflecting the model's patch-level spatial regularization, which prioritizes neighborhood consistency over discriminative separation. This trade-off, DINOv2 for element distinctiveness versus DINOv3 for spatial coherence, directly influences patch-level classification performance as evaluated in Step 4.

Step 4: Patch Classifier Training

For each element of interest, a binary one-vs-rest classifier is trained on the collected patch embeddings: positive examples are patches from that class's bounding boxes; negative examples are patches from negative bounding boxes and all other element classes. We compare four lightweight classifiers well suited to the high-dimensional ViT feature space: kNN as a distance-based baseline commonly used with ViT embeddings; and MLP, SVM with an RBF kernel, and RF as non-linear alternatives.

(a) DINOv2 (b) DINOv3

Figure 4*: First two principal components after PCA of patch embeddings obtained using different ViT models.*

Step 5: Inference

During inference, the ViT extracts patch embeddings from a new image, which the class-specific binary classifiers evaluate independently. For each classifier, if at least one patch is classified as positive, the element of interest is considered present in that image. This patch-level output can be visualized and provides inherent explainability, as this can be visually inspected to verify whether patches correctly cover regions of a target class.

Results and Discussion

This section evaluates our patch-level classification approach across seven building elements using four lightweight classifiers (kNN, MLP, SVM, RF) applied to the DINOv2 and DINOv3 embeddings. We aim to compare a kNN classifier, commonly used in ViT patch application tasks, with MLP, SVM, and RF classifiers that can capture more complex decision boundaries. We report Quantitative Results on class distribution balance, few-shot training set size, and per-class detection performance, then provide Qualitative Results on spatial prediction behavior.

Quantitative Results

Figure 5 and 6 reveal distinct performance patterns across the classifiers, backbones, and training configurations.

Class Distribution Balance (Figure 5): The redistribution ratio adjusts class balance in the patch classifier training set by undersampling the majority class to reach the target positive-to-negative ratio. DINOv2+RF achieved the highest performance at a redistribution ratio of 0.10, reaching 95.8% balanced accuracy. RF and SVM consistently performed better with DINOv2 than with DINOv3 across all distribution ratios. In contrast, kNN and MLP show a crossover pattern: DINOv2 outperforms DINOv3 for redistribution ratios below 0.05, but DINOv3 becomes superior above this threshold. kNN shows poor overall performance with substantial fluctuation, demonstrating high sensitivity to class distribution. MLP achieved 92.6% with DINOv2 (ratio 0.02) compared to 89.7% with DINOv3 (ratio 0.02), indicating that MLP and kNN classifiers benefit from different patch embedding structures.

Few-Shot Training Set Size (Figure 6): Performance trends diverge across classifier types as training examples grow from one to 21 images. RF and SVM

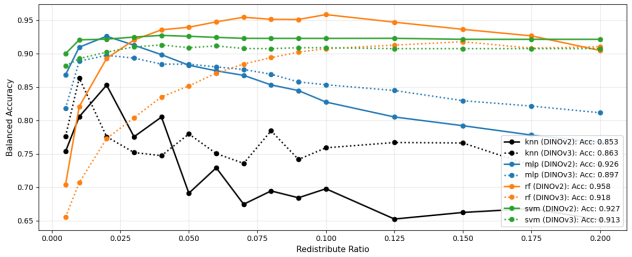


***Figure 5**: Performance scores **per redistribution ratio**, for different patch classifiers and dinov2 and dinov3 backbones.*

showed gradual improvement with additional training data: DINOv2+RF achieved the highest performance at 95.8% with 21 examples, substantially outperforming DINOv3+RF (91.2%)—a 4.7 percentage point advantage. Similarly, DINOv2+SVM with 21 examples outperformed DINOv3+SVM (+1.8 percentage points). In contrast, kNN and MLP exhibited more unexpected behavior – peaking at 3-5 examples before declining – seeming to be more sensitive to the chosen training samples than RF and SVM.

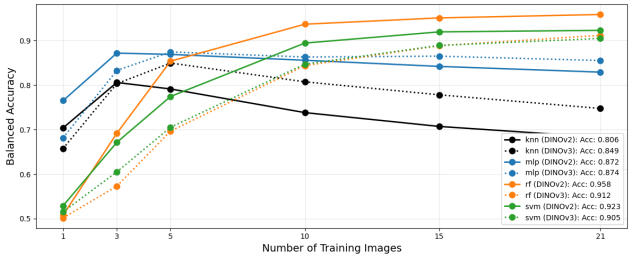

***Figure 6**: Performance scores **per number of example images**, for different patch classifiers and dinov2 and dinov3 backbones.*

These results reveal a trade-off between DINOv2 and DINOv3 embeddings. DINOv3 demonstrates gains exclusively with classifiers kNN and MLP at higher training sizes ($\geq$ 5 examples) and balanced distributions ($\geq$ 0.05 ratio), suggesting that its patch-level regularization primarily benefits kNN and MLP methods. However, with the sophisticated non-linear classifiers RF and SVM, DINOv2 consistently achieves superior performance across all conditions, with 4.6 and 1.8 percentage point advantages respectively at optimal settings. This indicates that while DINOv3 regularizes the embedding space for simple paradigms, DINOv2 retains greater representational capacity for complex decision boundaries, achieving the highest performance for patch-level building element detection. The results show that DINOv2 embeddings with RF offer the highest performance for patch-level building element detection.

Per-class Performance: **Table 2** presents metrics per-class using DINOv2+RF, 21 training images, and a redistribution ratio of 0.10. Roof-mounted elements (solar panels, dormers, chimneys, and roof windows) achieve exceptional accuracy (98–99%) with perfect precision, demonstrating that large, distinctive elements are reliably detected. Roof ventilation presents the most challenging case at 84.0% accuracy, because of its small size and high visual variability. Removable panels and balconies achieve strong performance (96% accuracy) with balanced precision-recall trade-offs. The method achieved 95.8% mean accuracy across all classes, with precision (96.8%) slightly exceeding recall (94.7%), indicating slightly conservative decision boundaries. Although the approach achieves strong performance for most element classes, it reveals limitations when elements exhibit high visual variability or appear at small scales, where patch embeddings struggle to capture sufficient discriminative information.

***Table 2**: Detection performance per facade element, mean over all elements, 100 samples test set.*

Class	Accuracy	Precision	Recall
Solar Panel	0.990	1.000	0.981
Dormer	0.991	1.000	0.981
Chimney	0.990	1.000	0.981
Roof Window	0.981	1.000	0.963
Roof Ventilation	0.840	0.889	0.784
Removable Panels	0.955	0.943	0.962
Balcony	0.961	0.943	0.980
Mean	**0.958**	**0.968**	**0.947**

Qualitative Results

Beyond quantitative metrics, the visual inspection of patch classification predictions provides interpretability. Figure 7 presents three examples illustrating both the strengths and failure modes of the approach.

Figure 7a shows a True Positive detection for roof windows: red patches adequately cover the regions containing the roof windows, demonstrating that the classifier correctly localizes the element across its spatial extent. Figure 7b shows a False Positive for removable panels, where a patch around the window frame is incorrectly highlighted. This is a plausible confusion: the removable panels in our dataset frequently occur in between window frames, and this positively highlighted patch is attached to a window frame too. Figure 7c illustrates a False Negative for roof ventilation: a small ventilation unit is visible on the roof but goes undetected. Given the fixed patch size of the ViT, small elements near patch boundaries are unlikely to be represented in a patch embedding, making detection for this small element in this configuration of pixel density and patch size less reliable. Overall, the approach correctly localizes elements of interest, though False Positives can arise from visual similarity to the target element class, and False Negatives from elements too small to be captured at the current patch resolution.

Case Study: Improving Data-Driven Retrofit Matching

The building element detection approach developed in this study enables practical applications. This section demonstrates how detected building elements from street-view imagery can improve a data-driven retrofit matching system, evaluates performance improvements across five retrofit datasets and discusses the broader implications for stakeholders in the building renovation sector.

(a) Roof Window TP (b) Removable Panel FP (c) Roof Ventilation FN

***Figure 7**: Qualitative results: Red patches indicate positive classifications.*

Added Value of Image Based Features

To evaluate the energy retrofit matching approach, we used multiple datasets from renovation advisors' assessments. Each dataset represents a renovation solution, with samples corresponding to individual dwellings and binary labels indicating applicability (per advisor judgment). Alongside these labels, we incorporated 66 features derived from open data — including construction year, building type, geometry, energy label, and occupant-related variables. Table 3 summarizes the datasets used. Removable panels are window-integrated facade elements which can be renovated by replacing them as a single unit with active ventilation.

***Table 3**: Energy retrofit datasets with label distributions (SFB: single-family building, MFB: multiple-family building).*

Dataset	Samples	Negative class	Positive class
Floor insulation SFB	7344	5217	2127
Cavity wall insulation SFB	6149	4940	1209
Roof insulation SFB	948	759	189
Removable panels SFB	255	189	66
Removable panels MFB	69	24	45

For each dataset, an RF classifier was trained and evaluated using grouped 5-fold cross-validation, where groups—defined by building complexes at the neighborhood scale—are kept within the same fold to prevent data leakage given the high uniformity within Dutch housing complexes. Cross-validation was repeated with different folds to yield 95% confidence intervals on balanced accuracy. The default 0.5 decision threshold was retained; threshold tuning confirmed this as a good trade-off between minimizing missed opportunities (low false negatives) and maximizing conversion rates (high precision), thereby avoiding costly false positives deferred to inspector review.

We then used our seven building element detectors to infer image-based features for all addresses in the datasets using Google Street View. Imagery was accessed via the Google Street View Static API under terms permitting non-commercial research use; coverage is extensive for the Dutch housing stock, and alternatives such as Cyclomedia exist should access or licensing constraints arise in other contexts. ViT inference takes < 50ms per image and the Street View Static API has a practical rate limit of 5 requests per second; the 14,765 addresses used in this study can be processed in under one hour. Querying the full Dutch housing stock (±5.5 million buildings) takes less than 15 days.

We evaluated three feature configurations: (i) 66 open-data features as a baseline ("Image features: no"), (ii) open-data features combined with seven Boolean element presence features derived from our detectors ("Image features: yes"), and (iii) open-data features combined with DINOv2's CLS token as a global image embedding, reduced to 20 dimensions via PCA ("Image features: CLS"). Results for all three configurations are reported in Table 4.

***Table 4**: Retrofit matching performance across three feature configurations: open data / no image features (baseline), open data + global image representation (CLS token), and open data + explicit building elements (seven Boolean features). Balanced accuracy ±95% CI.*

Dataset	Image features	Bal. Acc.	Gain
Floor insulation SFB	no	**62.3** ± 0.1	
	CLS	61.4 ± 0.1	
	yes	62.2 ± 0.1	
Cavity wall insulation SFB	no	63.1 ± 0.1	
	CLS	**63.5** ± 0.2	+0.4
	yes	63.1 ± 0.1	
Roof insulation SFB	no	58.6 ± 0.5	
	CLS	62.0 ± 0.5	
	yes	**63.4** ± 0.6	+4.8
Removable panels SFB	no	72.9 ± 0.6	
	CLS	77.6 ± 0.6	
	yes	**78.8** ± 0.5	+5.9
Removable panels MFB	no	55.8 ± 1.9	
	CLS	**67.4** ± 1.7	+11.6
	yes	56.6 ± 1.5	

The most substantial improvements occur for renovation solutions strongly correlated with visually detectable building elements. For instance, roof insulation shows a large improvement (+4.8 percentage points) when image-based Boolean features are added, reaching a balanced accuracy of 63.4%. This aligns with the contribution of roof-related element detection (e.g. dormers and roof windows). This improvement translates to gains in precision (55% to 60%) and recall (42% to 54%), reducing unnecessary advisor inspections of inapplicable housing by 5% while decreasing missed opportunities by 12%.

Removable panel detection yields particularly interesting results. For the "removable panels, single-family building" classifier, the image-based Boolean features achieve the best performance (78.8%, +5.9 percentage points), confirming that direct removable panel detection enhances the corresponding model. In contrast, the "removable panels, multi-family building" classifier exhibits a different pattern: CLS vector features lead to the largest improvement

(+11.6 percentage points), while the image-based Boolean features provide no significant gain. This result is based on a limited number of samples and should be confirmed using a larger dataset. Furthermore, it may be attributed to differences between single-family buildings and multi-family buildings, where removable panels are often more difficult to detect. Our results do illustrate that the CLS vector provides an indication of whether relevant visual information is present in a corresponding image. Targeted element detection then captures this global signal more explicitly, further boosting classifier performance.

Cavity wall and floor insulation show little to no improvement from image-based features. This is likely due to the small size of visual cues associated with these renovation measures. Presence of a cavity wall can be inferred from weep holes in the masonry. Presence of crawl space, which is necessary for floor insulation, can be inferred from small ventilation grilles at the bottom of facades. These details are not detectable at the resolution provided by the standard Google Street View API. However, sophisticated query strategies could provide the necessary detail for detection, enabling future performance gains for these classifiers. Overall, these results validate the practical value of integrating building-element detection into data-driven energy retrofit matching.

Impact of Data-driven Energy Retrofit Matching

When classifiers perform sufficiently well, this approach benefits multiple stakeholders. For renovation contractors offering standardized solutions, macro-level analyses of classifier predictions at regional or national scale can support market sizing, production planning, investment decisions, and industrialization, while micro-level, address-based information can help them reach suitable dwellings without extensive customization. Municipalities can use these tools to more effectively target homeowners of specific dwelling groups, increasing conversion rates for energy renovation. Housing associations can use these models to manage their stock and plan retrofit programs more efficiently.

Conclusion and Outlook

In this paper, we presented a scalable few-shot methodology for building element detection from street-view imagery through Vision Transformer patch classification. This work was based on the Master's thesis work of Slik (2025). The source code and labeled image datasets used in this study are available from the authors upon request.

From the ViT backbones evaluated, DINOv2 combined with RF or SVM yielded substantial performance improvements, with RF achieving 95.8% balanced accuracy compared to 91.8% with DINOv3. The adaptive cropping strategy increases positive patch samples by up to 10×. Overall, the methodology demonstrates potential in using ViT embeddings for domain-specific detection, with practical applications in energy retrofit matching, where it improves prediction accuracy by 4.8 percentage points for roof insulation applicability, effectively addressing data gaps in building stock databases.

Future work could improve performance through higher-resolution imagery or multi-scale detection strategies with shifted patch grids. Concretely, zoomed Street View API queries targeting facade details, super-resolution preprocessing, or tiled inference at multiple scales offer direct paths to detecting fine building details such as cavity wall weep holes, crawl space ventilation grilles, and roof exhaust units that remain below the current patch resolution. Moreover, rather than using a single frozen ViT configuration for all tasks, different backbones and classifiers could be selected by evaluating performance in specific scenarios, enabling task-specific optimization for address-level element detection within a comprehensive pipeline. Furthermore, researching building outlining techniques using cadastral data and segmentation models could strengthen confidence that detected elements belong to the target address. This methodology, including its extensions, readily scales to other national housing stocks—particularly those with limited open data—and to non-energy domains requiring building element inference.

AI-ASSISTED BRIDGE CONCEPTUAL DESIGN: A HYBRID KNOWLEDGE- AND LEARNING-BASED APPROACH TO AUTOMATED SPAN PLANNING

Han Qian[1], Tim Noack[1], Mengyan Peng[1], Marx Steffen[1] and Chongjie Kang[1]
[1]Technische Universität Dresden, Dresden, Germany

Abstract

Bridge conceptual design is challenged by heterogeneous boundary conditions, strict engineering constraints, and large solution spaces. This paper presents an AI-assisted pipeline for automated bridge conceptual design, focusing on early-stage span layout planning. The proposed approach integrates ontology-based semantic knowledge representation with reinforcement learning to enable automated decision-making while preserving engineering consistency. By embedding engineering constraints into the learning environment, the method supports efficient exploration of feasible span configurations. The results indicate that the proposed pipeline provides a robust and extensible foundation for AI-supported bridge planning in realistic engineering scenarios.

Introduction

Bridge conceptual design is a pivotal early-stage task in which key decisions such as span layout and structural system selection are made under heterogeneous boundary conditions, such as site conditions of terrain and crossed obstacles, clearance requirements, environmental restrictions, and project-specific constraints (Troitsky, 2019). While decisions at this stage strongly influence feasibility, cost, and downstream design flexibility, the workflow is still dominated by manual iterations and experience-driven heuristics. In today's digitalized and automation-oriented construction industry, this creates two persistent challenges: (i) early-stage information is often incomplete, symbolic, and distributed across different sources, and (ii) the design space is combinatorial, yet must remain consistent with engineering constraints.

Artificial Intelligence (AI) is increasingly adopted across civil engineering and construction to improve efficiency, consistency, and scalability of decision-making, which can be a viable path to address the fragmented nature of early-stage design information. Machine Learning (ML) has been used to support structural engineering beyond inspection, including design-related prediction and rapid evaluation. Supervised Learning (SL) and Deep Learning (DL) models are often adopted as surrogate predictors to approximate the mapping between design boundary conditions and design variables (Qian et al., 2024), or between design variables and structural responses (Zheng et al., 2020; Balmer et al., 2024). These ML-based methods enable efficient screening of conceptual alternatives and reduce repeated high-cost simulations. Recent work also explores transfer learning to improve robustness of learned predictors under limited data, which is common in civil engineering applications (Zhang et al., 2025). Beyond prediction, Reinforcement Learning (RL) is being investigated for automating design decisions that can be formulated as sequential optimization, e.g., learning to automatically design reinforced concrete structures (Jeong et al., 2021), and handling construction design coordination tasks such as automated reinforcement clash resolution in Building Information Modeling (BIM) (Liu et al., 2020). Nevertheless, purely ML-based approaches (SL/DL or RL) often lack explicit mechanisms to guarantee strict feasibility under hard engineering constraints and may remain difficult to interpret and justify in safety-critical conceptual design.

To address these limitations, knowledge-based and rule-based systems have been developed to preserve engineering consistency and enable transparent reasoning. Ontology-driven approaches can formalize domain entities, constraints, and relationships, thereby supporting deterministic inference and validation. Ontology- and rule-based systems have been used to encode engineering knowledge in an explicit, machine-interpretable form, enabling early constraint checking and reducing iterative design cycles (Cao et al., 2022). In bridge engineering, most ontology efforts have focused on rehabilitation and maintenance, e.g., knowledge bases for maintenance decision support, while comparatively few studies address ontology integration in bridge design workflows (Ren et al., 2019; Zhang et al., 2022; Aqlan et al., 2025). Recent work also emphasizes that systematic rule structuring and ontology-based knowledge organization remain important for transparency and traceable rule management in digital construction (Wen et al., 2024). However, knowledge-based systems alone are often conservative in practice. While they are strong at enforcing hard constraints and providing explainable logic, they typically lack flexible optimization capabilities when multiple soft objectives (e.g., economy, trade-offs between competing objectives) must be balanced under diverse boundary conditions.

These complementary strengths and weaknesses motivate hybrid AI strategies that combine knowledge-based constraint enforcement with learning-based exploration.

Accordingly, this paper proposes a hybrid AI-assisted framework for bridge conceptual design, with a focus on automated span planning. In contrast to purely constraint-guided RL and existing bridge layout automation methods, it uses ontology-based reasoning to translate boundary conditions into a structured feasibility space and employs RL within this constrained environment to explore and optimize span configurations under soft engineering preferences. By integrating explicit knowledge with adaptive decision-making, the framework aims to improve automation while maintaining engineering consistency, transparency, and extensibility for realistic bridge planning scenarios.

Methods

AI-assisted pipeline for bridge conceptual design

In bridge conceptual design, the involved tasks differ substantially in their data availability, constraint structure, and decision complexity, making the use of a single AI technique across all stages neither efficient nor reliable. This work therefore adopts a task-oriented AI-assisted pipeline in which different design subtasks are supported by AI methods that match their intrinsic characteristics.

As shown in Figure 1, the proposed pipeline decomposes bridge conceptual design into three main stages: (i) interpretation and structuring of boundary conditions, (ii) planning of bridge spans, and (iii) planning of superstructure cross-sections. Boundary conditions originate from diverse sources, including site conditions, regulatory requirements, and project-specific constraints. These inputs are predominantly semantic and rule-driven rather than data-intensive, and are therefore represented using ontology-based knowledge models. Ontologies enable consistent semantic interpretation of boundary conditions, support rule-based reasoning, and provide structured inputs for subsequent design steps. Bridge span planning constitutes the central layout decision within the pipeline. It involves selecting the number of spans, their lengths, and pier locations under complex geometric and functional constraints. This task exhibits a large combinatorial search space and strong interdependencies between design variables, making it unsuitable for purely rule-based enumeration. At the same time, strict engineering constraints must be satisfied to ensure feasibility. For this reason, span planning is addressed using a hybrid approach that combines symbolic design rules with RL, allowing automated exploration of feasible layouts while preserving engineering validity. Once a span layout is determined, the pipeline proceeds to the planning of superstructure cross-sections. In contrast to span planning, this task benefits from the availability of existing bridge data and relatively stable input-output relationships between boundary conditions and structural dimensions. As a result, supervised learning techniques are employed to predict key geometric parameters of superstructure components, while rule-based methods are applied where normative prescriptions are explicit and deterministic.

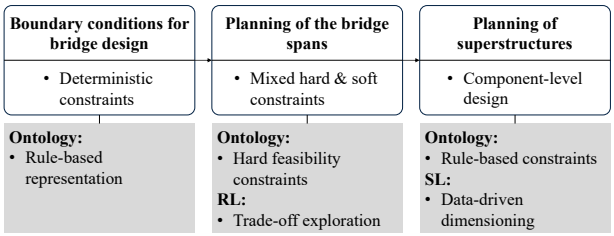

Figure 1: AI-assisted pipeline for bridge conceptual design

Hybrid methodology for bridge span planning

Within the AI-assisted conceptual design pipeline, bridge span planning represents the most critical decision-making task. The selection of span numbers, span lengths, and pier locations determines not only the overall structural layout but also construction feasibility, cost efficiency, and the quality of downstream design tasks.

Purely rule-based approaches have traditionally been used in early-stage bridge layout planning to ensure compliance with standards and engineering best practices (Troitsky, 2019). While such approaches provide strong guarantees of feasibility, they tend to be conservative and lack flexibility when confronted with complex or non-standard boundary conditions. Conversely, learning-based optimization techniques, such as RL, offer the ability to explore large design spaces and identify efficient solutions, but cannot inherently guarantee adherence to engineering rules and safety constraints. In bridge span planning, violations of such constraints are unacceptable, even at the conceptual design stage.

To address these complementary limitations, the proposed hybrid methodology combines rule-based reasoning with RL in a tightly coupled hybrid framework, as illustrated in Figure 2. The first step is to simplify the complex side conditions from three-dimensional (3D) to 2D topography. Explicit design rules and boundary conditions are then formalized using an ontology-based representation and used to encode domain knowledge and constraint logic, defining permissible, restricted, and forbidden regions for pier placement. RL is employed to perform sequential decision-making within this feasibility space defined by the ontology and further encoded design rules, because local support adjustments influence subsequent feasible actions and the overall quality of the final span layout. It enables automated exploration and optimization while maintaining engineering validity. Therefore, rule-based reasoning and RL fulfill distinct but interdependent roles. Semantic rules in Category A (see Table 1) act as constraints that shape the environment in which exploration takes place, reducing the effective search space and preventing infeasible solutions. RL, in turn, provides adaptability by optimizing layout decisions under these constraints and resolving trade-offs between competing objectives based on the rules in Category B (see Table 1), such as minimizing pier numbers while respecting economic span ranges. Rather than encoding all constraints only as reward penalties, the proposed framework externalizes hard, boundary-condition-dependent feasibility constraints through ontology-based

reasoning and uses RL to optimize softer layout preferences within the admissible design space.

The hybrid methodology is structured to support modular extension and transparent interpretation. The following sections detail the categorization of design rules, their ontology-based representation, and the RL model used to realize this hybrid approach.

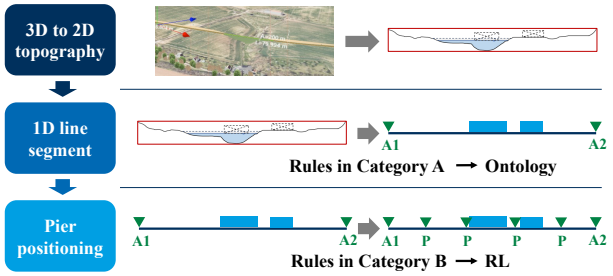

Figure 2: Hybrid methodology for bridge span planning

Design rules for bridge span planning

Design rules form the backbone of engineering knowledge in bridge span planning and play a central role in constraining and guiding the hybrid methodology. In the context of conceptual design, they are particularly important as detailed structural verification is not yet available, making explicit knowledge-based constraints essential for ensuring feasibility. For this work, span planning rules were systematically collected from multiple sources, such as German design standards, project-specific requirements, and engineering practice. The collected rules were then analyzed and structured with respect to their functions, rather than their original textual form. This functional analysis enables a clear distinction between rules that directly restrict geometric feasibility and those that provide qualitative or economic guidance for span layout decisions.

Table 1: Economical span ranges for different bridge types

Category A	Topography-dependent rules
Rule sources	• German design standards (e.g., DIN, RiZ-ING) • site-specific planning documents • engineering practice
Rule characteristics	• Hard constraints • Deterministic • Directly linked to terrain and obstacles
Typical rules	• Required clearance heights and widths for waterways and roads • Restrictions on pier placement in water bodies • Restrictions on pier placement in built-up areas and private property
Category B	Topography-independent rules
Rule sources	• Engineering handbooks • Guidelines • Expert knowledge
Rule characteristics	• Soft constraints • Heuristic and preference-based • Potentially conflicting
Typical rules	• Symmetry requirements of pier layout • Main span ≥ side spans • Trade-off between span length and number of piers • Economical span ranges for different bridge types

Based on this analysis, the design rules are categorized into two main groups according to their dependency on boundary conditions, which is demonstrated in Table 1. Category A rules are strongly dependent on topography and crossed obstacles, and define spatial constraints on span planning, such as clearance requirements over waterways and roads, and geometric limitations imposed by terrain conditions. These rules primarily determine whether a pier location is permissible, restricted, or forbidden along the bridge axis. Conversely, Category B rules are largely independent of local topography and describe general engineering principles for bridge span layout, e.g., symmetry requirements, and economical span length ranges for different bridge types. Unlike Category A rules, these rules do not impose absolute feasibility constraints but influence the quality and efficiency of candidate span layouts.

The separation of design rules into Category A and Category B supports their differentiated use within the hybrid span planning framework. Category A rules are primarily used to define hard constraints that shape the feasible design space, while Category B rules provide soft constraints and optimization guidance during layout generation. This structured rule system forms the basis for both ontology-based reasoning and RL, enabling explicit integration of engineering knowledge into automated bridge span planning.

Ontology-based rule representation and reasoning

To enable systematic and machine-interpretable application of topography-dependent design rules, an ontology-based representation is adopted for bridge span planning. Ontologies provide a formal and extensible framework for structuring heterogeneous engineering knowledge and are particularly suitable for representing explicit boundary conditions and hard feasibility constraints. In the proposed methodology, ontology-based reasoning is deliberately applied to the Category A rules.

The ontology used in this work is called Bridge Core Ontology (BCore), an extension of the Bridge Topology Ontology (BROT) proposed by Hamdan and Scherer (2020) which is again based on the Building Topology Ontology (BOT) described by Rasmussen et al. (2020). BCore was created with the ontology editor Protégé in the Web Ontology Language (OWL 2). BCore has multiple purposes in the field of bridge engineering, amongst them the semantic description of bridge boundary conditions. The Category A rules are implemented using the Semantic Web Rule Language (SWRL). Based on the bridge boundary conditions, they determine whether it is possible, inadvisable, or not possible to place a support (pier or abutment) at a specific point of the bridge axis.

The outputs of ontology-based reasoning consist of structured feasibility representations that define the admissible design space for bridge span planning. These representations serve as validated inputs to the RL environment, where Category B rules are subsequently integrated as optimization guidance. In this way, the ontology acts as a semantic filter that enforces hard boundary-condition-driven constraints, while leaving efficiency-oriented layout principles in Category B to be handled by learning-based decision making.

Learning-based decision making using RL

Based on the ontology-derived feasibility space, RL is used to generate bridge span layouts under complex boundary conditions. While ontology-based reasoning enforces hard constraints via Category A rules, Category B rules are embedded in the learning process to guide optimization toward efficient and balanced configurations. Operating within this rule-constrained environment, RL resolves trade-offs that are difficult to encode deterministically, enabling flexible yet engineering-consistent span planning with interpretable decision logic at the conceptual stage.

Problem formulation

Bridge span planning is formulated as a sequential decision-making problem in a custom Gymnasium (Towers et al., 2024) environment and modeled as a Markov Decision Process (MDP) (Garcia et al., 2013), defined by the tuple

$$M = \langle S, A, P, R, \gamma \rangle \quad (1)$$

where S denotes the state space, A the action space, P the state transition dynamics, R the reward function, and $\gamma \in (0, 1)$ the discount factor. The problem formulation in RL is illustrated in Figure 3.

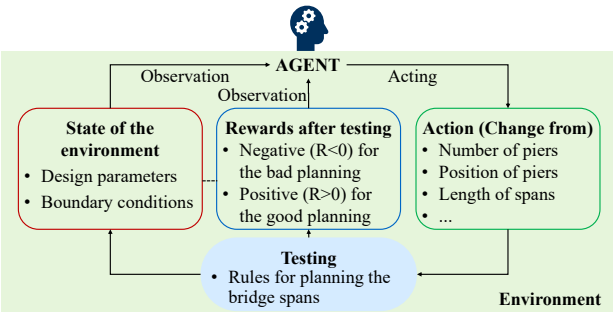

Figure 3: RL framework for bridge span planning

At each step, the learning agent interacts with an environment that represents the current bridge layout under given boundary conditions. The environment state $s \in S$ includes structured information derived from ontology-based reasoning, such as total bridge length L, admissible regions and forbidden zones that encode hard feasibility constraints (Category A rules). Additional state variables describe the current number of piers n, span lengths l_i, and pier positions x_i along the bridge axis. All quantities are normalized with respect to the total bridge length to ensure numerical stability during learning. The action space A comprises discrete layout edits, primarily moving piers forward or backward by a fixed step, and adding or removing piers within admissible regions. At each step, the environment executes the selected action, updates the state, computes a composite reward, and checks termination. State transitions P are deterministic given the selected action and current layout configuration. As shown in Figure 3, by observing a current state representing the bridge layout and boundary conditions, the agent is guided by current learned policy and selects an action that modifies pier positions or span layout and aims to maximize the cumulative reward. Then a testing procedure is applied in the environment, which evaluates the action against predefined rules and feasibility constraints. Valid actions lead to deterministic updates of the bridge layout and derived state variables, resulting in the next state. Actions violating hard feasibility constraints are rejected or penalized, so that infeasible states are not generated during learning.

Integration of design rules into the learning process

Category B rules encode soft principles and are incorporated into the RL framework as optimization guidance. Due to their qualitative nature and potential conflicts, these rules are not deterministic but are reflected in the reward formulation.

The reward function is defined as a weighted aggregation of multiple rule-related components:

$$R(s, a) = \sum_{i=1}^{N} \omega_i R_i(s, a) \quad (2)$$

where $R_i(s, a)$ denotes an individual reward component under specific state s after action a associated with a specific layout principle, and ω_i is the corresponding weighting factor. This formulation allows different engineering preferences to jointly influence the optimization process while preserving flexibility in resolving trade-offs between competing objectives.

In the current implementation, these reward components capture span validity, symmetry, uniformity, and span proportion preferences derived from Category B rules. The reward shaping provides continuous feedback that guides the learning agent toward high-quality span layouts. The reward function is designed to penalize layouts while rewarding solutions that achieve feasible span distributions. In the following, one representative reward, the component symmetry reward R_{sym}, is presented to illustrate how the Category B rule is translated into quantitative learning signals.

Symmetry of pier placement is evaluated based on the spatial distribution of pier positions along the bridge axis. For layouts with an odd number of piers, an additional requirement is imposed on the central pier. Let x_c denote the position of the middle pier, then its deviation from the bridge center is measured as:

$$e_{\text{center}} = |x_c - L/2| \quad (3)$$

For all layouts, symmetry of pier pairs is evaluated by comparing the sum of symmetric pier positions with the bridge length. For each mirrored pier pair (x_i, x_{n+1-i}), the pairwise symmetry error is defined as:

$$e_i = |(x_i + x_{n+1-i}) - L| \quad (4)$$

The overall symmetry error is computed as:

$$e_{\text{sym}} = \begin{cases} \frac{1}{\lfloor n/2 \rfloor}\left(\sum_{i=1}^{\lfloor n/2 \rfloor} e_i + e_{\text{center}}\right), & \text{if n is odd} \\ \frac{1}{\lfloor n/2 \rfloor}\sum_{i=1}^{\lfloor n/2 \rfloor} e_i, & \text{if n is even} \end{cases} \quad (5)$$

where $\lfloor n/2 \rfloor$ denotes the number of mirrored pier pairs. This formulation ensures that both mirrored pier alignment and, if applicable, the central pier position contribute to the symmetry test, while normalization prevents bias toward layouts with more piers.

Based on the computed symmetry error e_{sym}, the symmetry reward is defined as:

$$R_{\text{sym}}(e_{\text{sym}}) = \left(1 - \frac{e_{\text{sym}}}{T_{\text{sym}}}\right) R_{\text{sym,max}} \quad (6)$$

where T_{sym} represents symmetry threshold defining "acceptable" asymmetry and $R_{\text{sym,max}}$ denotes maximum achievable symmetry bonus magnitude. This reward provides a graded positive bonus when the layout is sufficiently symmetric (error below threshold) and a proportional penalty once the symmetry error exceeds the threshold, thereby encoding symmetry as a soft optimization objective rather than a hard constraint.

Beyond reward shaping, Category B rules are also used to define episode termination. An episode ends when a feasible span layout is achieved (success) or when the maximum step limit is reached. In the implementation, a solution is marked as DONE when all spans fall within the prescribed range and either (i) the layout meets a uniformity threshold, or (ii) it satisfies a symmetry threshold with the center span being the largest. This criterion reflects, that acceptable conceptual solutions may arise through different quality pathways rather than a single rigid condition.

Deep Q-Network (DQN) architecture and training

A DQN framework in RL (Mnik et al., 2015) is adopted to approximate the optimal action-value function $Q^*(s,a)$ for bridge span planning. Instead of explicitly modeling transition probabilities, learning is performed based on sampled transitions generated through interaction with the environment. Accordingly, the Bellman optimality principle is expressed in its sample-based form:

$$Q^*(s,a) = \mathbb{E}[r_t + \gamma \max Q^*(s_{t+1}, a') \,|s_t, a_t] \quad (7)$$

where s_t denotes the current state representing the bridge layout and boundary conditions at decision step *t*, while s_{t+1} is the subsequent state, a_t is the selected action modifying the current layout, r_t is the immediate reward obtained after applying action a_t, a' denotes an admissible action in the next state, and γ is the discount factor weighting future rewards.

In practice, the expectation is approximated using an experience replay buffer. During training, a separate target network with parameters θ is maintained to compute the temporal-difference target Q-values:

$$y_t = r_t + \gamma \max Q(s_{t+1}, a'; \theta) \quad (8)$$

where $Q(\cdot;\theta)$ denotes the target network used for stable target estimation. The main network parameters are updated by minimizing the squared temporal-difference error between the predicted Q-value and the target y_t. Then the target network parameters are periodically synchronized with the main network. This delayed update mechanism improves convergence robustness.

The network maps the environment state to Q-values for all admissible actions and is implemented as a multilayer perceptron (MLP) with two fully connected hidden layers and ReLU activations. Action selection follows an epsilon-greedy policy with probability ε, a random admissible action is chosen for exploration, otherwise, the action with the highest estimated Q-value is selected. The exploration rate ε is gradually decayed over training episodes. Training is conducted across diverse boundary conditions to promote generalization and to reliably produce feasible and efficient span layouts.

Results and case study

Results of ontology-based rule representation and reasoning

The ontology-based knowledge representation provides a structured and interpretable foundation for bridge span planning under heterogeneous boundary conditions. Design rules related to topography, crossed obstacles, clearance requirements, and pier feasibility are formalized as semantic entities and relations, enabling explicit reasoning over permissible (support-possible), restricted (support-not-recommended), and forbidden (support-not-possible) regions along the bridge axis.

The important classes of BCore are displayed in Figure 4. Every *Bridge carriesRoute InfrastructureRoute* which is composed of *RoutePoint*s. These points, being a *rdfs:subClassOf LocationPoint*, can be *locatedInZone. Zone*s can be, amongst others, a *Forest, WaterBody, Estate, Building* or another *Bridge*. Important *DataProperties* (attributes) in BCore are the coordinates of *RoutePoint* (*LocalX*, *LocalY*, *LocalZ*, *Station*; all of *Datatype xsd:decimal*) and its *xsd:boolean*-type properties *SupportNotPossible* and *SupportNotRecommended*. An *InfrastructureRoute* has the *DataProperties InfrastructureName* (*xsd:string*) and *InfrastructureWidth* (*xsd:decimal*).

With these semantics, the bridge's boundary conditions can be represented, as well as the Category A rules. Two examples of these rules are shown and explained in Table 2 and Table 3. They serve to ascertain that a pier or other bridge support cannot be placed on another *InfrastructureRoute*. All rules are implemented in SWRL and are thus hard *if-then*-rules. Other Category A rules include different types of *Zone*s, where a *RoutePoint* is located in. Depending on the type of *Zone*, either a support is not possible or not recommended at the respective *RoutePoint*. For example, in a *WaterBody*, a support is not recommended, while in a *Building*, it is not possible.

After creating instances of the *Bridge*, the carried route(s), surrounding *Zone*s and crossing routes, the bridge axis (= carried route) is divided into a high number of sections

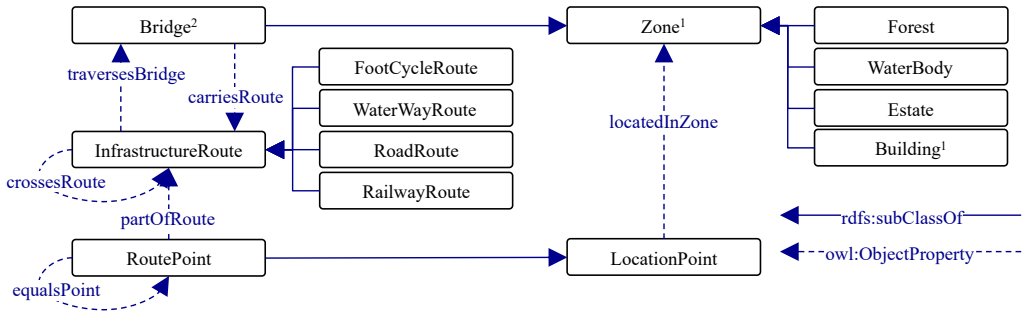

Figure 4: Diagram of BCore parts adapted from Rasmussen et al. (2020) for Zone [1] and Hamdan and Scherer (2020) for Bridge [2]

of the same length. A section length between 10 cm and 1 m is recommended. At the end of each section, a *RoutePoint* is created with its respective x-, y- and z-coordinates and its *Station* (kilometrage). In the proximity of the bridge, the other routes need their name, width, and *RoutePoint*s with their coordinates. Each *RoutePoint* that is located in a *Zone* needs to be connected to that *Zone* via the *locatedInZone*-property. After creating all these instances, a SWRL-capable reasoner (e.g., *Pellet*) needs to be run. For every point inside a zone or on a crossing route, the values of properties *SupportNotPossible* and *SupportNotRecommended* are inferred.

The points and their respective support-conditions can be exported or queried from the ontology.

Table 2: Rule route crossing point: description and SWRL-implementation

If two points from different routes have the same x- and y-coordinates, they are "equal" and their routes cross.

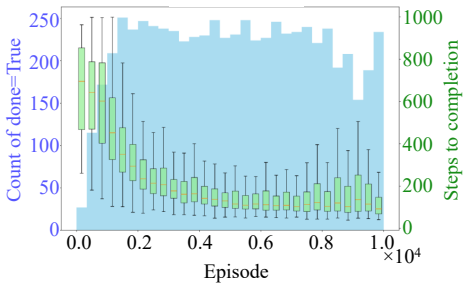
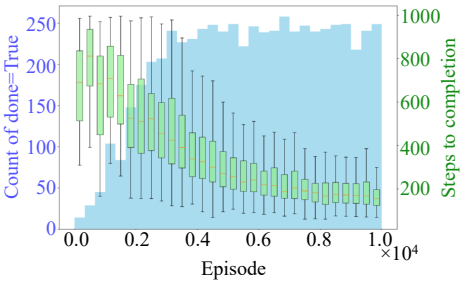
RL training and hyperparameter analysis

To achieve stable and efficient learning behavior in bridge span planning, a systematic hyperparameter tuning process was conducted. A broad range of parameters was explored, including training-related parameters (e.g., number of episodes and maximum steps per episode), DQN architecture parameters (e.g., network depth, neuron numbers, and replay memory size), and environment parameters (e.g., forbidden zone configurations and action step lengths), and reward-related parameters reflecting engineering objectives.



Special attention in this paper was given to parameters governing the exploration-exploitation balance, namely the epsilon target percent (etp) and epsilon decay percent (edp). These parameters define the decay schedule of the ε-greedy exploration strategy, where ε decays to etp within the first edp portion of training episodes. To evaluate training performance, two complementary metrics were adopted: (i) count of done, representing the number of episodes that successfully reached a valid span configuration within fixed episode intervals, and (ii) steps to completion, indicating the number of action steps required to reach termination in each episode. Together, these metrics provide insight into both learning effectiveness and planning efficiency.



(a) etp = 40 %, edp = 30 %

(b) etp = 40 %, edp = 80 %

(c) etp = 70 %, edp = 30 %

(d) etp = 70 %, edp = 80 %

Figure 5: Training evolution of DQN model with the examples under four representative parameter pairs of etp and edp

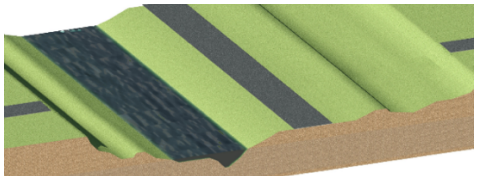


Figure 5 presents the training evolution with the examples under four representative parameter pairs of etp and edp, highlighting the interaction between exploration decay and learning stability. Apparently, for small values of (etp = 40%, edp = 30%) in Figure 5(a), the agent exhibits a rapid increase in successful episodes during early training stages. However, this improvement is not sustained, as the success rate decreases in later stages, and the variance of steps to completion increases. This pattern indicates early-stage overfitting, where the agent prematurely commits to suboptimal policies and loses robustness as training proceeds.

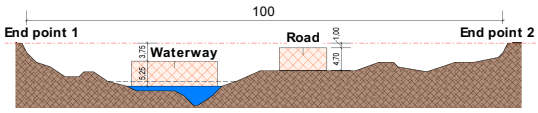
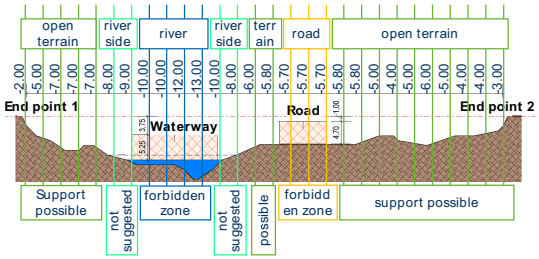
By comparing Figure 5(b) to (a) or Figure 5(d) to (c), increasing the decay period to edp = 80% significantly improves long-term stability. When comparing configurations with identical edp (see Figure 5(a) and (c), Figure 5(b) and (d)), a larger target exploration rate (etp = 70%) consistently yields more stable success rates and lower variance in step counts. These observations demonstrate that slower exploration decay and higher residual exploration are essential for avoiding local optima in bridge span planning tasks with complex constraints. Based on this comparative analysis, the parameter combination (etp = 70%, edp = 80%) was selected for subsequent experiments, as it provides the best balance between convergence speed, solution quality, and robustness.



Case study

To demonstrate the practical applicability of the proposed pipeline, a simple case study was conducted, as shown in Figure 6. Starting from a simulated 3D terrain model in Autodesk Revit (Figure 6(a)), the terrain data were first transformed into a 2D longitudinal section (Figure 6(b)), from which ontology-based reasoning identified forbidden zones and feasible support regions considering terrain geometry and crossed obstacles (Figure 6(c)).



Based on the resulting 1D design space derived from ontology, the trained RL agent was then applied to this scenario to generate an optimized bridge span layout (green marks in Figure 6(d)). The resulting configuration satisfies all feasibility constraints while achieving a balanced span distribution consistent with engineering design principles in Category B. The generated span layout was subsequently mapped back into the 3D terrain model (Figure 6(e)), producing a conceptual bridge span design aligned with the terrain and boundary conditions.

Conclusions and outlook

This paper presents an AI-assisted pipeline for bridge conceptual design, with a focus on automated span planning. Design rules are systematically collected and separated into topography-dependent feasibility rules and general layout principles related to efficiency and economy. The former are formalized through ontology-based reasoning to define the feasible design space, while RL is used to optimize span layouts under softer engineering preferences. The results demonstrate the feasibility of the proposed hybrid reasoning-and-learning framework for AI-assisted bridge span planning.

Despite these promising results, several limitations remain. Overall, the present study is intended as a proof-of-concept validation of the hybrid reasoning-and-learning framework rather than a comprehensive benchmark against alternative search strategies. From the ontology perspective, practical adoption is constrained by the effort and expertise required to develop and maintain

ontologies with specialized languages and tools, as well as the need for engineers to formalize rules, configure the knowledge base, and interpret outputs. This highlights an important direction for future research, i.e., improving automation and user-friendliness at the knowledge-engineering level. In this context, Large Language Model (LLM)-based agents may help lower this barrier by supporting semi-automatic rule formalization, ontology population, and natural-language interaction with the system. From the RL perspective, the model performance is also sensitive to the formulation of the reward function. Although rule-guided reward shaping enables the incorporation of engineering knowledge into the learning objective, the selection, weighting, and interaction of reward components strongly affect training dynamics and can encode subjective trade-offs, limiting generalization across boundary conditions and bridge typologies. Future work will therefore explore adaptive or hierarchical reward strategies, automated tuning of reward weights, and broader evaluation across unseen boundary-condition scenarios, including comparisons with constrained-search and heuristic baselines, to improve robustness and reduce manual calibration.

In summary, this work demonstrates that combining ontology-based reasoning with reinforcement learning enables a robust and extensible framework for AI-assisted bridge conceptual design. The proposed framework will be extended to the downstream design task of superstructure cross-section design in our research project by combining ontology-based rule reasoning and SL. The pipeline is intended as a decision-support tool that improves efficiency, consistency, and transparency in early-stage bridge planning, while laying the groundwork for more automated and user-friendly design workflows.

OPEN-SOURCE VLMS FOR ENGINEERING DRAWING METADATA: QWEN-VL TITLE-BLOCK DETECTION AND INFORMATION EXTRACTION

Mengyan Peng, Angran Cui, Steffen Marx, and Chongjie Kang
Dresden University of Technology, Institute of Concrete Structures
Corresponding author: mengyan.peng@tu-dresden.de

Abstract

Title-blocks in engineering drawings contain essential metadata, but automated interpretation remains difficult because of historical scans and heterogeneous layouts. This paper presents a vision-language model (VLM)-based workflow for title-block detection and structured information extraction using the open-source Qwen2.5-VL backbone. The workflow combines promptable visual grounding on full drawings with schema-constrained extraction from cropped title-block images. The study focuses on three representative fields: scale, drawing name, and route. Results show promising performance for both tasks and indicate that open-source VLMs can provide a simplified alternative to conventional multi-stage pipelines for architecture, engineering, and construction (AEC) document analysis.

Introduction

Engineering drawings remain a central information carrier throughout architecture, engineering, and construction (AEC) workflows. Despite the increasing adoption of digital design tools, large volumes of legacy drawings, often available only as scanned images, are still routinely accessed for maintenance, renovation, compliance checking, and digital asset management. Within these drawings, the title-block plays a critical role, as it encodes essential metadata such as the drawing title, scale, drawing number, creation date, author, and responsible organizations, making reliable extraction important for indexing, version control, and building information modeling (BIM) integration.

However, automated extraction of title-block information remains challenging in practice. Historical scans often exhibit low image quality, heterogeneous layouts, and inconsistent typography. Engineering drawings are visually complex documents in which textual content is embedded in spatially structured layouts and mixed with graphical elements, making reliable parsing difficult (Khan et al., 2025; Wang et al., 2024). Moreover, many older drawings contain handwritten or semi-structured annotations, further complicating recognition. While modern optical character recognition (OCR) systems perform well on clean, machine-printed text, their performance can decline for handwritten engineering-drawing content and under challenging imaging conditions (Peng et al., 2023; Peng et al., 2026).

To address these challenges, existing approaches to engineering drawing information extraction have often relied on rule-based heuristics or multi-stage learning pipelines. Rule-based methods often require manual customization and may become less robust when layouts deviate from expected templates (Gölzhäuser et al., 2023; Faltin et al., 2024). More recent data-driven approaches often adopt detector-based pipelines, sometimes augmented with large language models (LLMs) or vision-language models (VLMs) for post-processing and reasoning (Lombardi et al. 2025). While such hybrid solutions can improve extraction accuracy, they often involve complex multi-model workflows, may depend on proprietary components, and can require additional adaptation when applied to new document styles, particularly in privacy-sensitive AEC environments.

Recent advances in VLMs suggest that such models can align visual content with textual queries and generate structured outputs from complex images (Li et al., 2025; Shinde et al., 2025). However, their use for engineering drawings remains limited, particularly for workflows that employ the same open-source VLM backbone family for both title-block localization and structured information extraction. This gap motivates the VLM-based workflow proposed in this paper.

In this paper, we investigate a VLM-based workflow for title-block detection and structured information extraction using the open-source Qwen2.5-VL backbone. The two tasks are fine-tuned and evaluated separately: detection is formulated as promptable visual grounding on full engineering drawings, while extraction is performed on cropped title-block images. By using the same backbone family in both stages, the workflow avoids a heterogeneous multimodal toolchain and reduces pipeline complexity. Experimental results on bridge engineering drawings show promising performance and motivate further study of open-source VLMs for AEC document understanding.

Related Work

Engineering Drawing Information Extraction

Engineering drawing information extraction has attracted attention for decades, particularly due to the need for digitization and archival management (Scheibel et al., 2021; Kashevnik et al., 2023). Early work focused on

title-block localization and metadata extraction, a key step for indexing and retrieval from technical drawing archives (e.g., Najman et al., 2001). Traditional OCR-based pipelines often combine optical character recognition with layout-dependent heuristics, geometric rules, and manually designed templates to locate and crop title-blocks before field-level text recognition and cleaning (e.g., Ondrejcek et al., 2009). While often effective on standardized layouts, such methods may become less reliable on diverse templates and degraded scans. More recent work has explored hybrid pipelines that integrate detection models with LLMs to improve both localization and structured extraction on complex or noisy drawings (Lombardi et al., 2025).

Multi-model-based Pipelines

To overcome the limitations of rule-based systems, recent work has adopted learning-based pipelines that combine object detection with OCR. In such approaches, detectors such as You Only Look Once (YOLO) (Khanam and Hussain, 2024) or Faster R-CNN (Liu et al., 2017) are used to localize regions of interest, followed by text recognition and post-processing (Faltin et al., 2024). More recently, LLMs and VLMs have been integrated with visual pipelines to improve semantic interpretation and schema mapping (Li et al., 2019; Huang et al., 2022; Lombardi et al., 2025). Although such pipelines can improve accuracy, they often involve multiple interconnected components, which may increase deployment and maintenance effort.

VLMs in Document Understanding

Recent advances in VLMs support visual-text alignment and structured output generation from complex images. Models such as LayoutLM have shown strong performance in document understanding and information extraction by jointly modeling text and visual features (Xu et al., 2020; Xu et al., 2021; Huang et al., 2022). Benchmarks such as DocVQA further validate the usefulness of joint visual-textual representations in complex document tasks (Mathew et al., 2021). More recently, general-purpose VLMs such as GPT-4 and Qwen-VL have extended these capabilities beyond document-specific architectures and support prompt-based visual grounding, multimodal reasoning, and flexible output generation (Achiam et al., 2023; Bai et al., 2025). However, their use for engineering drawings remains limited, particularly for workflows that employ the same open-source VLM backbone family for both title-block localization and structured information extraction. This gap motivates the VLM-based workflow proposed in this paper.

Methodology

Overall Workflow

We propose a VLM-based workflow for title-block detection and structured information extraction using the same Qwen2.5-VL backbone family for both tasks, as shown in Figure 1.

At inference time, the workflow operates in two prompting steps. First, the complete engineering drawing is prompted to localize the title-block via visual grounding. Second, the cropped title-block region is prompted to extract structured information. This design avoids the use of standalone detectors or OCR engines within the proposed workflow.

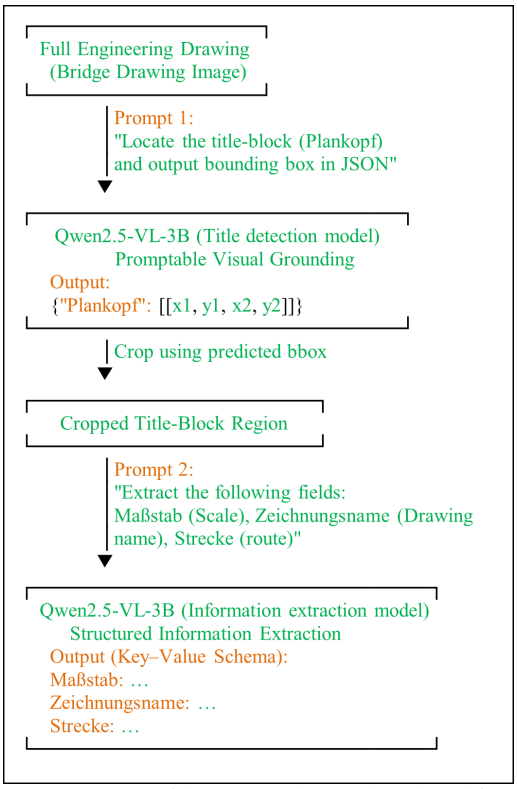

Figure 1: Overview of the proposed VLM-based workflow with separate task-specific stages for detection and structured extraction.

Title-Block Detection via Promptable Visual Grounding

Instead of training a standalone object detector, we formulate title-block localization as a promptable visual grounding task within a VLM. Given a full engineering drawing, the model receives the image together with a natural-language instruction (e.g., “locate the title-block” or “locate the Plankopf”) and directly outputs bounding-box coordinates in a structured JSON format.

This formulation avoids detector-specific training pipelines and allows localization targets to be specified flexibly through language. By performing localization within the same VLM backbone family used for the extraction stage, the predicted bounding boxes can be directly used to crop the title-block region for subsequent processing.

To support multilingual engineering documentation, we employ both English (“title-block”) and German (“Plankopf”) prompts during training and inference and observe consistent grounding performance under both formulations.

Structured Information Extraction

Following title-block detection, the cropped region is re-prompted to perform structured information extraction. We formulate this step as a prompt-based generation task, where the model is instructed to extract metadata fields and return them in a fixed key–value schema. In this study, we focus on three representative attributes commonly present in title-blocks of bridge engineering drawings, namely scale (Maßstab), drawing name (Zeichnungsname), and route (Strecke), as an initial step toward broader metadata extraction.

By explicitly constraining both the target attributes and the output format in the prompt, the model is used to perform OCR-like text recognition and semantic interpretation within a single prompted inference step, without relying on rule-based parsing or post-processing. This design supports structured extraction across layout variations and mixed printed–handwritten content commonly found in historical engineering drawings.

Model Fine-Tuning Strategy

To adapt the pre-trained VLM to the domain of engineering drawings, we apply parameter-efficient fine-tuning based on Low-Rank Adaptation (LoRA). While Qwen2.5-VL-3B-Instruct provides strong general-purpose visual and textual understanding, engineering drawings differ substantially from natural images in terms of visual structure, symbol usage, and domain-specific terminology. Fine-tuning is therefore used to better address this domain gap and improve performance in title-block detection and metadata extraction.

During fine-tuning, the vision tower is frozen to preserve stable low-level visual representations learned during large-scale pre-training. Trainable LoRA adapters, together with the multimodal projection layer, are introduced into the language model component to specialize the model for domain-specific tasks. This strategy significantly reduces the number of trainable parameters and the computational cost, while still supporting practical adaptation under limited annotated data. Although both tasks use the same Qwen2.5-VL-3B-Instruct backbone family, they are fine-tuned separately because they differ in input granularity, output format, and supervision type: detection uses full drawings with box-level supervision, whereas extraction uses cropped title-block images with field-level supervision.

Dataset and Annotation

Dataset Overview

For title-block detection, we use 500 full bridge engineering drawings with box-level title-block annotations for training and validation, comprising 450 training drawings and 50 validation drawings. In addition, an independent test set of 64 full engineering drawings, separate from the training and validation data, is used for evaluation.

For structured information extraction, we use a crop-level development dataset of 467 title-block images for training and validation, comprising 420 training samples and 47 validation samples. In addition, evaluation is conducted on two independent crop-level test sets consisting of 50 machine-printed and 50 handwritten title-block crops, respectively. These test sets are separate from the development data.

The dataset exhibits substantial variation in layout, typography, and image quality. Machine-printed title-blocks often contain denser information, tabular structures, and standardized fonts, whereas handwritten title-blocks typically have simpler layouts but introduce challenges such as writing-style variability, fading ink, and scanning artifacts. Together, these categories support evaluation across both contemporary and legacy engineering documents.

Annotation Schema

Each sample is annotated at two complementary levels for detection and information extraction.

```
{

Widerlager Achse 20\nStrecke: Hamburg – Berlin, km
0,628"
  }
 ]
}
```

Figure 3: Example annotation of structured information extraction.

First, box-level annotations define the spatial extent of the title-block within the full engineering drawing, as illustrated in Figure 2. For this task, the model is prompted to locate the title-block, and the corresponding ground-truth response provides rectangular bounding-box coordinates in JSON format. These annotations are used

to supervise and evaluate title-block localization performance.

Second, field-level annotations specify the ground-truth values for three target metadata attributes, namely scale, drawing name, and route within the title-block, as illustrated in Figure 3. Given a cropped title-block image, the model is instructed to extract these attributes and return them in a fixed key–value schema.

By representing both detection and extraction annotations as conversational image-text pairs with structured outputs, the dataset enables direct supervision of heterogeneous tasks within the same VLM backbone family. This design reduces the need for task-specific post-processing rules or layout assumptions and facilitates the combined use of the two models at inference time.

Experiments and Results

Experimental Setup

We evaluate the proposed VLM-based workflow on two related tasks: title-block detection and structured information extraction. Both tasks use the same Qwen2.5-VL-3B-Instruct backbone family but are fine-tuned separately because they differ in input granularity and output targets. During preliminary development, we explored a small set of LoRA configurations and selected the final settings based on stable convergence and validation performance. For title-block detection, the final LoRA configuration used rank 32, scaling factor 16, and dropout 0.05. For structured information extraction, the final configuration used rank 32, scaling factor 64, and dropout 0.05. The model was optimized using AdamW with an initial learning rate of 1×10^{-4}, a cosine learning-rate scheduler, and 70 warmup steps. Mixed-precision training with bfloat16 (bf16) was used to reduce memory consumption. For title-block detection, the model was fine-tuned for 8 epochs, and the best-performing checkpoint was selected based on validation loss. For structured information extraction, the final checkpoint was selected after 4 epochs, consistent with the observed validation-loss minimum around the fourth epoch.

Baselines

For title-block detection, we compare the fine-tuned Qwen2.5-VL-3B-Instruct model against two references: (1) YOLOv11-medium as a conventional detector baseline and (2) zero-shot Qwen2.5-VL-3B-Instruct without task-specific fine-tuning. All models are evaluated on the same 64-drawing test set using precision, recall, F1, and mean IoU at an IoU threshold of 0.5.

For structured information extraction, we compare the fine-tuned Qwen2.5-VL-3B-Instruct model against the corresponding zero-shot configuration without task-specific fine-tuning. Both models are evaluated on the same crop-level test sets of machine-printed and handwritten title-block images using Word Accuracy (WA) and Character Accuracy (CA). Per-field results are additionally reported for Maßstab, Zeichnungsname, and Strecke.

Title-Block Detection

We evaluate title-block detection using precision, recall, F1, and mean Intersection over Union (IoU) at an IoU threshold of 0.5. Predictions above the threshold are counted as true positives (TP), lower-overlap detections are treated as false positives (FP), and missed title blocks are treated as false negatives (FN).

Table 1: Comparative Performance for Title-Block Localization

Metric	Fine-tuned Qwen2.5-VL-3B	YOLOv11 -medium	Zero-shot Qwen2.5-VL-3B
Precision	93.8%	91.0%	0.0%
Recall	93.8%	95.3%	0.0%
F1	93.8%	93.1%	0.0%
Mean IoU	0.871	0.951	---
TP	60	61	0
FP	4	6	0
FN	4	3	64
Output Validity Rate	100%	98.4%	100%

Table 1 compares the fine-tuned Qwen2.5-VL-3B-Instruct model with the YOLOv11-medium baseline and the zero-shot Qwen2.5-VL-3B-Instruct baseline on the 64-drawing test set. The fine-tuned Qwen model achieves 93.8% precision and 93.8% recall, with an F1 score of 93.8% and a mean IoU of 0.871. This performance is comparable to YOLOv11-medium (F1=93.1%), although YOLO yields a higher mean IoU (0.951). YOLO produced a small number of duplicate or mislocalized predictions, which explains why the number of detections exceeded the number of test images. In contrast, the zero-shot Qwen model does not localize title blocks successfully in this setting, despite producing syntactically valid structured outputs. This highlights the importance of domain-specific fine-tuning for engineering drawings.

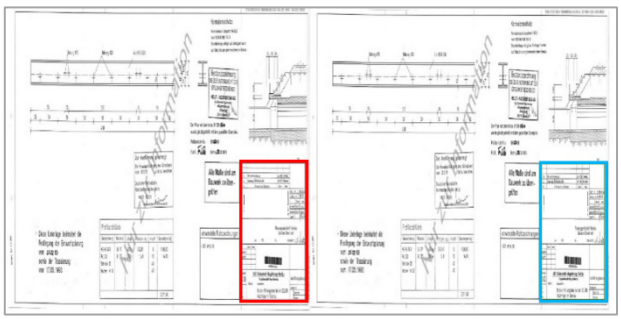

Figure 4: Representative result of title-block detection. Comparison between ground-truth annotation (red) and model prediction (blue).

For comparison, YOLO detections were converted into the same structured output format. The fine-tuned Qwen achieved a 100% output validity rate, meaning that valid structured outputs were generated for all test samples. As shown in Figure 4, the predicted bounding box closely

aligns with the ground-truth annotation in a representative drawing. Most detection failures occur in cases with unconventional title-block placement, severe visual degradation, or ambiguous boundaries between the title block and adjacent tabular regions. In a smaller number of cases, visually similar tabular areas are mistaken for title blocks, or the predicted box only partially covers the true title-block extent, leading to IoU values below the acceptance threshold.

Structured Information Extraction

To evaluate structured information extraction, we report both Word Accuracy and Character Accuracy, which capture complementary aspects of extraction quality. The metrics are computed directly on the extracted key-value outputs by comparing each predicted field value with the corresponding ground-truth value, without additional post-processing, normalization, or special handling of empty fields. Word Accuracy reflects semantic-level correctness and sensitivity to word-boundary errors, while Character Accuracy provides a more fine-grained assessment of character-level robustness.

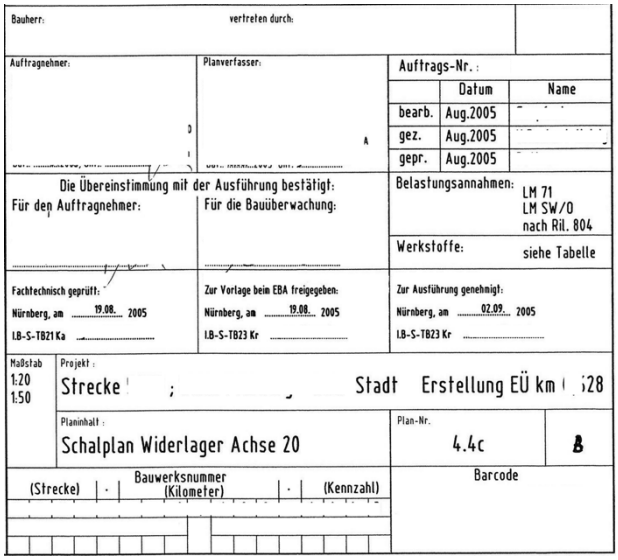

Figure 5: Example of machine-printed title-block. (Sensitive project-specific information has been anonymized for confidentiality.)

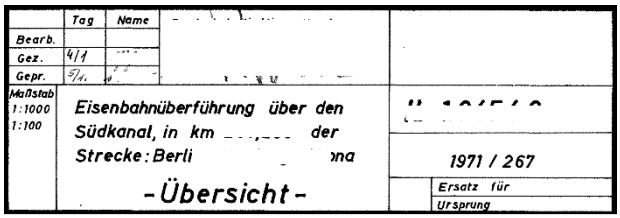

Figure 6: Example of predominantly handwritten title-block. (Sensitive project-specific information has been anonymized for confidentiality.)

We evaluate extraction performance on two independent crop-level test sets constructed from ground-truth title-block crops, as described in the Dataset Overview. One set contains 50 machine-printed title-blocks with dense layouts (Figure 5), and the other contains 50 predominantly handwritten title-blocks with relatively simple layouts but diverse handwriting styles (Figure 6). These results reflect crop-level extraction performance and are reported independently of the upstream detection stage. All results reported in this section correspond to the final configuration selected based on validation performance, as described in the Experimental Setup.

On the machine-printed title-block test set, the fine-tuned model achieves a WA of 0.78 and a CA of 0.76. On handwritten title-blocks, higher performance is observed, with WA reaching 0.83 and CA reaching 0.86. These results indicate promising extraction accuracy for both modern and historical title-block images.

Table 2: Comparative performance for structured information extraction on handwritten title-block crops (Field 1: Maßstab; Field 2: Zeichnungsname; Field 3: Strecke).

Metric	Fine-tuned Qwen2.5-VL-3B	Zero-shot Qwen2.5-VL-3B
Field 1 WA	0.9474	0.6023
Field 1 CA	0.9495	0.5865
Field 2 WA	0.7216	0.1868
Field 2 CA	0.8479	0.4320
Field 3 WA	0.8545	0.2836
Field 3 CA	0.8671	0.3536

To assess the effect of domain-specific adaptation in more detail, we further compare the fine-tuned Qwen model with the corresponding zero-shot configuration at the field level. Tables 2 and 3 report per-field WA and CA for the three target attributes (Maßstab, Zeichnungsname, and Strecke) on handwritten and machine-printed title-block crops, respectively.

Table 3: Comparative performance for structured information extraction on machine-printed title-block crops (Field 1: Maßstab; Field 2: Zeichnungsname; Field 3: Strecke).

Metric	Fine-tuned Qwen2.5-VL-3B	Zero-shot Qwen2.5-VL-3B
Field 1 WA	0.9900	0.5721
Field 1 CA	0.9892	0.5510
Field 2 WA	0.7132	0.1716
Field 2 CA	0.7510	0.3217
Field 3 WA	0.7398	0.2520
Field 3 CA	0.7117	0.3061

Per-field analysis reveals a clear difference in extraction difficulty across the three target attributes. Maßstab is consistently the easiest field, achieving the highest WA and CA in both handwritten and machine-printed title-blocks. This is likely due to its short and highly regular format. Zeichnungsname is the most challenging field, especially at the word level, which can be attributed to its greater length, frequent line breaks, and higher sensitivity to surrounding layout complexity. Strecke shows intermediate difficulty, although its performance decreases substantially in machine-printed title-blocks,

suggesting that dense tabular layouts and closely positioned neighboring text increase ambiguity in field boundaries. Across all three fields, the fine-tuned model substantially outperforms the corresponding zero-shot baseline, highlighting the importance of domain-specific adaptation for engineering drawings.

The higher overall extraction accuracy on handwritten title-blocks is consistent with the per-field comparison. Although Maßstab achieves slightly better results in machine-printed title-blocks, both Zeichnungsname and Strecke are extracted more accurately from handwritten samples. This indicates that, for these semantically richer fields, layout simplicity and reduced visual clutter may be more important than text regularity alone. By contrast, machine-printed title-blocks often contain denser tabular structures and more closely positioned text elements, which increase ambiguity in field boundaries and make extraction more difficult, especially for drawing names and route-related content.

Maßstab (scale): 1:20, 1:50
Zeichnungsname (drawing name): Erstellung EÜ Schalplan Widerlager Achse 20
Strecke (route): …Stadt km …28

Figure 7: Representative result of structured information extraction for a machine-printed title-block, corresponding to the title-block shown in Figure 5.

Maßstab (scale): 1:1000, 1:100
Zeichnungsname (drawing name): Eisenbahnüberführung über den Südkanal Übersicht
Strecke (route): Berli…ona, km …

Figure 8: Representative result of structured information extraction for a predominantly handwritten title-block, corresponding to the title-block shown in Figure 6.

Figures 7 and 8 present representative qualitative examples of structured information extraction on machine-printed and handwritten title-blocks, respectively. In each example, the model correctly identifies and extracts multiple metadata fields, including scale, drawing name, and route, despite variations in layout, typography, and content density.

Overall, the results indicate that a fine-tuned VLM can support OCR-like text recognition and structured information extraction for title-block content without relying on external OCR engines or rule-based post-processing. This highlights the practical potential of the proposed VLM-based workflow for engineering document analysis.

Small-Scale Pipeline Evaluation

We additionally evaluated the workflow on 20 real full bridge engineering drawings on an NVIDIA RTX A5000 GPU with 24 GB of memory. The set reflects challenging and practically relevant legacy-archive conditions, including dark, speckle-noisy scans and mixed machine-printed layout fields with handwritten technical annotations. Title-block detection achieved Precision/Recall/F1 = 85%/85%/85%, with a mean IoU of 0.633. On the corresponding 20 title-block crops, extraction from ground-truth crops achieved a WA of 0.6458 and a CA of 0.7475, whereas extraction from Qwen-predicted crops achieved a WA of 0.6771 and a CA of 0.7712. Per-field trends remained consistent with the main benchmark: Maßstab was the easiest field, Zeichnungsname the most difficult, and Strecke intermediate. Notably, extraction from Qwen-predicted crops did not lead to a performance drop in this small-scale evaluation and even showed slightly higher WA and CA, suggesting that the predicted boxes were sufficiently accurate for downstream extraction and may, in some cases, reduce surrounding visual clutter. The average runtime was 2.97 s per drawing for title-block detection and 8.91 s per title-block crop for structured information extraction, with peak allocated GPU memory below 10 GB in all settings. These results indicate that the workflow is practically feasible for offline archive-style processing on a 24 GB-class GPU.

Discussion and Limitations

The experimental results indicate that the same open-source VLM backbone family can be used for both title-block detection and structured information extraction on engineering drawings. Unlike conventional detector-based pipelines, the proposed VLM-only workflow uses the same VLM backbone for both localization and interpretation, reducing system complexity while showing promising performance across heterogeneous drawing styles. In the present study, the two tasks are fine-tuned separately and combined at inference time.

One factor that may contribute to this behavior lies in the nature of title-blocks themselves. Although title-blocks exhibit substantial variation in layout, typography, and language across organizations and time periods, they are typically semantically well-defined regions that encode standardized metadata. Promptable visual grounding may help the model leverage semantic cues rather than relying solely on geometric or appearance-based patterns, which may contribute to localization performance even under unconventional layouts or degraded scan quality. This differs from traditional object detectors, which may require additional adaptation under distribution shifts or limited training samples.

Another advantage of the proposed approach is the conceptual consistency between detection and extraction through the same VLM backbone and prompt-based interaction paradigm, which may reduce intermediate conversions and error propagation in multi-stage workflows.

The information extraction results further indicate that the model shows promising performance across different title-block styles. Higher accuracy is observed on handwritten title-blocks, which can be attributed to their typically simpler layouts and lower information density compared with modern machine-printed title-blocks. In contrast, printed title-blocks often contain dense tables, multiple scale entries, and additional graphical elements, increasing extraction complexity. These observations

suggest that layout complexity may be an important challenge, in addition to handwriting, for structured extraction in engineering drawings.

From a practical perspective, the proposed VLM-only workflow offers several potential advantages for deployment in AEC environments. The use of a single open-source model reduces engineering overhead, improves reproducibility, and facilitates on-premise deployment, which may be beneficial in contexts involving privacy, regulatory compliance, and long-term maintainability. These properties may make the approach relevant for real-world engineering archives, where heterogeneous document collections and limited annotation budgets are common.

Despite its promising performance, the proposed workflow has several limitations. First, the current study focuses on three representative metadata fields, namely scale, drawing name, and route, which, while practically relevant, do not cover the full range of information present in title-blocks. Extending the schema to additional fields, such as drawing numbers, revision indices, dates, and responsible organizations would further improve applicability.

Second, although promptable visual grounding performs well on most drawings, detection errors still occur in edge cases involving unconventional layouts, severe visual degradation, or ambiguous title-block boundaries. Addressing such cases may require additional contextual prompts, multi-step reasoning, or lightweight layout priors.

Third, the workflow does not explicitly handle non-textual elements commonly found in engineering drawings, such as stamps, signatures, symbols, or dimension annotations. Integrating symbol understanding or multimodal reasoning over graphical primitives remains an open challenge.

Finally, the current dataset is limited to a bridge-engineering context, and broader generalization to other engineering domains, regions, and historical conventions remains to be validated. While the small-scale pipeline evaluation (n = 20) provides encouraging results, systematic validation on a larger full-drawing test set is still needed. Future work will therefore examine the complete workflow on full drawings using predicted title-block localization, extend the approach to other drawing domains such as buildings, Mechanical, Electrical, and Plumbing (MEP) systems, and other infrastructure types, and investigate broader baseline comparisons, including detector-plus-OCR pipelines or document-specialized models. Extending the workflow to new domains will likely require additional domain-specific data at both stages, including full-drawing box annotations for title-block localization and crop-level key-value annotations for structured extraction, as well as adaptation of the target metadata schema, prompt design, and task-specific fine-tuning. Larger-batch throughput analysis beyond the current single-sample sequential runtime setting also remains future work.

Conclusions

This paper shows that a single open-source VLM backbone family can provide a promising basis for unified title-block detection and structured information extraction in engineering drawings. By formulating title-block detection as a promptable visual grounding task and performing metadata extraction through prompt-based generation, the proposed approach combines detection and interpretation within a VLM-based workflow built on the same backbone family without relying on standalone detectors or external OCR engines.

The results across modern and historical drawings indicate that VLM-based approaches show promising performance across heterogeneous layouts and visual conditions, suggesting their potential for broader use in engineering document analysis workflows.

Overall, this work highlights the potential of open-source VLMs as a simplified and reproducible alternative to conventional multi-model pipelines for engineering drawing understanding. It also offers a useful starting point for future research on richer metadata schemas, deeper semantic understanding, and scalable digitization of engineering archives using open-source VLMs.

Data and Code Availability

The study uses the publicly available Qwen2.5-VL model (https://huggingface.co/Qwen/Qwen2.5-VL-3B-Instruct). The base architecture was not modified. The engineering drawing dataset is confidential but may be shared upon reasonable request for non-commercial research purposes, subject to institutional approval.

AUTOMATED BIM LOD INFERENCING: A HYBRID APPROACH USING KNOWLEDGE GRAPHS AND MULTIMODAL LARGE LANGUAGE MODELS

Taeyoon Kim[1], Ghang Lee[1]
[1]Yonsei University, Seoul, Rupblic of Korea

Abstract

Automated Level of Development (LOD) assessment in Building Information Modeling (BIM) is hindered by semantic ambiguity in specifications and geometric complexity of objects. Existing rule-based and vision-based methods lack contextual reasoning or struggle with fragmented, occluded geometry. This study proposes a hybrid framework combining a three-layered knowledge graph—built top-down via LLM requirement extraction and bottom-up via visual population—with a geometric pipeline reassembling meshes and exposing occluded components. A multimodal LLM cross-references graph-derived criteria with multi-view geometry, producing explainable assessments. A four-condition ablation study achieves 83.47% accuracy while reducing false negatives, confirming feasibility for explainable BIM quality assurance.

Introduction

Research Background

As digital transformation accelerates within the construction industry, Building Information Modeling (BIM) has established itself as a core database for managing information throughout the entire project lifecycle, moving beyond simple 3D geometric modeling. To maximize the utility of BIM data, it is essential to verify the accuracy of the information and ensure compliance with the Level of Development (LOD) standards required for each project phase. However, existing LOD verification methods heavily rely on manual inspection by experts, which incurs significant time and costs. Furthermore, conventional rule-based automation tools lack the flexibility to handle various geometric variations and complex exceptions. While recent studies have attempted to leverage Artificial Intelligence (AI) to address these issues, two fundamental barriers remain: the "semantic gap" and "geometric complexity."

Problem Statement

The first challenge is the semantic gap between human language and machine understanding. LOD specifications are written in natural language, possessing linguistic characteristics that are difficult for machines to interpret intuitively. For instance, umbrella terms such as "All Reinforcement" do not map one-to-one with specific objects (e.g., main bars, stirrups) within the model. Additionally, context-dependent terms like "Connection" exhibit polysemy, where the target object for inspection changes depending on whether the system is Steel or Precast Concrete. Simple text-matching algorithms may utilize static dictionaries, but they fail to dynamically infer these hierarchical and contextual relationships, preventing the scalable application of automated verification.

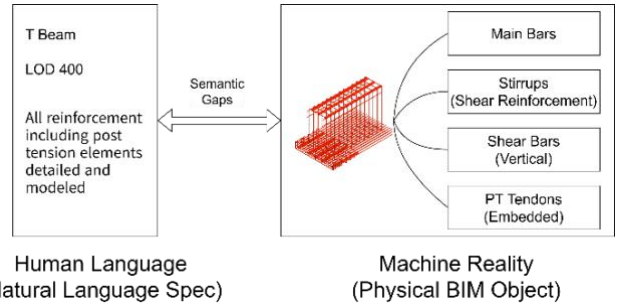

Figure 1 The semantic gap in LOD verification.

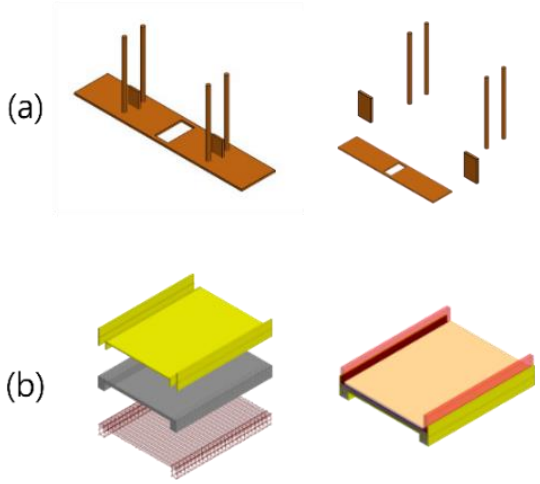

Figure 2 Visual illustration of geometric complexity in BIM objects. (a) Fragmentation: A single embedded component is geometrically constructed from multiple disconnected meshes. (b) Occlusion: A baseplate connection hides internal reinforcement behind opaque surfaces, impeding visual identification.

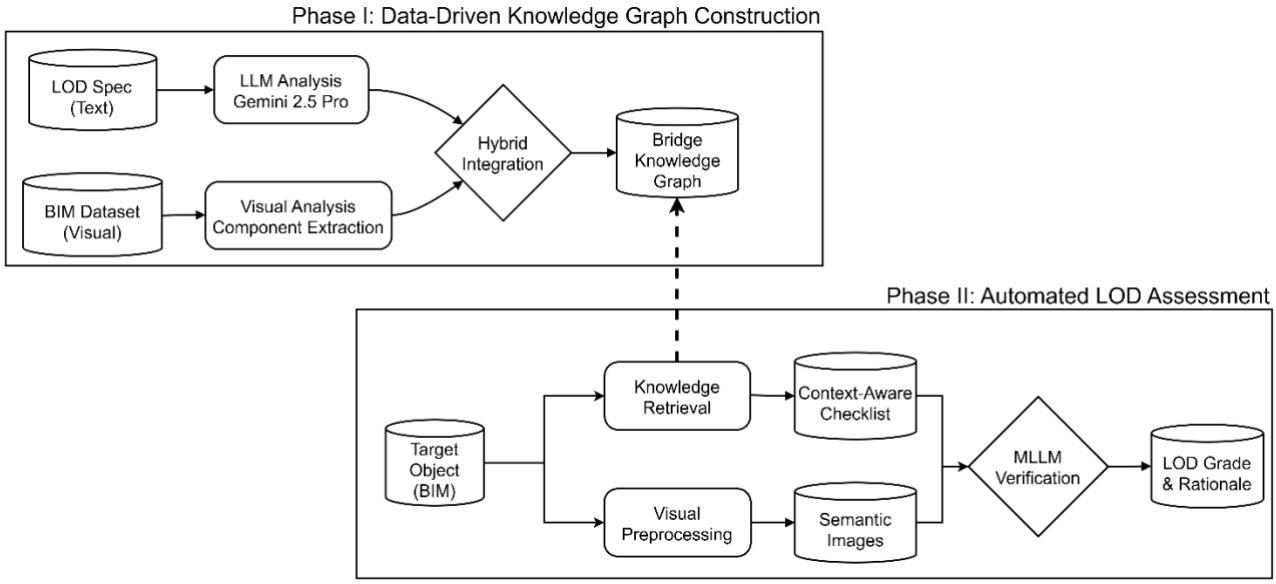

Figure 3 The architecture of the proposed dual-phase LOD assessment framework

The second challenge is geometric complexity. Although a BIM object may logically represent a single element (e.g., a Precast Concrete T-beam), its sub-components often exhibit geometric fragmentation. For instance, a single embedded steel part is frequently composed of multiple disconnected meshes—where the base plate and studs are modeled as separate geometric entities—lacking a unified topological structure (fragmentation). Conversely, objects often contain critical internal components, such as reinforcement within a baseplate connection, that are visually obscured by external surfaces (occlusion). If such objects are simply captured as raw images, the AI model is likely to misinterpret the fragmented meshes as separate unrelated objects, while failing to recognize the hidden internal components.

Research Objective and Organization

The objective of this research is to establish an intelligent quality assessment system that integrates domain knowledge with visual reasoning. Unlike black-box AI approaches, this study proposes a knowledge graph-based framework to ensure explainable assessments. Specifically, the system aims to (1) resolve linguistic ambiguities in LOD standards by constructing a logical reasoning engine, and (2) overcome visual occlusion and fragmentation through semantic geometric preprocessing. By bridging these semantic and geometric gaps, the framework enables MLLMs to perform rigorous and traceable LOD verification.

Related Works

This section reviews existing literature on BIM object classification and quality assessment, categorizing them into (1) geometry and metadata-based approaches, (2) deep Learning-based visual classification, and (3) Recent MLLM applications. It highlights the limitations of each approach and defines the differentiation of the proposed research.

Geometry and Metadata-based Approaches

Early studies focused on utilizing geometric features or textual metadata of BIM objects for classification. (Wu and Zhang, 2019) proposed a hybrid algorithm combining geometric features with keyword matching to enhance BIM interoperability. However, this method relies heavily on pre-defined rules, lacking flexibility for irregular objects that deviate from standard specifications. Similarly, (Abualdenien and Borrmann, 2022) utilized ensemble learning to classify the Level of Geometry (LOG) based on geometric complexity (e.g., area, volume). While effective for assessing geometric precision, this approach fails to semantically identify the presence of specific components (e.g., bolts, nuts), which is the core requirement for actual LOD assessment.

Vision-based Deep Learning and Data Dependency

To overcome the limitations of metadata reliance, research on converting 3D BIM objects into 2D images for classification using Convolutional Neural Networks (CNN) has gained traction. (Yang et al., 2026) improved classification performance for architectural and MEP objects using multi-view images. However, these Supervised Learning approaches entail a significant critical limitation: they require the costly pre-construction of massive, labeled datasets containing thousands of images.

To address performance issues,(Yu et al., 2023) and (Utkucu et al., 2024) proposed Ensemble Deep Learning techniques and Random Forest integration to enhance accuracy and compatibility with classification systems like Uniclass. Despite these improvements, they still fail to overcome the fundamental "Data Hunger" problem; whenever a new LOD standard or a new object type is introduced, new data must be collected, and the model must be re-trained. Furthermore, relying solely on exterior visual features prevents these models from identifying

occluded components—such as rebar inside concrete—which are essential for detailed LOD verification.

Multimodal LLMs and Ontology Approaches in Generative Interpretation

Recently, studies utilizing MLLMs have emerged to achieve Zero-shot classification and reduce data construction costs. (Wang, X. et al., 2025) demonstrated the use of models like GPT-4V to detect surface cracks on steel bridges, and (Zeng et al., 2024) estimated building age solely from facade images. While these studies show the potential of MLLMs, they are limited to surface-level image analysis. They have not attempted to integrate domain knowledge (knowledge graph) to evaluate objects with complex hierarchies and contexts, such as BIM elements. Without structured knowledge, general-purpose MLLMs are prone to hallucinations and fail to grasp the specific engineering nuances required for LOD assessment.

Recent advancements in Natural Language Processing (NLP) and ontology have significantly improved the structuring of unstructured construction data, primarily enhancing information extraction and retrieval tasks. For instance, (Nahri et al., 2025) utilized transformer-based models to extract explicit requirements from technical specifications, while (Yin et al., 2023) developed an ontology-aided approach to translate natural language queries for retrieving information from existing BIM models. Similarly, (F.h et al., 2025) formalized the ISO 19650 standard into the BIM-OIM ontology to support process compliance. While these studies effectively parse explicit text or validate established processes, the domain of generative modeling presents an opportunity for further exploration regarding the "Semantic gap." Current methods typically focus on direct mapping, and there is potential to extend these approaches to include the inferential reasoning required to translate abstract "Human Standards" (e.g., vague LOD descriptions) into concrete "Deep Standards" (e.g., specific component hierarchies). This study aims to build upon these foundations by introducing a semantic bridge to infer implied domain concepts—such as deducing required Connection Assemblies from a text that mentions anchor rods—thereby facilitating the automated decision-making process in BIM object creation.

Methodology

Framework Overview

This study proposes a comprehensive framework designed to bridge the semantic gap between human requirements and machine interpretation for automated LOD verification. The proposed system is structurally divided into two primary phases: (1) Phase I: Data-Driven knowledge graph Construction and (2) Phase II: Automated LOD Assessment. In the first phase, a Bridge knowledge graph (KG) is constructed as a foundational reasoning engine. Instead of relying on static rule-based definitions, this knowledge base is developed through a hybrid data-driven process where natural language requirements are parsed by LLM, specifically Gemini 2.5 Pro, while physical component vocabularies are derived from the visual analysis of high-fidelity BIM data. In the second phase, the system executes the assessment by cross-referencing this pre-validated knowledge with the geometric data of the target BIM object. This dual-phase approach ensures both the scalability of knowledge acquisition and the consistency of real-time verification.

Phase I: Data-Driven knowledge graph Construction

Three-Layer Graph Architecture

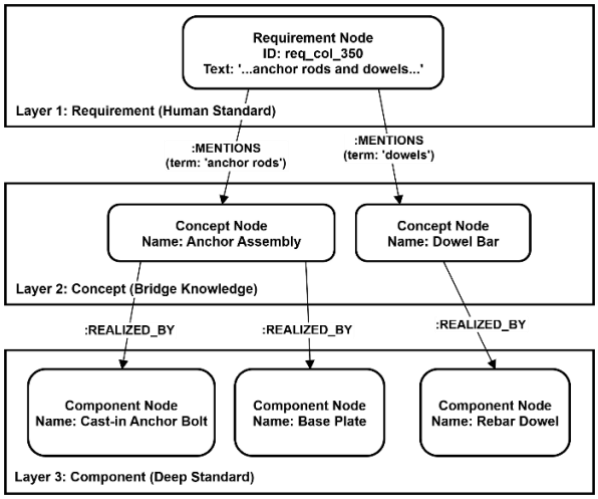

Figure 4 The three-layered architecture of the Bridge knowledge graph.

A critical limitation of existing LOD verification methods is the inability to rigorously map abstract natural language requirements to specific 3D objects. In this study, we distinguish between two levels of specification: "Human Standards," defined as the natural-language requirements stated in LOD specifications (e.g., "Include anchor rods and dowels"), which are intended for human interpretation and often underspecified for automated inspection. In contrast, "Deep Standards," denote a machine-interpretable representation of these requirements, expressed as structured inspection criteria that explicitly define each required sub-component in terms of its identity and expected geometric form (e.g., "Cast-in Anchor Bolt: cylindrical rod embedded in concrete"). The term “Deep” emphasizes that these standards capture latent, operational constraints implicit in human-readable specifications but not explicitly stated. The core objective of the proposed knowledge graph is to bridge this gap by systematically translating Human Standards into Deep Standards, enabling reliable reasoning and verification by downstream visual and geometric analysis modules.

To achieve this, we designed a three-layer graph architecture, as illustrated in Figure 4. The top layer, Requirement Nodes, encapsulates the raw textual requirements extracted from standard specifications. For example, as shown in the diagram, a requirement for LOD 350 Columns might state: "Include anchor rods and dowels." The bottom layer, Component Nodes, consists of concrete physical elements existing in the modeling

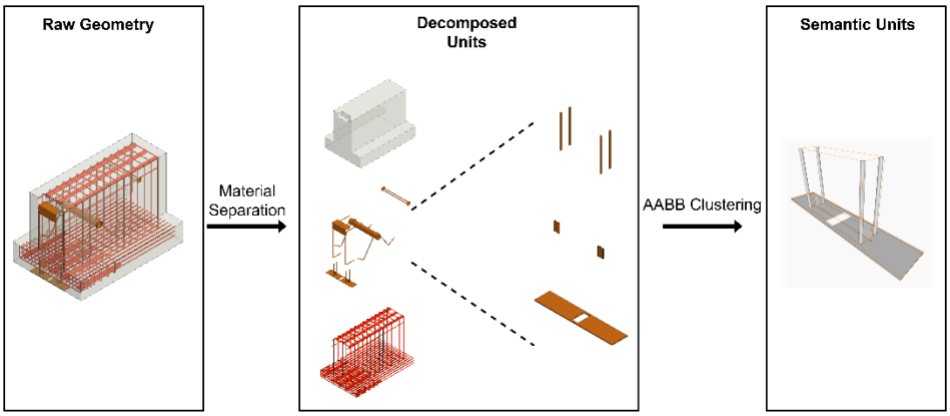

Figure 5 Transformation from raw geometry to semantic units. Visualization of the preprocessing steps: Raw input, Decomposed units via material separation, and Re-assembled semantic units via AABB clustering.

environment, such as "cast-in anchor bolt," "base plate," and "rebar dowel." Connecting these two is the Concept Node Layer (Bridge Layer). This intermediate layer acts as a semantic hub that abstracts ambiguous terms into system-specific engineering concepts. In Figure 4, the term "anchor rods" from the requirement is mapped to the concept "anchor assembly" (via the "mentions" relationship), which is then physically realized by components like "Cast-in Anchor Bolt" and "Base Plate" (via the "realized_by" relationship). This structure effectively resolves linguistic ambiguity by integrating diverse expressions into unified technical definitions.

It should be noted that the semantic mapping between layers in the current knowledge graph was manually curated. While LLMs assisted in extracting requirements and suggesting candidate concepts, the final alignment was performed through manual validation. Consequently, when a new LOD standard is introduced, the Requirement layer must be reconstructed, whereas the Concept and Component layers—representing reusable engineering vocabulary—can be largely retained and extended incrementally.

Hybrid Learning Pipeline

To populate this three-layer structure, we employed a Hybrid Learning Pipeline that synthesizes both textual and visual data. First, adopting a top-down approach, we utilized GPT-5.1 to analyze unstructured PDF standard documents. The model extracts core requirements and infers implied engineering concepts (implied concepts) to construct the Requirement and Concept layers. Simultaneously, a Bottom-Up approach was applied using Visual Analysis techniques on a dataset of high-fidelity (LOD 400) BIM models. By scanning these models, the system extracted a "Visual Vocabulary" of actual existing components to populate the Component Layer. Finally, through a Semantic Alignment process, these two streams were mapped to complete a validated knowledge graph that eliminates the discrepancy between "what is required" (Human Standards) and "what is modeled" (Deep Standards).

Phase II: Context-Aware & Explainable Assessment

Context-Aware Knowledge Retrieval

During the verification phase, the system utilizes the pre-constructed knowledge graph as a deterministic reasoning engine. When a user selects a BIM object, the system queries the graph using the object's classification code (e.g., OmniClass). The query engine performs Context-Aware Retrieval, dynamically interpreting ambiguous terms based on the object's system type—for instance, mapping the term "Connection" to "Anchor Bolts" for a steel column, while mapping it to "Shear Tabs" for a beam. This process instantly generates a precise, object-specific checklist without redundant inference computations.

Semantic Geometric Preprocessing

In typically complex BIM environments, internal components are often obscured by finishing materials (Occlusion) or exist as fragmented meshes (Fragmentation). To address this, the visual preprocessing module transforms raw geometry into machine-readable "Semantic Units," as illustrated in Figure 5.

The process begins with Raw Geometry, where internal reinforcement and embed plates are hidden within the concrete mass (Left). The module first executes Material Separation, decomposing the object into distinct layers—separating opaque concrete from internal steel elements—to generate Decomposed Units (Middle). This step effectively creates "X-ray Views" that reveal previously occluded structures.

Subsequently, the system employs Axis-Aligned Bounding Box (AABB) Clustering to reassemble these scattered parts. By analyzing spatial proximity, fragmented meshes (e.g., separate bolts and plates) are merged into unified Semantic Units (Right). This final representation provides the MLLM with a clear, obstacle-free view of the target components, ensuring accurate identification.

Evidence-Based MLLM Verification

Finally, Google's Gemini 2.5 Pro is employed as the central Multimodal LLM (MLLM) verification engine,

evaluating LOD compliance by cross-referencing the logical checklist derived from the knowledge graph with the preprocessed visual evidence. To prevent logical circularity—where the same model validates its own reasoning—this framework utilizes a cross-model verification strategy: OpenAI's GPT-5.1 was employed during the initial phase to generate the logical rationales and Knowledge Graph, while Google's Gemini 2.5 Pro is used independently for the final inspection phase. Unlike traditional black-box AI models that output opaque probability scores, the proposed system generates traceable rationales for its decisions. For instance, instead of merely labeling an object as "LOD 350," the system explicitly validates whether specific criteria—such as the visual presence of "Lifting Anchor Assemblies"—are met.

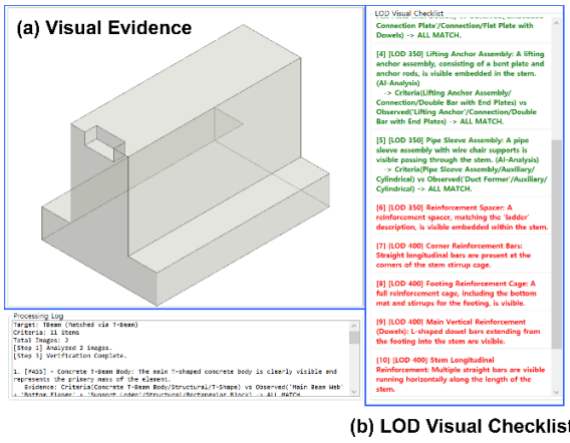

Figure 6 The integrated verification dashboard within Autodesk Revit.

To ensure seamless integration into the engineer's workflow, this verification logic is embedded directly within the BIM authoring environment via the Revit API, as illustrated in Figure 6. The system provides a real-time LOD Visual Checklist panel that displays the itemized inspection results derived from the knowledge graph. Compliant items are intuitively highlighted in green with an "ALL MATCH" tag, allowing users to instantly verify the satisfaction of specific requirements. This interactive feedback mechanism transforms the framework from a theoretical model into a practical decision-support tool, offering granular transparency beyond simple binary classifications.

Experimental Design and Validation Strategy

This section details the experimental framework established to assess the feasibility and performance of the proposed MLLM based LOD evaluation system. The composition of the dataset and the comparative scenarios designed to verify the impact of knowledge graph integration are described below.

Experimental Setup and Dataset

Dataset Composition

To evaluate the system's versatility across diverse construction disciplines, this study utilized the Level of Geometry (LOG) dataset (Abualdenien & Borrmann., 2022), a widely recognized benchmark in LOD research. The dataset encompasses a broad range of BIM families from structural, architectural, and MEP domains.

For the experimental scope, 31 representative families were selected, covering four LOD levels (LOD 200, 300, 350, and 400). This selection resulted in a total of 124 verification cases. These objects were specifically chosen to test the system's robustness against geometric complexities, including intricate internal components such as reinforcement cages, anchor bolts, and embed plates, which are rigorously modeled to comply with high-LOD standards.

Comparative Scenarios

To quantitatively measure the contribution of the proposed methodology, we conducted a comparative analysis between two distinct scenarios:

Baseline (Vanilla MLLM): This scenario represents the conventional verification method where raw text requirements from standard LOD Specifications are directly input into the MLLM without semantic processing. Under this baseline condition, an average of 4 criteria were applied per level, totaling 496 verification items. These criteria relied primarily on text-based descriptions, limiting the verification to abstract specifications rather than quantitative geometric analysis.

Proposed Method (Proposed KG+MLLM Approach): This scenario utilizes the Bridge knowledge graph constructed in this study. It applies the "deep standards checklist"—derived from the hybrid ontology learning pipeline—along with semantic visual preprocessing. This approach automatically generated 253 Concept Nodes and 626 Detailed Features. Consequently, the proposed method provides approximately 5.1 times more data points than the baseline, significantly enhancing the granularity of verification by grounding the process in actual model geometry.

Implementation Details

Model Implementation Details All experiments were conducted using the Gemini 2.5 Pro model via the API. This model was selected for its superior multimodal reasoning capabilities and extended context window, which are essential for processing the complex interplay between visual inputs (semantic units) and textual logic (knowledge graph queries).

Evaluation Metrics and Ground Truth

The quantitative evaluation employed confusion matrix metrics (TP, TN, FP, FN), determined based on the Cumulative Nature of LOD. This principle dictates that geometric features present in a lower LOD must persist in higher LOD levels.

To ensure reliability, the Ground Truth (GT) for comparison was established through a hybrid validation protocol. This approach utilized GPT-5.1 for initial automated verification, followed by rigorous manual inspection by researchers to finalize the dataset. The specific metrics are defined as follows:

True Positive (TP): System correctly classifies a Valid Model (e.g., Model 400) as Pass.

True Negative (TN): System correctly classifies an Invalid Model (e.g., Model 300 claiming to be 400) as Fail.

False Positive (FP): System incorrectly classifies an Invalid Model as Pass.

False Negative (FN): System incorrectly classifies a Valid Model as Fail.

Results and Discussion

Calibration: Threshold Sensitivity Analysis

Before performing the comparative analysis, a calibration experiment was conducted to determine the optimal "Decision Boundary" for the MLLM-based verification. Unlike rule-based systems, vision-based AI verification involves semantic ambiguity due to occlusion or resolution limits. Therefore, selecting an appropriate pass rate threshold is critical to balance sensitivity (Recall) and specificity (Precision).

Table 1: Sensitivity Analysis of Feature Emergence LOD Thresholds

Threshold	Self-Check (TP Rate)	Rejection (TN Rate)	Balance Score (TP+TN)
20%	99.2%	64.1%	1.63
40%	94.3%	85.3%	1.80 (Max)
60%	85.4%	93.5%	1.79
80%	65.9%	98.4%	1.64
100%	50.4%	98.9%	1.49

Table 1 presents the system's performance across pass rate thresholds ranging from 20% to 100%. The "Self-Check" score indicates the probability of a valid model passing its own standard, while the "Rejection" score indicates the probability of a lower-LOD model failing a higher standard.

The analysis reveals that the 40% threshold serves as the optimal operating point, maximizing the Balance Score (1.80). At this threshold, the system correctly identifies 94.3% of valid models while successfully rejecting 85.3% of invalid claims. Conversely, stricter thresholds (80-100%) caused a sharp decline in Recall (down to 50.4%), confirming that requiring a 100% feature match is impractical due to visual occlusion in 2D renders.

Consequently, this study adopts 40% as the standard threshold for the final comparative analysis.

Comparative Performance Analysis

Table 2 presents the ablation study results under the calibrated 40% threshold across four conditions: Vanilla MLLM (baseline), KG Only, Cluster IMG Only, and KG+Cluster IMG (proposed).

The Vanilla baseline exhibited a Recall of only 21.61% with 243 False Negatives, confirming that unstructured LOD descriptions cause the MLLM to default to negative predictions. Its Precision of 100% (zero FPs) reveals an extreme conservative bias rather than genuine accuracy.

Introducing semantic decomposition alone (KG Only) raised Recall to 51.61% by breaking abstract criteria into ~5.1 concrete inspection items, but plateaued at 67.34% accuracy due to insufficient visual resolution from a single overview image. Conversely, providing cluster images without structured criteria (Cluster IMG Only) yielded the worst performance (Recall: 17.74%), even below the baseline—demonstrating that detailed visual inputs without a semantic framework for interpretation lead to near-systematic rejection.

The proposed KG+Cluster IMG framework achieved the highest performance across all metrics (Accuracy: 83.47%, F1: 86.15%, Recall: 82.26%), confirming a complementary synergy: the Knowledge Graph provides what to inspect, while cluster images provide where to

Table 2: Performance Comparison between Baseline and Proposed Framework

Metric	Vanilla MLLM	KG Only	Cluster IMG Only	KG+Cluster IMG
Accuracy	51.01%	67.34%	48.19%	83.47%
F1 Score	35.54%	66.39%	29.97%	86.15%
Precision	100.00%	93.02%	96.49%	90.43%
Recall	21.61%	51.61%	17.74%	82.26%
True Positive (TP)	67	160	55	255
True Negative (TN)	186	174	184	159
False Positive (FP)	0	12	2	27
False Negative (FN)	243	150	255	55

inspect. Neither alone is sufficient, but their combination boosts Recall by 30.65 percentage points over KG Only.

The ablation results further reveal that FPs originate primarily from semantic decomposition rather than visual input: the KG-Only case produced 12 FPs, compared with only 2 for the Cluster-IMG-Only case. The combined framework yields 27 FPs, representing a favorable trade-off, as it recovers 188 TPs at a 1:7 TP-TP ratio. This balance is operationally desirable in engineering quality assurance, where undetected deficiencies (FN) pose substantially greater risk than over-acceptance (FP).

Overall, the F1 Score surged from 35.54% to 86.15%, signifying a qualitative leap from unusable baseline performance to engineering-deployable reliability. The ablation confirms that automated LOD verification requires both structured semantic criteria and spatially decomposed visual evidence.

Conclusion

This study addressed the critical challenges in automated BIM Quality Assurance—specifically the "Semantic Gap" arising from linguistic ambiguities in LOD specifications and the "Geometric Complexity" caused by fragmentation and occlusion in 3D models. To bridge these gaps, we proposed a novel hybrid assessment framework that integrates a Bridge knowledge graph with a Semantic Geometric Preprocessing pipeline, validated through a MLLM (Gemini 2.5 Pro).

The experimental results quantitatively demonstrate the superiority of the proposed "Deep Standards" approach over conventional text-based methods. By translating abstract human requirements into system-specific visual inspection items, our framework achieved an overall accuracy of 83.47%, marking a significant improvement of 32.46% compared to the baseline. Notably, the recall rate increased dramatically from 21.61% to 82.26%, proving that the integration of the knowledge graph effectively mitigates the issue of missing feature detection inherent in traditional approaches. A four-condition ablation study further revealed that neither semantic decomposition (KG Only: 67.34%) nor geometric preprocessing (Cluster IMG Only: 48.19%) alone achieves comparable performance—confirming that the two components exhibit a complementary synergy, where the knowledge graph provides "what to inspect" and cluster images provide "where to inspect." The sensitivity analysis further confirmed that a feature Emergence threshold of 40% offers the optimal balance between precision and recall, ensuring robust performance even with complex geometric variations.

The qualitative contribution of this research lies in its transition from "Black-box" AI to an "Explainable" verification system. Unlike purely vision-based deep learning models that require massive labeled datasets, our system generates traceable rationales by cross-referencing logical criteria with semantic visual evidence. The implementation of "Semantic Units"—reassembled from fragmented meshes and visualized through material-based layer separation—enables the MLLM to accurately identify internal components previously obscured by occlusion.

In conclusion, this framework successfully automates the translation of "Human Standards" into machine-interpretable "Deep Standards," providing a scalable and transparent solution for LOD verification. Future work will focus on expanding the dataset through systematic LOD augmentation—selectively adding or removing sub-components from existing high-fidelity families to generate boundary-condition models at each LOD transition—thereby enabling more rigorous evaluation of generalizability. Additionally, the "Visual Vocabulary" of the knowledge graph will be extended to cover a broader range of construction disciplines, and real-time inference speed will be optimized for large-scale infrastructure projects. This research paves the way for the next generation of intelligent BIM auditing tools, where domain knowledge and visual reasoning operate in synergy.

Abstract

Manual P&ID review is time-consuming, while existing image-based or hard-coded automation methods lack efficiency. We propose a hybrid framework that extracts P&ID data from DXF files and converts natural language rules into FOL-based Python verification modules. By restricting the LLM to code generation, the framework ensures deterministic rule verification via formal logic. Evaluated on four industrial drawings (140 objects, 587 checks), our approach achieves a 97.5% F1-score, compared to 55.9% for the image-based LLM baseline. This enables non-experts to automate design, conditional, and engineering rules, advancing QA in digital twin environments.

Introduction

Piping and Instrumentation Diagrams (P&IDs) are critical engineering documents in plant facility design, containing information on equipment, piping systems, instrumentation, and process flows. Quality assurance of P&IDs is essential for plant safety, operational efficiency, and compliance with industry standards. However, the current review process still relies heavily on experienced engineers who must manually cross-reference thousands of drawings against multiple design specifications. This process is labor-intensive and vulnerable to human errors, particularly when dealing with complex and project-specific design rules.

The recent emergence of Large Language Models (LLMs) has opened new possibilities for bridging the gap between natural language specifications and executable code. Yet the direct application of LLMs for P&ID verification raises serious concerns: hallucinations during inference and the non-deterministic nature of outputs pose significant risks in safety-critical engineering contexts where reproducibility and accuracy are required. These limitations highlight the need for a hybrid approach that leverages the flexibility of LLMs for code generation while delegating the actual verification to deterministic reasoning engines.

Existing approaches to automated P&ID quality assurance fall into three broad categories, each with notable limitations. Image-based methods using computer vision achieve high symbol recognition accuracy but cannot verify compliance with semantic design rules and are sensitive to drawing quality (Alimin et al., 2025; Kim et al., 2025). Rule-based systems provide deterministic validation but require substantial expert effort for rule encoding and lack flexibility when adapting to project-specific requirements (Balhorn et al., 2025). Machine learning approaches such as Transformer-based semantic analysis show promise on large datasets but raise concerns about interpretability and portability across heterogeneous engineering environments (Gómez-Vega et al., 2025). A detailed review of these studies is provided in Section 2.

To address these gaps, this study proposes an automated P&ID verification framework that combines DXF-based data extraction with First-Order Logic (FOL)-based rule verification, restricting the role of LLMs to code and parser generation rather than direct validation. The core contributions are as follows:

1) We present a hybrid verification framework that extracts engineering objects directly from DXF-format CAD files through layer analysis and pattern recognition and transforms natural language design rules into executable Python verification functions via FOL formalization and LLM-assisted code generation. By confining LLM involvement to the code generation phase, the framework ensures that safety-critical verification outcomes remain deterministic and reproducible.
2) We formalize nine categories of Annotation Rules (AR) and Basic Design Rules (BR) into FOL expressions that serve as unambiguous, machine-verifiable specifications. This neuro-symbolic approach enables users with limited coding expertise to modularize complex design rules without manual hard-coding.
3) We validate the framework on four industrial P&ID drawings comprising 140 engineering objects and 587 rule checks. The proposed approach achieves an overall extraction F1 of 97.5% with a 100% rule compliance pass rate, compared to 55.9% F1 for the image-based LLM baseline. Equipment and Line extraction maintain 100% F1 across all four drawings without parser modification, demonstrating generalization beyond a single test case.

Related Work

Rule-Based Verification Systems

Schulze Balhorn et al. (2025) proposed a systematic approach that converts P&IDs into DEXPI-based structured data or graph representations to detect design rule violations through explicit pattern matching. Their method demonstrated clear advantages in identifying specific violation patterns and maintaining compatibility with industry standards but requires substantial effort for rule definition and lacks flexibility in processing natural language specifications. Additionally, scalability is limited when adapting to diverse project requirements.

Machine Learning-Based Approaches

Gómez-Vega et al. (2025) introduced Smart P&ID, which extracts text and attribute data from databases and CSV files, and transforms piping information into token sequences processed by Transformer-based models such as DistilBERT. Their approach showed high accuracy in detecting semantic inconsistencies in large datasets and demonstrated promising adaptability to rule changes. The proposed method faces challenges in interoperability and portability to other engineering environments, as it is heavily dependent on specific Smart PID data structures and does not fully account for legacy CAD systems or image-oriented PDF formats commonly used in the field.

Image-Based Detection Methods

Alimin et al. (2025) employed computer vision techniques including YOLO, Faster R-CNN, and SIFT/ORB algorithms for symbol detection and geometric verification in P&IDs. While achieving over 90% recognition accuracy in symbol identification, these methods are limited to detecting visual inconsistencies and cannot verify compliance with semantic design rules. Furthermore, the performance of these approaches is highly sensitive to image quality and resolution, limiting their applicability in real-world scenarios where drawing formats and quality vary. Beyond these three categories, Additional related work in DEXPI-based interoperability, graph-based P&ID analysis, and digital twin-integrated validation will be addressed in the journal extension of this study.

Methodology

This study develops an automated rule verification system for P&ID drawings through a two-phase approach. First, we conduct a comparative test to evaluate data extraction performance between image-based LLM approaches and DXF-based direct parsing. Second, based on the extraction results, we implement a FOL-based rule verification framework that transforms natural language design specifications into executable verification modules. This section describes experimental design, data extraction methodologies, and rule verification architecture.

Rule Set Composition

P&ID design review rules can be categorized as follows:

- Annotation Rules (AR): Rules related to notation and compliance with international standards.
- Basic Design Rules (BR): Rules related to the presence of essential design information.
- Conditional Rules (CR): Rules related to conditional design requirements.
- Design Rules (DR): Rules related to compound design principles.
- Engineering Rule (ER): Rules related to engineering logic and calculations.

These rules verify the presence or absence of required information elements and check basic formatting compliance, without involving complex conditional logic, engineering calculations, or cross-drawing relationships. Since this study focuses on establishing baseline extraction and verification capabilities for AR and BR rules, selecting a drawing that comprehensively tests these rule categories provides the most robust validation of the proposed framework's fundamental capabilities.

For the test, nine design rules were implemented from a total of eleven rules defined across the AR and BR categories, excluding rules that involve inter-rule dependencies. The AR rules (AR-1 to AR-5) verify drawing number uniqueness, entity identification schemes, pipe nominal diameter, pipe number, and material class. The BR rules (BR-1 to BR-4) verify name,

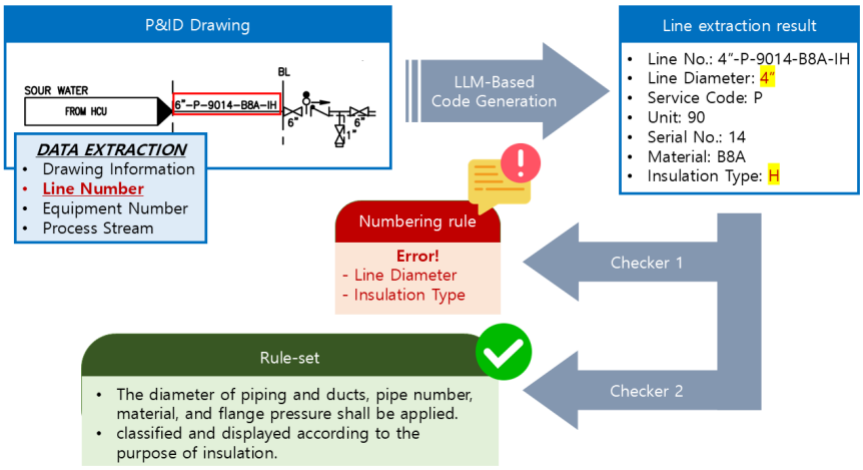

Figure 1. P&ID Compliance Checking via LLM-based Code Generation Framework

specification, type, and references to connected drawings (Table 1).

Table 1. Selected AR and BR rules

Class	Code	No.	Keyword
Annotation	AR	01	Drawing Number
	AR	02	Object ID
	AR	03	Line Diameter
	AR	04	Line Number
	AR	05	Line Material
	AR	06	Valve Failure mode
Basic Design	BR	01	Equipment ID
	BR	02	Equipment Spec.
	BR	03	Equipment Type
	BR	04	Process Flow
	BR	05	Manhole/Tray

These nine rules are applied to all extracted entities, including equipment, piping, instruments, and connected drawings.

Ground truth annotations were manually created. All equipment tags, line numbers, service codes, material classes, and instrumentation tags were extracted and cross-verified against the original design specification documents. Each extracted item is classified as True Positive (TP), False Positive (FP), or False Negative (FN) against the ground truth. Precision, Recall, and F1 Score are computed per category and macro-averaged across categories. These metrics are employed not as machine learning performance indicators but as standard information retrieval measures to quantify extraction completeness and correctness under a unified evaluation framework for both approaches.

P&ID Drawing

Seven P&ID drawings from an industrial Sour Water Stripper unit (A39002-500-A 101 through A107) were available for this study. Drawings A101–A103 are Symbol & Legend sheets defining project-wide naming conventions and serve as the reference for numbering rule verification. The remaining four drawings (A104–A107) are P&IDs, each containing equipment, piping lines, and process stream information subject to AR and BR rules (Table 2).

Table 2. Reviewable rules in each P&ID drawing

P&ID No.	Class	Adaptable Rules
A39002-500-A 101	Standard	1
A39002-500-A 102	Standard	1
A39002-500-A 103	Standard	1
A39002-500-A 104	Drawing	11
A39002-500-A 105	Drawing	9
A39002-500-A 106	Drawing	10
A39002-500-A 107	Drawing	11

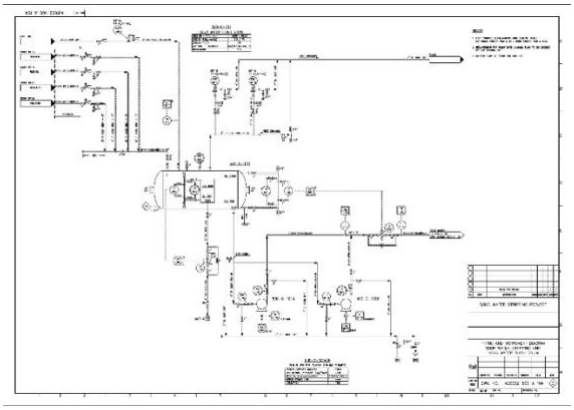

Figure 2. A39002-500-A 104 P&ID drawing

Among these, Drawing A104 (Sour Water Flash Drum) was obtained in both PDF and DXF formats to enable a fair comparison between the image-based LLM extraction (Approach A) and DXF-based parsing (Approach B). Drawings A105–A107 were obtained in DXF format only and were used together with A104 to evaluate the generalization of the proposed framework across drawings of varying complexity. The four P&IDs collectively contain 180 items

Table 3. Test data summary across four drawings

P&ID No.	Drawing Info	Equipment	Lines	Process Streams	Total
104	10	2	26	7	45
105	10	3	19	5	37
106	10	4	22	6	42
107	10	5	34	7	56
Total	40	14	101	25	180

Experiments

Approach A: Image-based LLM Extraction

The first approach utilizes a LLM equipped with vision-language capabilities to directly extract design information from P&ID drawings rendered as PDF images. This approach represents the prevalent image-based LLM methodology in recent automated P&ID interpretation research and serves as the baseline for comparing the performance of the proposed DXF-based automated review framework.

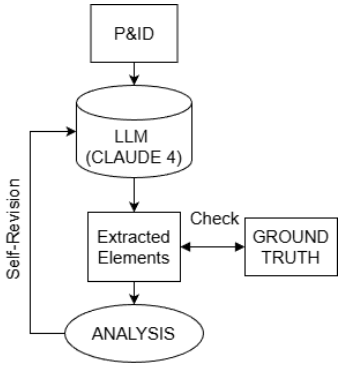

Figure 3. The flow of Image-based LLM Extraction

In this methodology (Figure 3), P&ID drawings are converted into high-resolution images and used as the primary input. Without the aid of dedicated CAD parsing or rule-based engines, the model simultaneously performs text and symbol recognition to extract engineering data, such as equipment, piping, and instrumentation. The interpretation relies solely on the model's visual reasoning and internal domain knowledge. To ensure structured outputs, a specific prompt restricts the response format to JSON, explicitly defining key data fields—including drawing numbers, equipment tags, and piping specifications—required for Annotation Review (AR) and Basic Review (BR).

Claude Sonnet 4.5 (Anthropic, 2025) was employed for this extraction task as a widely accessible vision-enabled LLM. The Opus model was excluded due to prohibitive token costs and significantly slower inference speeds for large image inputs. Since Approach A aims to establish a representative baseline rather than to maximize LLM performance, Sonnet 4.5 was deemed sufficient for this purpose. The model processes the drawing image and a structured prompt concurrently to return engineering data in a predefined JSON schema. The extracted data are then evaluated against the ground truth for a quantitative comparison with the proposed method.

However, this approach possesses inherent structural limitations. Since drawing legends cannot be explicitly fixed as external knowledge, consistency in symbol interpretation is not guaranteed. Furthermore, it lacks the capability to verify complex logical structures, such as Conditional Rules (CR) or Detailed Design Rules (DR). Most notably, the occurrence of hallucinations during the inference process and the non-deterministic nature of the outputs pose significant challenges for safety-critical design reviews that demand high reliability. By establishing Approach A as a baseline, this study aims to highlight these deficiencies and demonstrate the superior reliability of the proposed DXF-based framework utilizing FOL.

Approach B: DXF-Based Direct Parsing

The second approach leverages the original CAD file format (DXF) to extract engineering information directly from vector data without image conversion (Figure 4).

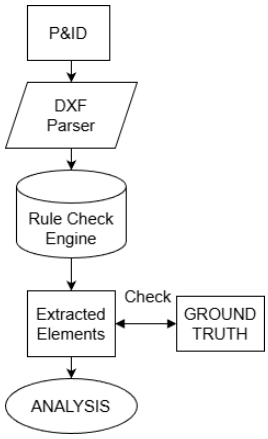

Figure 4. DXF-based data extraction pipeline

The DXF-based extraction approach offers several critical advantages over conventional image-based methods in terms of data integrity and analytical precision. By eliminating degradation from image conversion and vision interpretation errors, this method ensures lossless information preservation and facilitates spatial relationship analysis. Furthermore, it allows for direct access to the CAD organizational structure, including layer-based filtering, block definitions, and embedded metadata, thereby enhancing attribute richness. Beyond its technical accuracy, the DXF approach is highly scalable as processing time remains independent of image resolution. Most importantly, it yields deterministic results, ensuring reproducible extraction without the stochastic variation typically associated with image-based processing.

The role of LLMs in the framework is strictly limited to code and parser generation, not direct rule verification. This architectural choice mitigates hallucination risks while leveraging LLM flexibility.

The DXF-based data extraction process is structured into three distinct stages to ensure high fidelity and structural integrity.

- Stage 1: Entity Parsing. The ezdxf library for Python is employed to parse the DXF file, extracting all text-bearing entities while preserving their original Cartesian coordinates and layer associations. This stage captures raw textual content directly from the CAD environment without information loss.
- Stage 2: Pattern-Based Classification. Extracted text elements are categorized using domain-specific regular expressions derived from project-specific naming conventions formulated in accordance with identification of equipment tags, line numbers, and other standardized engineering identifiers.
- Stage 3: Coordinate-Based Attribute Association. Spatial analysis links equipment tags with their corresponding specifications through a deterministic search algorithm operating within a defined radius (default: 150 DXF units) around each identified tag. To ensure association accuracy, invalid patterns—including instrument tags, specification table headers, and control keywords—are filtered through rigorous exclusion rules. This mitigates data misinterpretation risks arising from spatial proximity of unrelated elements.

The verification engine consists of two checking modules.

Checker 1(Numbering Rules) verifies the formal integrity of the extracted information based on the numbering scheme defined in the Symbol & Legend sheet (A39002-500-A 101-103) of the P&ID drawing (Figure 5).

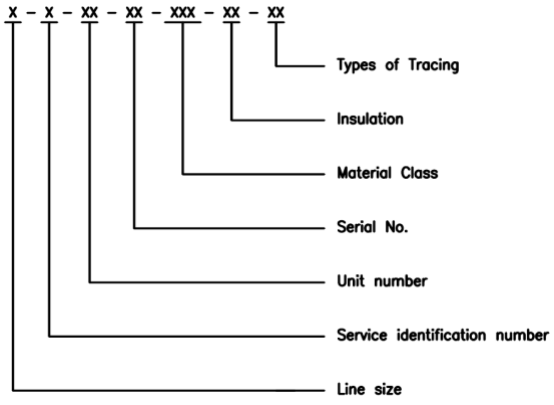

Figure 5. Line Identification

Checker 2 (AR & BR): This module examines whether mandatory information required by each rule is present and evaluates attribute completeness. Inspired by (Pan et al. 2023) neuro-symbolic framework, we adopt a similar three-stage paradigm—formulation, reasoning, interpretation—but adapt it specifically for P&ID verification. To establish unambiguous verification criteria, design rules are formalized using FOL.

FOL is essential for P&ID rule verification for three reasons. First, it eliminates ambiguity in natural language rules through precise semantic expression. For instance, the vague statement "Appropriate insulation shall be used for high-temperature piping." becomes:

$\forall x\,(\text{Pipe}(x) \wedge \text{HighTemperature}(x) \geq 65 \rightarrow \text{Insulated}(x)$.

Second, FOL systematically represents complex conditional rules and nested logical structures, enabling integration of multi-condition design rules (e.g., rules involving operating pressure, temperature, material, and fluid properties) into unified logical expressions. Third, formally expressed rules enable mechanical verification through automated theorem provers or model checkers, allowing pre-validation of logical consistency and conflict detection among rules.

Experimental Result

LLM Extraction Method Performance

To maximize extraction performance, the methodology underwent three iterations with progressive improvements:

Table 4. F1 Score Comparison by Data Categories

Category`	Test 1	Test 2	Test 3
Drawing info	100%	100%	100%
Equipment	100%	100%	100%
Lines	48%	48%	48%
Process streams	71.4%	71.4%	71.4%
Overall	55.9%	55.9%	55.9%

Table 5. Iterative Refinement Process

Class	Revision Detail	Result
Iteration 1 (Baseline)	Direct extraction using the base prompt without post-processing.	F1 55.88
Iteration 2 (Post processing)	Applied automated post-processing includes text normalization and format verification against P&ID naming conventions.	F1 55.88
Iteration 3 (Error Pattern Correction)	Analyzed common error patterns from previous iterations and incorporated specific correction rules including size extraction, service code verification, and missing entity detection.	F1 55.88

The image-based approach demonstrated several systematic failures:

1. Text recognition errors: Misrecognition of characters in low-contrast regions

2. Spatial relationship inference: Difficulty in correctly associating spatially disconnected text elements with their corresponding equipment or piping symbols, leading to attribute misassignment.

3. Overlapping element confusion: Inability to disambiguate text when overlapping with graphical symbols, leader lines, or dense annotations, resulting in incomplete or erroneous extraction.

4. Implicit attribute loss: Failure to extract attributes not explicitly labeled in text form, such as connection relationships inferred from line continuity or material specifications derived from line style conventions.

These limitations align with fundamental challenges of image-based approaches documented in prior studies (Alimin et al., 2025), demonstrating the inherent trade-offs between vision model flexibility and extraction reliability.

DXF-based Method Performance

The proposed DXF-based extraction and rule verification pipeline was applied to all four process drawings (A104–A107). Table.6 presents the extraction accuracy compared with the ground truth across 180 items. Drawing Info, Equipment, and Lines achieved 100% F1 across all four drawings. The three unmatched items occurred exclusively in A107 Process Streams, where F1 dropped to 53.3% (Precision 50.0%, Recall 57.1%), while A104–A106 maintained 100% in all categories.

Table 6. Extraction accuracy compared with Ground Truth

Category	Ground Truth	Extracted	Matched	F1
Drawing Info	40	40	40	100%
Equipment	14	14	14	100%
Lines	101	101	101	100%
Process streams	25	26	22	86.3%
Total	180	181	177	97.5%

Error analysis of A107 Streams identified 4 true positives, 4 false positives, and 3 false negatives. All errors originated from streams lacking explicit FROM/TO boundary markers in the DXF source: (1) anchor text absence preventing stream detection (1 case), (2) label-boundary mismatching causing line number misreading or false extraction (2 cases), and (3) incorrect direction assignment due to ambiguous spatial layout (1 case). These are inherent limitations of text-based spatial matching, not parser logic defects.

Table 7 presents the rule verification results. Checker 1 performed 119 numbering-format checks and Checker 2 conducted 468 AR/BR rule checks; all 587 items passed with zero errors. Thirteen warnings were issued for material class codes not registered in the rule-set list and missing equipment attributes in the DXF source. These warnings indicate incomplete source data rather than rule violations and therefore do not affect the pass/fail determination.

Table 7. AR/BR rule verification results across four drawings

Rule	Keyword	Checked Items	Warning
AR-1	Drawing Number	4 Drawings	0
AR-2	Object ID	140 IDs	0
AR-3	Line Diameter	101 Lines	0
AR-4	Line Number	101 Lines	0
AR-5	Line Material	101 Lines	10
BR-1	Equipment ID	14 Equipment	0
BR-2	Equipment Spec.	14 Equipment	2
BR-3	Equipment Type	14 Equipment	1
BR-4	Process Flow	25 connections	0

The AR rules (AR-1 to AR-5) verify formal integrity of drawing numbers, entity identification schemes, and piping attributes including nominal diameter, line number format, and material class. The BR rules (BR-1 to BR-4) validate the completeness of equipment information and process flow references to connected drawings. All nine rules passed across the four drawings, confirming compliance with the project naming conventions defined in the Symbol & Legend sheets (A39002-500-A 101–103).

Analysis of LLM Extraction vs. DXF parsing

In the context of P&ID information extraction, LLM–based approach demonstrated effectiveness in identifying textual elements and equipment tags within drawings. However, several structural limitations were observed in the extraction of piping and process-related data. First, due to the nature of image-based inputs, text misdetection and information loss occurred depending on drawing resolution and visual noise. In addition, probabilistic inference during numerical data extraction introduced the possibility of incorrect outputs. Furthermore, frequent false detections were observed when spatially adjacent elements visually interfered with each other, resulting in mixed or conflated data. These issues can be attributed to the inherent sensitivity of vision-based algorithms and probabilistic models to complex physical layouts and visual variability within engineering drawings.

- Data Integrity: By eliminating image conversion, information loss and visual interpretation errors are fundamentally avoided.
- Geometric Precision: Direct utilization of numerical coordinate data enables sub-millimeter–level accuracy in spatial relationship analysis.
- Structural Accessibility: CAD-native metadata, including layer hierarchies, block definitions, and line types, allows for explicit identification of semantic relationships among design elements.
- Computational Efficiency and Reliability: The approach maintains consistent processing performance independent of image resolution and guarantees reproducibility through deterministic, non-probabilistic outcomes.

Nevertheless, the DXF-based approach has its own limitations. When explicit boundary markers such as FROM/TO anchor texts are absent from the source drawing, the coordinate-based stream detection relies on spatial heuristics that can misidentify stream boundaries or flow directions. This was observed in A107 Process Streams, where the absence of boundary markers led to line number misreading, false extraction, and direction assignment errors, resulting in an F1 of 53.3%. These errors are inherent to text-based spatial matching rather than defects in the parser logic, and they define the current boundary condition of the framework.

Consequently, for design rule checking in plant engineering where high reliability and strict reproducibility are critical, the DXF-based structural approach is considered to provide a more stable and trustworthy data processing foundation than an LLM-only model. Table 8 presents this comparison: on the same drawing (A104), Approach B achieved 100% F1 across all categories, whereas Approach A reached 55.9%. When Approach B was extended to four drawings without parser modification, Overall F1 remained at 97.5%, with the reduction attributable solely to process stream detection in A107.

Table 8. Performance and iteration comparison table to match ground truth

Class	Approach A (LLM)	Approach B (Code)	
Drawing	A104	A104	A104-107
Input Data	PDF	DXF	
Method	Vision LLM	DXF Parsing	
Iteration	3	1	
Drawing info F1	100%	100%	100%
Equipment F1	100%	100%	100%
Line F1	48%	100%	100%
Process F1	71.4%	100%	86.3%
Overall F1	55.9%	100%	97.5%

Discussion

The experimental results demonstrate that the proposed framework achieves high accuracy in extracting Equipment and Line information from DXF-format P&ID drawings, successfully passing all 587 design rule checks across four test drawings containing 140 engineering objects. Notably, the parser and rule engine developed for A104 were applied to A105–A107 without modification, and Equipment and Lines maintained 100% F1 across all drawings. This provides evidence that the DXF parsing algorithm and FOL-based rule verification engine can generalize effectively across real-world plant engineering drawings of varying complexity. By structuring high-level and complex rules from the P&ID rule definition document into formal logic (FOL), the proposed approach mitigates the hallucination issues frequently observed in standalone LLM-based methods and enables deterministic and reproducible verification results.

When LLMs were applied independently, they exhibited strong reasoning capabilities but failed to provide reliable verification outcomes due to persistent hallucination problems. In the plant engineering domain, where design quality is directly linked to safety incidents, probabilistic models alone are insufficient to guarantee the level of accuracy and consistency required for design verification. Notably, AR and BR rules that could not be reliably validated by standalone LLMs were verified with high accuracy through the proposed framework, which combines LLM-based code generation with symbolic logic verification. This result highlights the practical effectiveness of the proposed approach.

Compared to traditional manual drawing review processes, the proposed automated data extraction and rule verification system significantly reduces review time and effectively minimizes the risk of human error. By integrating the flexibility of LLM-based code generation with the deterministic reliability of formal logic-based verification, the proposed approach overcomes key limitations of existing automated P&ID quality verification studies.

The proposed framework addresses LLM hallucination issues through a carefully designed separation of concerns. LLMs are restricted to two specific roles: (1) transforming natural language rule specifications into structured FOL representations, and (2) generating Python verification code from these formal logic structures. The actual verification process is performed entirely by deterministic symbolic reasoning engines, eliminating the probabilistic uncertainty inherent in direct LLM-based verification. This architectural design ensures that while the system benefits from LLM flexibility in code generation, the safety-critical verification outcomes remain reproducible and deterministic.

However, the framework's current boundary condition was revealed in A107 Process Streams, where F1 dropped to 53.3%. All errors occurred in streams lacking explicit FROM/TO boundary markers, indicating that the coordinate-based spatial matching is sensitive to the completeness of anchor text in the source DXF. This limitation does not affect Equipment or Line extraction, which rely on self-contained tag patterns, but it suggests that process stream detection requires either enhanced spatial heuristics or supplementary metadata to achieve robustness comparable to other categories.

Conclusions

This study proposes an automated data extraction and design rule compliance verification system for P&ID drawings in the plant engineering domain. The proposed system parses DXF-format P&ID drawings to extract engineering objects such as Equipment, Lines, and Instruments as structured data and automatically verify compliance with design standards using FOL-based rule engine. Experimental validation on four P&ID drawings containing 140 engineering objects demonstrates that the system achieves 100% F1 for Equipment and Line extraction and 97.5% Overall F1 and successfully performs exhaustive verification of 587 design rule checks across nine categories of AR and BR rules.

The main contributions of this research are as follows. First, a DXF-based P&ID parsing algorithm was developed to automatically extract engineering objects through layer structure analysis and text pattern recognition. Second, an FOL-based rule verification engine was implemented to formally represent plant design standards and perform systematic compliance verification. Third, an end-to-end automation pipeline was established that integrates drawing input, data extraction, rule verification, and result report generation, thereby substantially reducing the manual review burden on design engineers.

This study acknowledges several limitations that warrant further investigation. First, although validation was extended to four P&ID drawings comprising 140 engineering objects, all drawings originate from a single industrial project, which limits conclusions about generalization performance across diverse projects, drawing conventions, and industrial contexts. Second, the current implementation addresses nine categories of AR and BR rules, whereas real-world projects require more

comprehensive coverage including equipment-specific requirements (e.g., manhole and tray installation specifications) and failure mode documentation standards. Future research will address these limitations through a phased approach:

- **Immediate Extension**: The scope of validation will be expanded to various industrial plant types, including petrochemical and power generation, and water treatment facilities. By securing real-world project drawings, the research will broaden the application of AR and BR rules to verify the system's generalization performance and derive industry-specific adaptation requirements.
- **Medium-term Goals**: Technical capabilities will be developed to support CRs, DRs and ERs. This involves advancing context-aware verification logic based on FOL expressions, integrating domain-specific calculation engines for pressure drop and heat balance verification, and establishing a cross-drawing consistency-checking mechanism.
- **Long-term Vision**: Achieving Digital Twin integration with real-time verification capabilities. This encompasses developing bidirectional synchronization between P&ID models and Digital Twin platforms, implementing continuous quality assurance during design iterations, and establishing automated compliance reporting aligned with international standards (ISO, ASME, API).

This study demonstrates the practical feasibility of automated P&ID quality verification in plant engineering contexts. The successful validation of AR and BR rules on industrial drawings, combined with the framework's user-centric design that enables non-programmers to define rules in natural language, suggests significant potential for industry adoption.

However, successful deployment in engineering organizations will require addressing several practical considerations: (1) integration with existing CAD workflows and document management systems, (2) establishment of verification protocols for LLM-generated code before production use, and (3) development of user training programs for effective rule specification and result interpretation.

Despite these implementation challenges, the adoption of automated verification systems is expected to deliver substantial benefits including reduced design review time (potentially 50-70% reduction based on pilot testing), improved consistency in rule application, and prevention of human errors in repetitive checking tasks. These improvements directly contribute to enhanced safety outcomes and economic efficiency in plant engineering projects, while freeing experienced engineers to focus on high-level design decisions and complex problem-solving activities.

In the future, this study lays the foundation for extending beyond single-project verification to automated quality assurance encompassing CRs, DRs and ERs. This extension will contribute to comprehensive quality assurance automation within digital twin environments, supporting broader digital transformation initiatives in plant engineering and operations.

Abstract

Artificial Intelligence (AI) is assuming a central role in the AECO industry, supporting automation, workflow optimization, and decision-making. Despite rapid technological advances, the use of AI in design practice remains underexplored, particularly regarding the sociotechnical dynamics that favor or hinder its adoption within BIM processes. This study introduces Actor-Network Theory (ANT) to the field of BIM-AI research, focusing on design firms. The goal is to develop an ANT-based method to guide researchers in analyzing how actor networks can be mobilized to support the implementation of AI in BIM design workflows.

Introduction

In recent years, Building Information Modeling (BIM) has become a central component of information management in the construction sector, supported by increasingly sophisticated software technologies (Eastman et al., 2008). Understanding how AI may influence BIM processes requires examining the technological maturity of design firms and their ability to select, integrate, and coordinate heterogeneous digital tools. In particular, mapping internal information flows is essential for assessing how new technologies modify or optimize the circulation of data across departments, operational staff, clients, and external consultants (Cavka et al., 2015). Although the literature recognizes the strategic importance of BIM, its effectiveness depends on the clear definition of project objectives and BIM uses, which guide responsibilities and workflow organization (Raj et al., 2025). At the same time, organizational change is shaped by external environmental, economic, and policy conditions (Pettigrew, 1987), and the availability of standards, protocols, and best practices remains a key enabler of BIM implementation (Hochscheid & Halin, 2018), supporting more advanced environmental and performance analyses (Alnaser et al., 2024). AI tools encompass a broad domain of techniques dedicated to automation, with machine learning (ML) and deep learning (DL) representing the most widely adopted approaches (Alves et al., 2025). Despite their potential, the effective integration of AI in the AEC sector depends on professionals' perceptions, competencies, and attitudes (Albukhari et al., 2025). As highlighted in a recent AIA report (2024), AI is now used across a wide spectrum of activities - from chatbots supporting operational tasks to the generation of visual content in early design phases (Xu et al., 2024), as well as linguistic analysis, text revision, and automated transcription of meetings and workplace communications. AI therefore influences both the technological dimension and the organizational processes of design firms (Wang et al., 2025), making it essential to identify the factors that enable or hinder its adoption. Despite growing interest in AI applied to BIM, the existing literature remains fragmented. Current studies tend to focus on specific applications (Al-Muntaser et al., 2024), project-based case studies (Attia, 2025), perceived risks (Bolpagni et al., 2021), or benefits (Chen et al., 2024; Alves et al., 2025; Albukhari, 2025). However, a qualitative sociotechnical perspective capable of systematically examining the drivers of BIM-AI integration - and how these are translated into professional practice - has not yet been developed. In particular, a holistic framework that guides researchers in studying the BIM-AI domain is still lacking. Actor-Network Theory (ANT) offers a promising lens for addressing this gap. ANT conceptualizes both "non-human" actors (artefacts, processes, standards, regulations) and "human" actors (roles, professionals, institutions) as entities capable of shaping action within a network (Latour, 2005). This perspective enables researchers to examine how technology implementation is translated and adapted within specific institutional, organizational, or project contexts. Previous studies have applied ANT to analyze BIM maturity development (Edirisinghe, 2021), planning practices (Rydin, 2013), BIM implementation in large organizations (Lindblad & Vass, 2015), municipal land-allocation processes involving BIM, GIS, and Digital Twins (Hamarashid, 2021), sustainability certification networks (Frank et al., 2022), and collaboration in industrialized housing (London & Pablo, 2017). Yet, despite these contributions, the perspective of design firms - particularly regarding the integration of AI into everyday BIM-based practice - remains underexplored. This study addresses this gap by investigating and systematizing the key components influencing the integration of AI into BIM processes in design firms. By adopting a structured methodology, the research aims to clarify how technological, organizational, and environmental conditions shape AI

adoption. More specifically, the literature review conducted in this study seeks to: (1) identify existing frameworks for BIM implementation; (2) examine current applications of AI in design; (3) extract the key factors relevant to design firms; and (4) develop an ANT-based diagram to guide future data collection and analysis.

Methodology

This paper presents the initial phase of a broader research project that investigates BIM-AI implementation in design firms from a comparative international perspective. The study is structured into two sequential phases. The first phase - reported in this article - consists of a systematic literature review aimed at identifying existing frameworks, methodological approaches, and thematic areas relevant to BIM-AI integration. Guided by this objective, the present contribution addresses two research questions:

How is BIM implementation conceptualized within design firms?

What are the key components for evaluating BIM-AI implementation in design?

To answer these questions, the study adopts a qualitative methodology grounded in a structured literature review articulated into four phases (Figure 1). The first phase involved planning and defining the review protocol, including research questions, keywords, and inclusion criteria:

- Types: articles and conference papers;
- Period: 2010-2025;
- Language: English;
- Open access;
- Keywords: Table 1.

Table 1: Keywords used in the literature reviews

"BIM implementation" OR "BIM adoption"	AND	"design firm" OR "design firms" OR "design organization" OR "design organizations" OR "SME"
"AI implementation" OR "AI adoption"	AND	"design firm" OR "design firms" OR "design organization" OR "design organizations" OR "SME"

Applying these criteria, 132 documents were initially identified. After screening for relevance, 18 publications focusing on BIM implementation in design firms and 23 addressing AI in design were selected for in-depth analysis. The subsequent sections examine the research methods and thematic areas emerging from these studies. Based on this analysis, the factors related to AI within BIM-based design processes are extracted, categorized, and used to support the construction of the actor-network that informs the ANT-based framework proposed in this research.

Figure 1: Synthesis of methodology

BIM implementation in design firms

BIM implementation is commonly defined as the set of organizational activities undertaken to prepare for, initiate, or enhance digital deliverables and related workflows (Succar & Kassem, 2015). As a consolidated methodology and a driver of innovation in the construction sector (Eastman et al., 2008), BIM has become a central component of contemporary design practice. However, its interpretation and application remain highly heterogeneous across countries and even among firms operating within the same market (El Masry & Chronéer, 2025). The reviewed studies confirm this variability, showing that BIM implementation in design firms has been examined through a wide range of methodological approaches (Table 2). A substantial portion of the literature adopts survey-based methods to assess readiness, perceived benefits, barriers, and organizational needs. Examples include studies on BIM usage in Hong Kong (Chan, 2014), BIM adoption in Indian architectural firms using the TOE framework (Ahuja et al., 2016), BIM-Lean integration and standardization practices (Bolpagni et al., 2017), knowledge and skills gaps (Abd Hamid et al., 2020), maturity factors in Italian firms (Troiani et al., 2020), and barriers and benefits in Algerian practices (Tehami & Seddiki, 2023). Large-scale surveys, such as Wang et al. (2022), extend this perspective by examining national trends and regulatory pressures through TOE, DOI, and time-series analyses involving over one thousand Chinese firms. Sadeh et al. (2021) further show how MSMEs perceive BIM benefits across operational and informational dimensions while facing persistent constraints related to expertise and interoperability. Other contributions adopt mixed-methods or qualitative approaches to explore organizational dynamics in greater depth. Liu et al. (2020) combine questionnaires and interviews to investigate micro-level BIM implementation in UK design firms, while Tong et al. (2021) develop an organizational readiness framework integrating the MIT90s model and BIM maturity literature. Action Research (AR) is used to examine BIM as an organizational transformation process, as in Arayici et al. (2011) for an architectural SME and in Hochscheid & Halin (2020) for French architecture firms. Additional studies explore collaboration between BIM and Lean experts (Davoudabadi et al., 2022), obstacles to BIM implementation in Middle Eastern contexts using Grounded Theory (Altassan et al., 2023), and multi-level workflow analysis through process mapping and Social Network Analysis (Bonanomi, 2019). Taken together, these contributions show that BIM implementation in design firms is not a uniform or linear process but a complex organizational transformation, typically examined in the early and intermediate stages of digital transition. The literature increasingly recognizes the value of socio-technical perspectives, often supported by mixed methods (Figure 2), to understand the interplay between practices, technologies, and organizational structures. Within this context, the introduction of Actor-Network Theory (ANT) represents an innovative and still

underexplored contribution, offering a framework capable of capturing the heterogeneous networks of human and non-human actors that shape BIM implementation in design firms.

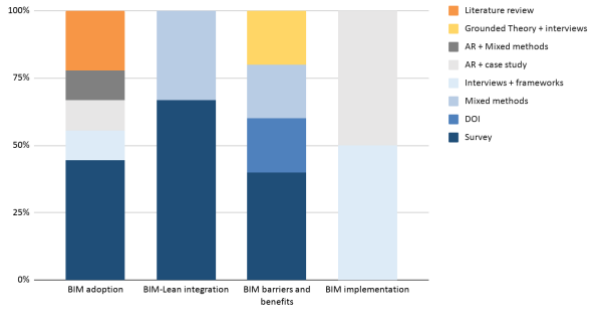

Figure 2: Thematic areas identified across the selected studies

AI application in design

The rapid growth of interest in AI-based solutions in recent years is largely driven by the widespread availability of tools such as ChatGPT, Claude, and Gemini, which have popularized AI among a broad audience despite being primarily individual, user-oriented systems. In contrast, organizations require AI solutions capable of operating within structured workflows, supporting collaborative environments, and integrating with existing information systems. Ma et al. (2025) highlight three organizational conditions that strongly influence AI adoption: collaboration with advanced technology providers, internal R&D capabilities, and continuous staff training. Similarly, Aiudi et al. (2025) show that AI reshapes SMEs' strategic decision-making by increasing decision speed and formalization, although financial, technical, and cultural constraints still limit full integration. These findings indicate that effective AI implementation requires formalized workflows, clear access and usage permissions, alignment with organizational objectives, appropriate technical enablers, human-centered considerations, and external support structures (Proietti, 2025). Within the design domain, AI is progressively shifting practice from intuition-based decision-making toward data-driven and performance-oriented processes. Applications include spatial planning, parametric modeling, generative design, and performance-based analysis, enabling designers to explore broader solution spaces while simultaneously addressing functional, structural, and environmental constraints (Albukhari, 2025). Recent studies highlight the growing influence of generative AI in early design phases, where it supports concept exploration, layout generation, and the rapid production of multiple alternatives, accelerating the translation of project requirements, site conditions, and user intentions into visual and formal proposals (Jang et al., 2025). BIM-based datasets provide a structured foundation for machine learning and deep learning models, supporting applications ranging from facility management and sustainability assessment to energy optimization, cost prediction, Heritage BIM, object-based modeling, and generative design (Alves et al., 2025). Empirical studies confirm this trend: AI-enabled BIM environments can assist designers in evaluating radiation exposure, sun hours, shadow performance, LEED-related indicators, and energy consumption at early stages (Al-Muntaser & Ashur, 2024). Despite these advancements, AI applications remain unevenly distributed across design phases, with design development and construction documentation still comparatively underexplored (Jang et al., 2025). This diversification of AI applications is illustrated in Figure 3, which synthesizes the breadth of AI research across the AEC and design domains in selected studies. The largest segments correspond to consolidated areas such as AI for decision-making and management, AI-BIM for performance simulation, and generative design workflows, confirming the centrality of AI in supporting analytical and early-stage design tasks. Other segments represent emerging or specialized domains - including bio-inspired computational design, knowledge-driven generative modeling - indicating a progressive expansion of AI beyond purely technical tasks toward cognitive, pedagogical, and biomimetic applications. The presence of categories such as AI for construction processes, computer vision for the built environment, and AI for BIM lifecycle management demonstrates that AI is increasingly being applied across the entire project lifecycle.

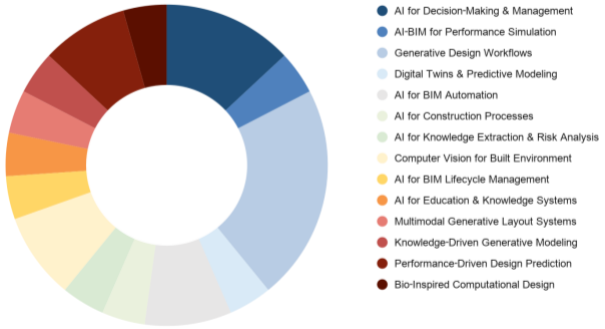

Figure 3: AI Application in design in selected studies

BIM-AI key factors

To compare how the selected studies address the factors influencing BIM-AI implementation, each publication was coded using a four-level scale reflecting the degree of thematic relevance: primary focus (3), substantially discussed (2), mentioned (1), and not addressed (0). This coding system enables a comparative reading of the literature by showing not only whether a theme appears, but also the extent to which it is developed within each study. Figure 4 synthesizes these results, illustrating the relative prominence of the key factors across the corpus and highlighting the thematic patterns that characterize current research on BIM-AI integration in design firms.Technology stands out as the most emphasized factor, with the highest proportion of "Primary" coding (60%), confirming that technological readiness - particularly in terms of tools, systems, and digital infrastructures - remains the dominant concern in the literature. Closely related factors such as interoperability-compatibility- complexity and information management also receive high levels of attention, reflecting persistent challenges associated with fragmented digital ecosystems, inconsistent modelling practices, and limited standardization. In the context of AI, these technological constraints become even more critical, as AI-enabled processes depend on structured, accessible, and high-quality data. Organizational factors display a similarly strong presence. Roles and expertise, training, and top management commitment register substantial levels of primary and secondary coding, indicating that human capital, leadership, and internal capability-building are consistently recognized as essential enablers of digital transformation. These findings align with prior research showing that BIM adoption - and, by extension, BIM-AI integration- depends heavily on organizational vision, staff competencies, and structured change management processes. In contrast, market-related factors such as client demand, standards and policies, and market pressure appear with more variability. Their uneven distribution suggests that external influences on BIM-AI adoption differ significantly depending on national regulatory environments, procurement cultures, and the maturity of the surrounding ecosystem. Nonetheless, when these factors are addressed, they emerge as decisive drivers - particularly in contexts where mandates, standards, or procurement requirements act as catalysts for digital transformation. Project-related factors, including project delivery systems, lean principles, and process and project management, appear less frequently in the literature. Their lower coding values highlight a gap in current research, despite the fact that contractual structures, coordination routines, and project governance models can significantly influence how digital tools are mobilized within project networks. Similarly, pilot projects and external partners show the lowest levels of primary coding, indicating that empirical experimentation and inter-organizational collaboration remain underexplored dimensions of BIM-AI research.

Table 3: Coding scale for thematic relevance

Code	Label	Color
3	Primary focus	
2	Substantially discussed	
1	Mentioned	
0	Not addressed	

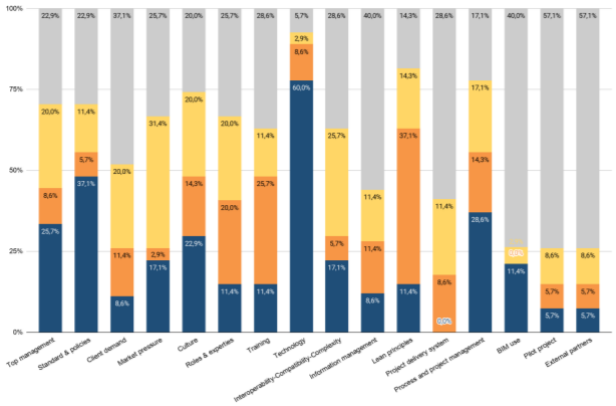

Figure 4: BIM-AI Key factors of the selected studies

The ANT diagram

This study proposes a socio-technical methodology based on ANT to study the BIM-AI implementation in design firms. The proposed ANT diagram is structured into four macro-areas that synthesize the main key factors identified in the literature. These key factors are organised into stakeholders characteristics ("human"), market, project, and technology characteristics ("non-human") (Figure 5), and are further articulated into two additional subgroups:

1. Stakeholders characteristics: internal and external;
1. Market characteristics: standard & regulations and environmental & socio-cultural factors;
2. Project characteristics: project delivery systems and project management;
3. Technology characteristics: BIM and AI.

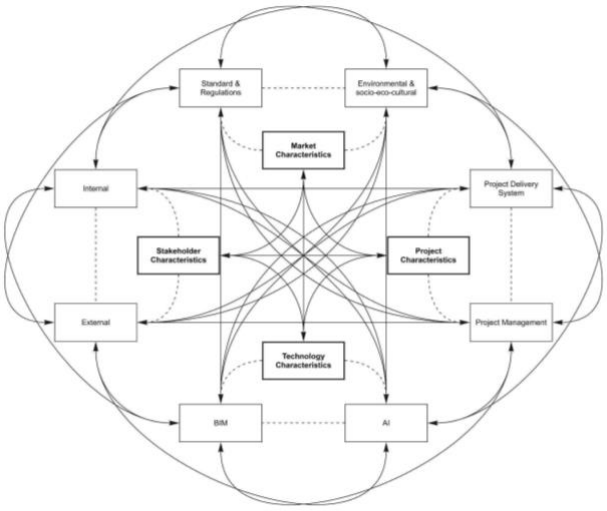

Figure 5: ANT diagram

This structure supports future analysis and enables the examination of social composition and decomposition of key actors. Also, the ANT diagram helps the research team to use the connections between the identified actors as a basis to formulate the questions for semi-structured interviews and case studies.

Stakeholder characteristics

As part of the ANT diagram development, the research team classified stakeholders involved in design, construction, and operation processes. Table 4 provides a summary of the identified human actors categorized into an "Internal stakeholders" and "External stakeholders".

Table 4: Stakeholder characteristics components

Internal stakeholders	External stakeholders
Public/Private owners	Local/National authorities
Trade unions	Regulatory/Permitting agencies
Architect	Insurance companies
Engineer	Financial institutions
Project manager	Environmental agencies
BIM professionals	Public community
General contractor	Technology vendors
Consultants	Real estate stakeholders
Surveyors/GIS experts	Utility providers
Fabricators/Suppliers	Academic/Professional training providers
Facility operators	
ICT/IT department	

Market characteristics

Table 5 provides a summary of the identified Market characteristics ("non-human" actors) categorized into "Standard & regulations" and "Environmental & socio-cultural factors".

Table 5: Market characteristics components

Standard & regulations	Environmental & socio-cultural factors
National legislation	Sustainability & environmental policies
Mandatory regulations	Education & training culture
Technical standards/codes	Professional/Digital readiness
BIM standards	Cultural attitudes
Design and construction guidelines	Local demand
Facility management protocols	Economic factors
Government Digitalization Programs	
Data Management Standards	

Project characteristics

Although the literature has extensively examined organizational, technological, and human-related factors, the role of the Project Delivery System remains relatively underexplored. For this reason, its inclusion among the key components of the network represents a relevant and innovative contribution. Table 6 reflects this advancement by categorizing project characteristics into "Project management" and "Project delivery system".

Table 6: Project characteristics components

Project management	Project delivery system
Project objectives	Design Build (DB)
Design management	Design Bid Build (DBB)
Quality control	Construction Manager at Risk (CM@R)
Model-based coordination practices	Integrated Project Delivery (IPD)
Lean principles	
Integrated information flows	
Decision-making	

Technology characteristics

Table 7 provides a summary of the identified Technology characteristics ("non-human" actors) categorized into "BIM" and "AI".

Table 7: Technology characteristics components

BIM Use Case	AI General use
Concept	Generation, review and synthesis of texts and documents
Rendering	Generation of images and graphic content
Design and Modelling	Transcription and analysis of meeting notes

Analysis and Simulation	Workflow automation
Collaboration & Coordination	Data analytics & BI
Time Scheduling (4D)	**AI Domain-specific use**
Cost Estimation (5D)	Generative design and design optioning
	Automated documentation
	Visual programming & parametric modeling
	Security, analytics and computer vision
	Rendering
	Model coordination
	Scan-to-BIM

Discussion

The literature on BIM implementation within design firms has predominantly examined barriers, adoption levels, benefits, and internal organizational dynamics. While these studies offer valuable insights, they often adopt an inward-looking perspective that frames BIM primarily as a technical or managerial issue. By contrast, the ANT lens adopted in this study shifts attention toward the heterogeneous network of relations that shape the implementation of new processes, technologies, and standards. Through ANT, BIM-AI integration emerges as a socio-technical reconfiguration involving negotiations, translations, and alignments among multiple actors. The ANT diagram developed in this research operationalizes this perspective by making visible the connections across stakeholder groups, technological components, market conditions, and project characteristics. These connections provide the analytical basis for investigating how specific relationships influence BIM-AI adoption. For example, linking internal stakeholders (e.g., BIM professionals) with AI general uses (e.g., workflow automation) highlights how modelling practices may be reshaped by automated processes and what organizational conditions support such transitions. Similarly, connecting standards and regulations with AI domain-specific uses (e.g., security and analytics) underscores the importance of protocols, data governance, and regulatory frameworks in enabling responsible AI integration. The interplay between project management practices (e.g., lean principles) and AI-enabled analytics illustrates how information flows, decision-making routines, and continuous improvement processes evolve when AI tools are introduced. Likewise, examining project delivery systems alongside BIM-AI objectives clarifies how contractual structures and collaboration models influence technological adoption. Finally, connecting internal stakeholders with AI domain-specific uses supports an investigation of how organizations plan to embed AI within BIM workflows, redistribute responsibilities, and develop new competencies. Overall, these insights address RQ1 by showing that BIM implementation in design firms is best understood as a dynamic socio-technical process and by demonstrating how ANT can structure their analysis. They address RQ2 by identifying the key factors that influence BIM-AI integration. These findings provide a structured foundation for the empirical phase of the research, where the ANT-based framework will be tested and refined across different organizational contexts.

Conclusions

This study proposes an ANT-based diagram to support researchers in analyzing how AI becomes integrated within BIM processes in design firms. The main contribution lies in the development of a structured methodology that applies an ANT lens to interpret the sociotechnical relationships that enable or hinder BIM-AI implementation. By positioning human and non-human actors at the same analytical level, ANT provides a robust and transferable framework capable of capturing how technologies, standards, roles, and organizational routines interact during implementation. The proposed diagram serves as the conceptual foundation for the next phase of the research, which will involve empirical investigations through semi-structured interviews and case studies across different organizational contexts. This subsequent phase will allow the research team to test and refine the framework, assessing its ability to identify enabling conditions, tensions, and translation processes within BIM-AI networks. The expected outcomes will advance current knowledge on BIM implementation by offering an interpretative tool that supports both academic inquiry and professional practice in the AECO sector. Overall, the study contributes a novel sociotechnical perspective to the emerging field of BIM-AI integration and provides a methodological pathway for future empirical work.

Acknowledgments

This doctoral research is funded under the Italian National Recovery and Resilience Plan (PNRR) by the European Union through the NextGenerationEU, and co-funded by a design firm. The author wishes to express her gratitude to the organization that hosted the research stay abroad for the support provided to the activities.

Abstract

Existing generative design approaches for floorplan generation rarely incorporate fabrication constraints, limiting their applicability in industrialized construction. This study presents a fabrication-aware generative design framework for hybrid prefabrication based on Stable Diffusion XL. The framework integrates spatial, functional, and manufacturing constraints to balance design flexibility and production efficiency. A two-stage training strategy generates both conceptual layouts and module-integrated solutions. Experiments demonstrate the generation of boundary-compliant layouts and standardized module allocation under diverse boundary conditions and text-based requirements. An interactive workflow supports convergence from conceptual designs to fabrication-aligned solutions, bridging early-stage architectural intent with downstream fabrication requirements.

Introduction

While data-driven layout generation has accelerated early-stage concept exploration, architectural workflows frequently treat downstream fabrication as an afterthought. Recent surveys highlight significant advancements across rule-based, optimization-driven, and data-driven floorplan synthesis, yet they consistently underscore bottlenecks regarding constraint satisfaction and practical constructability (Weber et al., 2022). In parallel, modular building automation has progressed by leveraging BIM-centric data representations and specialized configurators to explicitly systematize modules alongside their spatial relationships (Liu et al., 2024). Merging these high-capacity generative priors with standardized prefabrication rules presents a clear opportunity for industrialized construction.

Yet existing approaches remain split. Mainstream generative floorplan frameworks, such as HouseDiffusion, (Shabani et al., 2023; Zhang & Zhang, 2025), operate primarily on idealized, rectangular room abstractions and do not account for prefabricated assemblies. Conversely, modular-layout methods, such as CoGAN (Ghannad & Lee, 2022) and graph-based BIM pipelines (Gan, 2022b), enforce modular structure but often offer limited design variety and are not integrated with generative frameworks.

To bridge this gap, the goal of this research is to develop a Fabrication-aware generative design framework for prefabrication that accepts predefined modules as input and incorporates them into the customized floor plan generation. The framework aims to increase the adoption of standard modules within a boundary-compliant layout, enabling efficient exploration of feasible configurations while preserving production efficiency in industrialized construction.

Literature review

This section reviews computational methods for automatic floor plan generation. The references are limited to industrialized construction. In addition to top-down and bottom-up methods, relevant BIM-based parametric methods are also included. To maintain the high quality, the analyzed studies are only sourced from journal publications.

Top-down methods

The top-down approach follows a decomposition workflow, where a floor plan is divided into discrete modular units, or referred to as modularization. Lin et al. formulate the modularization process by first segmenting the original space into smaller regions and then merging them to obtain an optimal layout under shape and size constraints. The generation is evaluated via two indicators, number of modules and the diversity of modules with different dimensions (Lin et al., 2025). The generation achieved optimal modular key plan convergence in 50 iterations, with automated runtimes averaging only 7.4 seconds. Cao et al. translate the decomposition process as the decomposition process as matching predefined modules to the given floor plan. The difference compared to Lin's approach is that the floor plan is fixed, while the prefabrication strategy, including panelized units and modular units, is determined by evaluating the construction cost and durations (Cao et al., 2024). The study demonstrated that shifting to a fully volumetric strategy over a fully panelized one can accelerate construction schedules by up to 23%, although it concurrently inflated material and shipping costs by roughly 22%.

Bottom-up methods

The bottom-up approach starts with the definition of standard modules and establishes the generative rules for module placement. Guided by objective functions, the optimal layout is created. Zheng et al. develops a generative design method for the floor layout of modular buildings. The method uses room module, corridor module and stair module as building blocks. The meta-heuristic rules are provided by geometric and functional relationship between module units. The objective functions include project cost and layout penalties (Zheng et al., 2024). The generation could escape local minima to discover globally optimized volumetric configurations within 42 generations (under 870 seconds). Sheijani et al. adopt a bottom-up approach to automate layout generation for office buildings. The generation is framed as identifying the most inclusive path for placing modules (Sheijani et al., 2024). The results show that the approach can condense the standard front-end schematic design phase from a typical timeframe of multiple weeks down to just 5 to 7 days.

BIM-based parametric methods

Beyond these two methods, there are BIM-based generative design approaches that accommodate a broader range of building topologies. Gan developed a customized BIM object library where elements with different embodied carbon and cost index could be matched with the model geometry and material information to create the alternative designs (Gan, 2022a). The generative framework by Gan (2022a) can create between 1,000 and 1,500 new design options in approximately 30 minutes. Li et al. proposed a parametric generative design method for precast buildings using BIM and graph convolutional neural networks. The layout is explicitly parameterized through a set of spatial and geometric features, and the resulting designs are evaluated and optimized with respect to wind pressure performance (Li et al., 2024). The method achieves a highly accurate layout prediction rate of 98.79% (R^2) on testing sets for evaluating surface-averaged wind pressure coefficients. However, the BIM-based approach is less efficient during the layout generation, when design exploration is primarily driven by functional program, rather than specific building elements.

In short, the top-down strategy tends to defer module design to the final stage, which may result in numerous irregular modules, thereby reducing manufacturing efficiency and increasing overall project costs. Although prior studies have considered fabrication constraints and modularization efficiency (Cao et al., 2024; Lin et al., 2025) in the post-design phase, they overlook the opportunity for early manufacturer engagement. Delayed engagement might lead to prolonged lead times for procuring building materials before fabrication. In contrast, the bottom-up approach integrates standard modules directly within the generative process, potentially overcoming these limitations (Sheijani et al., 2024; Zheng et al., 2024). However, the generation process is usually driven by a set of rules which limits their scalability and usually consumes longer iterations. Last but not least, the bottom-up approach is not flexible with respect to predefined building boundaries and room adjacency requirements.

Methodology

Dataset preparation

Training data are derived from the SwissDwellings (Van Engelenburg et al., 2025) database, which provides apartment layouts as vector room outlines. Figure 1 summarizes our two-stage preprocessing pipeline. Stage 1 converts each vector layout into a semantic raster target and a set of conditional inputs, including the site context, a partial layout graph, and a structured prompt. Stage 2 augments this dataset with fabrication labels by sampling candidates from the Stage 1 model, filtering invalid instances using geometric checks, and matching them to standardized wet-core modules.

Problem Formulation

We define fabrication-aware floorplan generation as learning the parameters θ of a conditional generative model, $p\theta(F^{img} \mid G^{img}, T_{desc}, T_{fab}, V_{Module}, Mode)$. As illustrated in Figure. 1, given multi-modal inputs that encode spatial, functional, and fabrication constraints, the model synthesizes a floorplan image $F^{img} \in R^{\{512\times512\times3\}}$. The objective is to maximize the likelihood of generating coherent, feasible, and architecturally valid designs that are consistent with both functional program and manufacturing realities. The input modalities are defined as follows:

Layout Graph Image (G^{img}) A 2D raster image that encodes the spatial topology as adjacency graph $G^{vec} = (V, E)$, where V denotes functional room values of types and locations, and E denotes the adjacencies to be satisfied. The graph input is rasterized on canvas $\mathbf{G^{img}}$, and it may be partial ($G_{partial}$), specifying only key relationships, or complete ($G_{complete}$), defining the full topology.

Module (V_Module): We predefined five module prototypes with various dimensions, as shown in Module Library in Figure 1.

Floorplan Description (T_desc): A structured prompt of language specification, describing the functional program, including the room types and locations. For example: "Floorplan with a Northeast Bedroom, a West Corridor." The description may be partial or complete, depending on the level of details the user wishes to impose.

Fabrication Information (T_fab): A structured prompt of language specification, describing manufacturing constraints that ground the design in the selected construction system. For example: "use bath-kitchen module, less panels, medium doors, medium windows." This input may also be partial or complete, allowing different degrees of fabrication control.

Mode: A mode switcher that identify whether the model generate layout with only design constraints or generate layout that be aware of fabrication constraints.

Meanwhile, the model output is defined as follows:

Floorplan Image (F): A high-resolution raster image of a complete floorplan. The generated plan must jointly satisfy the constraints imposed by all input modalities. Specifically, it should:

(1) Respect the spatial topology encoded by the layout graph image G.

(2) Fulfill the functional program (room types and locations) described in T_desc.

(3) Comply with the fabrication constraints, including clear placement of predefined modules (e.g., bathroom, kitchen) and compatibility of remaining spaces with the stated construction system (e.g., timber panels).

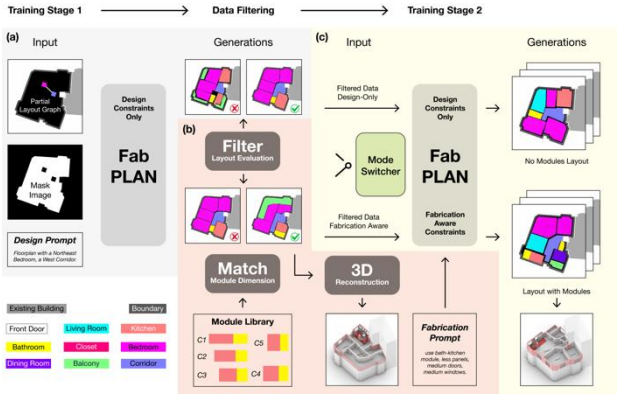

Figure 1: Framework of Fab-aware GD Framework

Fab-aware GD Framework using SDXL

As also described in Figure 1, we propose a Fab-aware GD framework built on Stable Diffusion XL (SDXL) (Podell et al., 2023), where the UNet, the core denoising network responsible for transforming random noise into coherent images, is fine-tuned with hybrid conditioning to support both design exploration and fabrication aware generation. To maintain general design capability while enforcing fabrication constraints, we introduce a mode-switching strategy. When under design mode, the model is conditioned on **G** and **T_desc**, encouraging broad layout diversity within the boundary and adjacency constraints. When under fabrication-aware mode, the model is additionally conditioned on the module specification **V_Module** and **T_fab**, biasing generation toward layouts that can accommodate standardized modules and compatible panel logic. This dual-path conditioning prevents overfitting to modular templates while enabling reliable module-aware outputs.

During fine-tuning, both modes are sampled within each training epoch using filtered design-only data and synthetically enriched fabrication-aware data. This yields a single UNet that can be toggled at inference time to produce either unconstrained conceptual layouts or fabrication-ready layouts that explicitly integrate standardized modules. In effect, the framework unifies early-stage architectural exploration and downstream manufacturing feasibility within a single SDXL-based model.

Data Preparation and Two-Stage Training Pipeline

To generate layouts that are both spatially valid and compatible with fabrication constraints, as demonstrated in Figure 2, we adopt a two-stage training pipeline with dataset filtering and synthetic fabrication-aware enrichment.

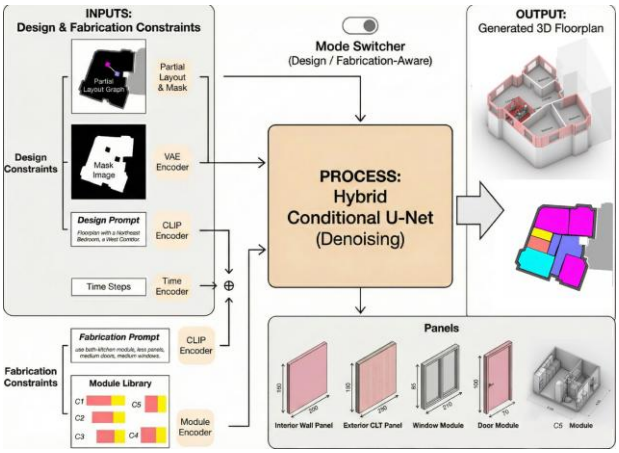

Figure 2: Data Preparation and Two-Stage Training Framework

Training Stage 1: Design-Centric Initialization

We first train the base model with design constraints only to establish robust spatial priors. The model receives partial layout graphs (room types, locations, and adjacency), mask images (the region model should denoise), and structured prompt design prompts. It then generates candidate floorplans without fabrication inputs.

Data Filtering and Module Matching

Stage 1 outputs are screened to remove invalid or low-quality layouts. The retained plans are passed to a module dimension matching procedure that fits standardized components from a module library (C1–C5, e.g., bathroom and kitchen units). The selection of five module prototypes is motivated by the geometric variation of standard residential wet-core units, ranging from compact square layouts to elongated narrow configurations. These modules represent bathrooms and kitchens, which are among the most service-intensive and costly elements in prefabricated housing. While the number of possible module types is not inherently limited, expanding the library would increase the complexity of module embedding and training, whereas practical industrial systems typically rely on a relatively small family of standardized products. The five-module library therefore provides a balanced test set that captures representative variation while remaining computationally and practically tractable."

For successful matches, the system reconstructs the layout in 3D and automatically generates fabrication prompts describing the applied module and panel constraints. This yields a synthetic fabrication-aware dataset pairing geometry with explicit manufacturing information.

To ensure high-quality training data for the diffusion model, raw generated layouts are passed through an automated rule-based validation pipeline. A generated

layout is classified as invalid or low-quality if it fails any of the following four objective criteria:

- Room Shape Convexity: Deformed or highly irregular room polygons are rejected using a compactness index (ratio of room area to its axis-aligned bounding box area). Layouts falling below a mean threshold of 0.85 are discarded.
- Aspect Ratios: Rooms with extreme, unbuildable proportions (e.g., long, thin slithers) are flagged by checking side-length ratios.
- Connectivity: A room-contact graph is built by analyzing polygon intersections. A layout is invalid if a room has no feasible spatial connection to the rest of the dwelling (e.g., a bathroom that is isolated and cannot be accessed from a corridor or living room).
- Essential Room Types: To be valid, a residential layout must contain a core set of functional zones: a kitchen, a bathroom, and a living or sleeping area.
- Module Feasibility: Bathroom, kitchen, and combined total area ratios are computed against the module's specifications. A module is considered feasible if all three ratios fall within a 15% tolerance threshold.

Training Stage 2: Fabrication-Aware Refinement

After assembling the filtered design-only dataset and the synthetically enriched fabrication-aware dataset, we fine-tune the SDXL UNet with a dual-path strategy controlled by a mode switcher. (1) Mode A (design-only): The model is conditioned on the layout graph image and design prompt (and boundary masks, if applicable). This path preserves spatial generality and layout diversity, and prevents overfitting to modular templates. (2) Mode B (fabrication-aware): The training target is the same floorplan image, but the model is additionally conditioned on module specifications and fabrication prompts. This path enables dimensional feasibility and module accommodation. Mini-batches are routed between the two modes using a fixed sampling policy, yielding a single unified model. At inference, the same UNet can be toggled to generate either concept-level layouts or module-integrated layouts that better satisfy fabrication constraints.

Results

We evaluate the proposed fabrication-aware generative framework in three experiments: (1) controlled comparisons between design-only and fabrication-aware outputs under identical boundary and partial inputs, (2) robustness to different boundary conditions and partial-input completeness, and (3) iterative, user-in-the-loop customization including module freezing. All results are generated from partial inputs to reflect early-stage design practice.

Fabrication-Aware Generation

Figure 3 compares design-only and fabrication-aware generation using the same boundary condition. Design-only outputs satisfy the partial topology and program intent, but do not explicitly allocate space for standardized modules, often implying partition or opening patterns that are difficult to align with fabrication systems. With fabrication-aware conditioning enabled, the model consistently introduces module-compatible allocations and clearer service clustering while maintaining boundary compliance and the intended spatial logic.

Using identical inputs, we further test prompt-level controllability within fabrication mode across three variants: baseline module integration, reduced panel/door/window complexity, and increased panel/door/window richness. The results show that the model can shift between assembly-simplified and architecture-enriched solutions without breaking module fit or topology.

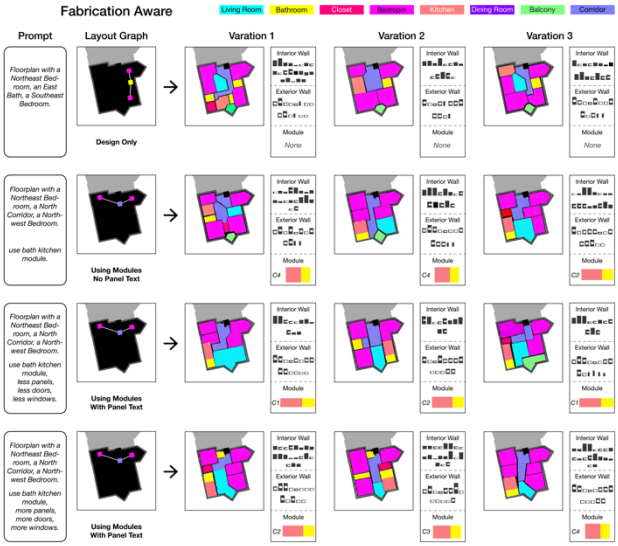

Figure 3: Design-only vs fabrication-aware outputs with identical boundary and partial inputs

Various Partial Inputs

As illustrated in figure 4, we evaluate fabrication-aware generation across diverse boundary conditions and varying levels of partial input. For both regular and irregular envelopes, the model preserves boundary compliance and maintains plausible module placement aligned with the provided adjacency cues. When the partial input is sparse, the module specification acts as a stabilizing prior, producing a broad set of feasible configurations. As the partial input becomes more detailed, the output distribution narrows and more consistently reflects user intent. These results indicate that Fab-aware generation remains robust under both geometric variability and incomplete early-stage requirements.

Iterative Customization

Figure 5 demonstrates an interactive workflow in which users progressively refine partial inputs rather than specifying all constraints upfront. Starting from an initial partial graph and boundary, the model produces multiple candidate solutions. The user then selects a preferred outcome and adjusts the partial input to steer the next iteration.

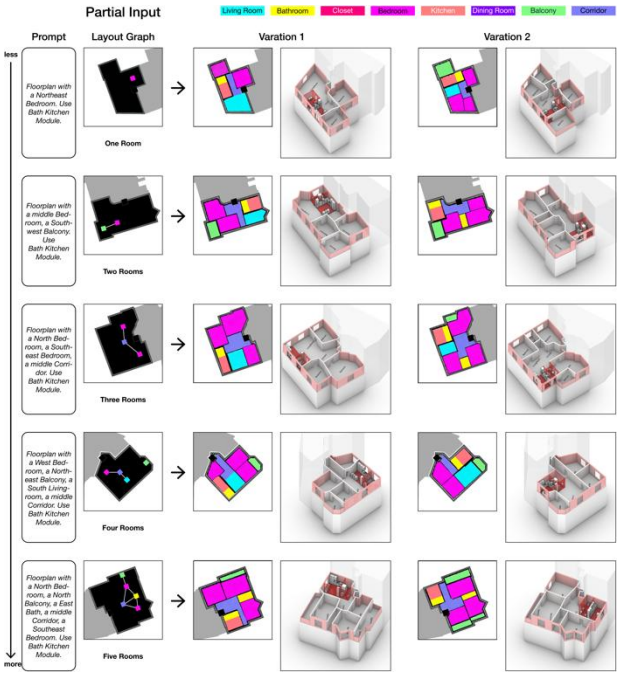

Figure 4: Fabrication-aware results across different boundaries and increasing partial-input completeness.

Modifying constraints directly shapes the design space. For instance, adding constraints yields more precise, less diverse outcomes; editing constraints corrects local functional issues while preserving global structure; and removing constraints increases diversity under the same boundary and module rules. Finally, users can freeze accepted module positions and dimensions, prompting the model to regenerate surrounding spaces while respecting the locked design decisions. This supports gradual convergence from conceptual exploration to fabrication-aligned layouts.

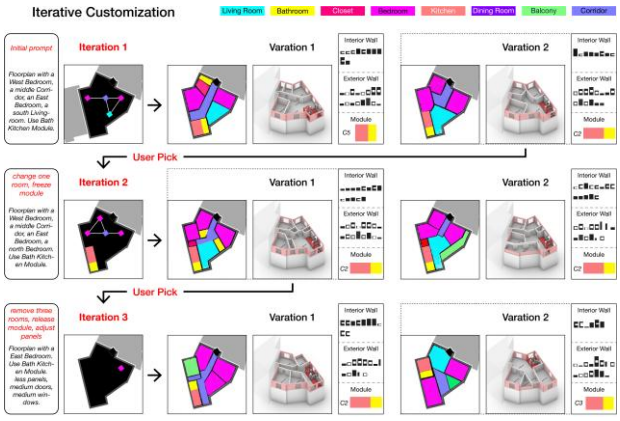

Figure 5: Iterative customization: initial partial input, user selection, add/edit/remove constraints, and module freezing with regenerated layouts.

Evaluation

Our framework is designed for floor plan generation where designers progressively specify site boundaries, partial layouts, and wet-core modules. There is no comparable prior SOTA methods that support the same combination of partial layout input and module-aware generation within a single generator. The framework was quantitatively evaluated on a held-out test split of 1,000 site conditions and prompts. We tracked perceptual visual similarity via Fréchet Inception Distance (FID). A lower FID is better, as it means the generated images are indistinguishable from real drawings. Besides, Module Feasibility is recorded as the percentage of samples whose decoded wet-core matches the specified module.

Table 1 presents a comparative benchmarking of the full framework against three key ablations, quantifying how each component affects architectural validity and module integration. In the default configuration, the full framework achieves the strongest overall performance, attaining a high spatial realism score (FID=5.68) and highest geometry pass rate and module feasibility (85.6%). Deactivating the mode switcher leads to a noticeable deterioration in performance, with module feasibility dropping to 64.2% and FID numbers increasing from 5.68 to 6.54. Omitting the data pipeline's geometric screening yields the poorest performance across the board. Under this scenario, module feasibility drops to its lowest point at 57.8%, while the FID worsens to 8.21. In particular, fine-grained geometric checks like shape convexity drop from 91.8% to 82.6%.

Table 1 Fabrication-aware ablation test

	FID	Mod Fea %	Geometry Pass Rate %			
			Conv	Ratio	Conn	Type
Ours (Full)	5.68	85.6	91.8	85.4	81.4	94.2
w/o Switcher	6.54	64.2	89.4	83.8	69.6	92.7
w/o Filter	8.21	57.8	82.6	77.1	72.4	90.8

Discussion

This study presents a fabrication-aware floorplan generation framework that unifies early-stage spatial reasoning with downstream manufacturability. By fine-tuning the UNet under hybrid conditioning and a mode-switching scheme, the model can generate both concept-level layouts and module-integrated solutions from partial inputs while respecting a fixed boundary. The results indicate that diffusion-based models can serve as a practical bridge between architectural intent and fabrication constraints without relying on brittle, hand-crafted placement rules.

A key contribution is the two-mode training strategy. The design-only path preserves broad generative capability and avoids narrowing the model to a small set of modular templates. The fabrication-aware path introduces explicit module and panel constraints, improving dimensional feasibility and constructability. This separation appears to be critical: without the design-only channel, the model risks reduced diversity and over-regularized outputs; without the fabrication-aware channel, module fit remains inconsistent. The combined approach yields a single

deployable model that can be toggled by conditioning, which is advantageous for real design workflows where the level of constraint evolves over time.

The results also highlight the value of the synthetic enrichment pipeline. Module matching and fabrication-prompt generation convert raw design outputs into a structured dataset that injects manufacturing knowledge into training. This offers a scalable alternative to manually annotated fabrication-aware datasets, which are expensive and scarce. The observed robustness across boundaries and partial-input amounts suggests that the enrichment strategy effectively teaches module accommodation as a generalizable behavior rather than a memorized pattern.

However, several limitations remain. First, representing layouts solely as raster outputs may obscure geometric precision needed for detailed coordination, especially for tolerance-sensitive assemblies. Second, the module matching success rate and its dependency on library richness likely influence overall performance; limited module typologies may bias the generator toward a narrower solution space. Third, the current framework infers constructability primarily through textual and library-based constraints rather than explicit structural, MEP routing, code compliance, or egress simulation. These aspects may require additional conditioning signals or post-generation validation.

Conclusion

Overall, our proposed Fab-aware GD framework demonstrates that diffusion models can support boundary-compliant, module-aware floorplan generation from partial inputs, offering a scalable approach to balancing design flexibility with fabrication efficiency. The mode-switching paradigm and synthetic fabrication enrichment provide a practical foundation for hybrid prefabrication workflows where manufacturability must be introduced progressively rather than imposed upfront.

Future work could focus on (1) integrating vector or parametric representations for higher geometric fidelity, (2) expanding module libraries and supporting multi-objective optimization across cost, carbon, and schedule, (3) incorporating explicit code and performance-aware validators in the loop, and (4) evaluating the system with professional designers to quantify usability, time savings, and trust. A promising direction is a closed-loop pipeline where diffusion-based generation, rule-based checking, and module library updates continuously inform one another.

SYN3D-LLM: SYNTHETIC 3D POINT CLOUDS GENERATED THROUGH LLM DISCUSSION

Nils Soeren Krause[1], Joern Ploennigs[1]
[1]University of Rostock, Germany
AI for Sustainable Construction

Abstract

Creating synthetic datasets that capture the diversity of real-world sites and measured point clouds remains challenging. The paper introduces SYN3D-LLM, a dialog-driven large language model framework for generating semantically annotated synthetic 3D point clouds by producing executable code through an iterative designer-critic loop. Experimental evaluations of the framework demonstrate that it improves the pass rate by discussing and testing generated code and by assessing the geometrical consistency between the initial prompt and the generated data. The paper demonstrates that SYN3D-LLM is versatile in generating point clouds for various cases.

Introduction

Most Scan-to-BIM, SLAM, or semantic segmentation models in the Architecture, Engineering, Construction, and Operations (AECO) sector are trained on real measured point clouds. This has the benefit of representing real-world conditions and complexities such as noise, occlusions, and varying point densities.

On the other hand, it requires extensive data collection efforts, including scanning diverse environments and manual annotation of point clouds, which can be labor-intensive and time-consuming. Furthermore, survey papers indicate that many Scan-to-BIM approaches are primarily evaluated on proprietary or project-specific datasets, hindering objective comparison within the State-of-the-Art (Abreu et al., 2023). This lack of standardized benchmarks limits reproducibility and comparability of workflows (Xu and Stilla, 2021; Luo et al., 2026) and the development of generalized models.

To address this challenge, researchers are exploring the use of synthetic point clouds (Noichl et al., 2021) as a complement to real measures to introduce a larger variety of data. Synthetic point clouds can provide a reliable foundation for benchmarking, as demonstrated by synthetic datasets such as ModelNet in Wu et al. (2015), which is widely used for object recognition. Studies such as those by Yue et al. (2025) show that synthetic point clouds are effectively augmenting real-world data, leading to improved performance of the trained model. The authors used a diffusion model to generate synthetic data, which, as before, requires training on large amounts of real data. Limiting this is the potential diversity of the generated data. Similar challenges arise in approaches that generate synthetic point clouds from IFC models Zou et al. (2026), which must be modeled and are available in only a limited variety.

To overcome these limitations, scalable and diverse synthetic point cloud generation methods are needed. We present SYN3D-LLM as an approach for generating synthetic point cloud data using large language models (LLMs) that do not require pre-training on real-world point clouds. While SYN3D-LLM does not introduce a new methodology, its contribution lies in integrating LLM-based self-refinement for AECO-specific point cloud generation. Beyond demonstrating that it is possible to generate synthetic point clouds with LLMs, we want to investigate the reliability and accuracy of the generated data in engineering contexts. We therefore focus on two key research questions:

- **RQ1:** How reliably does the proposed SYN3D-LLM framework generate executable point cloud code under iterative designer-critic refinements?
- **RQ2:** How accurately do the generated point clouds comply with the geometric dimensions and semantic constraints specified in the input prompts?

To address those research questions, SYN3D-LLM does not generate point clouds as a one-shot solution, but it uses an iterative framework to critically review and improve the point cloud drafts. To remove the requirement of data for training that generative models like Generative Adversary Networks (GAN) or Diffusion Models (DM) have, the approach relies on the LLMs capability to generate code from natural language prompts. For this SYN3D-LLM introduces a review-loop where the LLM assumes two roles: (i) as a code-generating designer and (ii) a code-reviewing critic. This enables SYN3D-LLM to generate point clouds of a wide complexity across a variety of construction types. The main contributions of this paper are:

Proposing SYN3D-LLM framework: Introduction of a dialog-based self-discussion framework in which an LLM generates synthetic point clouds as a programming designer.

Scalable, labeled data generation: An approach for generating different building classes, and directly annotated point cloud scenes for the AECO sector.

Evaluation of SYN3D-LLM: Investigation of the Pass rate and increasing token cost of iterations. As well as

constraining checks on the input and output information for geometrical consistency, and the semantic labels of the required information from the input prompts.

First, we introduce SYN3D-LLM in the SOTA context and distinguish it from existing work of synthetic point clouds for Scan-to-BIM workflows and semantic segmentation. Next, we describe the design and the functioning of the proposed framework in the methodology section. This is followed by data evaluation, a discussion of the results, an outlook, and a conclusion.

State-of-the-Art

The motivation for synthetic point clouds in the Scan-to-BIM context stems from the limitations of classical workflows and the growing need for benchmarks, scalable point cloud training data for machine learning and AI applications (Abreu et al., 2023).

Traditional Scan-to-BIM workflows consist of several processing steps, starting with point cloud measurement, followed by geometry segmentation and segment classification, and culminating in the reconstruction of 3D models or IFC data. The problem is that most approaches are project-specific and work primarily on the data for which they were developed. As data acquisition and pre-processing, including labeling, are time-consuming (Abreu et al., 2023), most approaches are limited in their generalizability.

To address these problems, simulation-based approaches generate synthetic point clouds from existing 3D models. Virtual laser scanning of BIM or CAD models can produce labeled point clouds automatically (Noichl et al., 2021). These approaches create synthetic point clouds by sampling points from the surfaces of explicit geometric representations, with semantic labels inherited from the underlying CAD or BIM structure (Pierdicca et al., 2019). In particular, IFC-based environments enable the simulation of laser-scanning processes to generate semantically annotated point clouds for Scan-to-BIM applications (Ma et al., 2021). Experimental results demonstrated in that case that synthetic point clouds enhanced the semantic segmentation tasks and reduced the amount of manually annotated real-world data required for training and semantic segmentation (Xiao et al., 2022; Stefanelli et al., 2022). But in these approaches, the variability of the generated data is constrained by the availability and diversity of predefined geometric models used for the simulated generation of synthetic point clouds.

Machine learning approaches usually target generative latent-space models. Achlioptas et al. (2018) introduced a deep generative model for point clouds by training autoencoders (AE) and modeling the latent space using Generative Adversarial Networks (GANs) and Gaussian Mixture Models (GMMs). This approach demonstrated the ability to reconstruct previously unseen point cloud samples from the ModelNet dataset.

More recent work uses 2D diffusion models to generate architectural images Paananen et al. (2024), floor plans He et al. (2023), or building designs Zhong et al. (2024). These applications remain 2D, limiting their applicability to 3D point cloud generation. The use of diffusion models for 3D point cloud generation is presented in Yue et al. (2025), where the authors propose a method to generate synthetic point clouds to augment real-world training data. This method still relies on large amounts of real-world data to train the diffusion model and, therefore, does not address the core limitations.

In addition, generative text models such as Large Language Models (LLMs) are increasingly being used in the AECO domain. Zheng and Fischer (2023) uses an LLM for natural language processing to develop an assistant for information retrieval from BIM models, and Wei and Li (2025); Du et al. (2026) use LLMs to generate floor plans. In context of point clouds, Hong et al. (2023) and Ye and Gao (2024) use LLMs for 3D interpretation of point cloud data to solve tasks such as captioning, question answering, navigation, and guidance via prompting. Xu et al. (2024) presents PointLLM, which combines point clouds and text for classification and description. Similarly, Yang et al. (2025) proposes LiDAR-LLM, which uses this combination to process LiDAR data. Further applications include point cloud registration with MiniGPT-3D Tang et al. (2024) and segmentation with SegPoint He et al. (2024). While these works demonstrate the potential of LLMs for point cloud tasks, the generation of point clouds with LLMs remains underexplored (Liu et al., 2024).

The challenge with LLMs like GPT-4 Achiam et al. (2023) is that they can analyze and generate text, but they cannot directly generate point clouds, as these data are typically unstructured data, stored in binary or other non-textual formats. LLMs have demonstrated strong capabilities in generating code from natural language Poldrack et al. (2023), and various libraries for processing and creating point cloud data exist, such as PyVista, Open3D, PyntCloud, or Laspy. Yet, using these libraries requires domain knowledge and additional manual programming effort. This opens an alternative path for point cloud generation, in which LLMs generate executable code that produces point cloud data directly, without requiring pre-existing 3D models or real-world training data.

While LLMs are good at code generation, they may lack domain knowledge and knowledge about the point cloud libraries mentioned above (Gu et al., 2025). In addition, LLMs are prone to hallucinations, have limited spatial understanding, and exhibit limited reasoning about causal constraints (Ploennigs et al., 2025). Therefore, special precautions are needed to ensure that code-based point cloud generation yields feasible results. The key advantage of the LLM-based approach is its ability to translate natural language into executable code, enabling prompt-driven scene generation without predefined rule sets.

These limitations motivate the exploration and design of a discussion-based LLM framework called SYN3D-LLM, for generating synthetic, semantically point clouds.

Methodology of the Framework

The workflow of the framework is presented in Figure 1. It starts with a *user prompt* that specifies what kind of point cloud should be generated. This user prompt is extended by the Designer with a *system prompt* that provides additional instructions for generating the point cloud. This encompasses strict code generation constraints, including the output schema, programming language (Python), and a restriction that external libraries are not allowed. It also provides information on the helper functions that the LLM can use to generate the point clouds. For example, helper functions exist for creating wall or ceiling structures filled with surface points. After the user prompt and the Designer system prompt are combined, the Designer generates a first code version. This code is not directly executed, but is sent to another LLM, called the Critic.

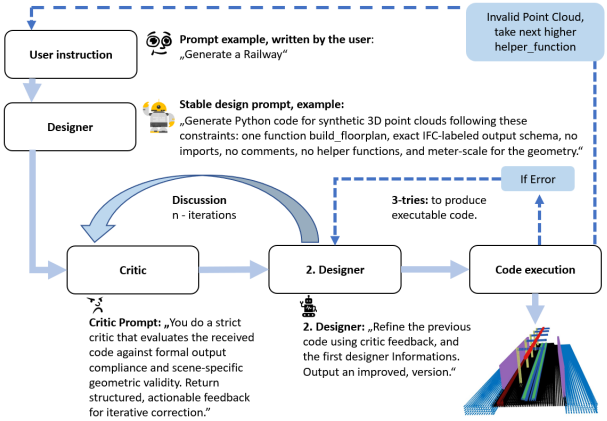

Figure 1: The proposed framework of SYN3D-LLM with its self-discussion functionality to obtain executable code through an iterative process for generating synthetic point cloud data.

The Critic receives the Designer's drafted code, another system prompt defining how it should review the code, and the information from the user prompt. The Critic's response is then sent, together with the previously created code, to the next iteration of the exchange between the Designer and Critic. The Designer then creates an improved code version based on the Critic's feedback and the user prompt. The framework performs a fixed number of Designer and Critic iterations, set to two by default, and the first design draft. With each draft and iteration, the framework has multiple tries to generate executable code (default: 3). The iteration setup represents a controlled experimental design rather than an optimisation stopping strategy. Increasing the number of iterations can improve refinements, but it also increases computational cost. The code's execution is checked by running it automatically in a Python environment. If execution succeeds and a constraint checker verifies that the point cloud contains points, the framework proceeds with the export. Over the iterations, the generated point cloud code becomes progressively more detailed. These improvements are not driven by changes in the *user prompt*, but emerge from the iterative refinement process between the Designer and Critic.

While writing the code, the LLM is instructed in the system prompt to label the individual objects and components based on the scene description.

The discussions between the Designer and Critic are automatically logged to *.CSV* and *.JSON* files for evaluation.

After all iterations are complete, the final code is executed to generate the point cloud. It is saved in three different formats: *.e57*, *.xyz*, and *.ply*.

The framework is complemented by a Graphical User Interface (GUI) in Open3D. It provides access to the settings (e.g., number of iterations), system prompts, and all scene descriptions and variations to generate the data. In the GUI, the discussions between the Designer and Critic are logged in real-time. The GUI also allows the selection of different building types and infrastructure scenarios. For each scenario, a different prompt templates exist that contains the system prompt for the Designer, along with helper functions and the system prompt for the Critic. Currently, templates exist for high-rise buildings, industrial halls, streets (with traffic signs), railway tracks, bridges, and apartments in different shapes. The code is available on GitHub [1].

Validation

The evaluation of SYN3D-LLM focuses on the framework itself and on the plausibility of the point clouds generated from the initial geometric dimensions specified by the combination of the **user prompt** and the **system prompt**. Standard baseline metrics were not applied, since commonly used measures such as Intersection over Union (IoU) or Chamfer Distance (CD) require ground-truth data, which are not available for the proposed SYN3D-LLM framework. The evaluation is exploratory, focusing on plausibility rather than strict geometric accuracy. Instead,

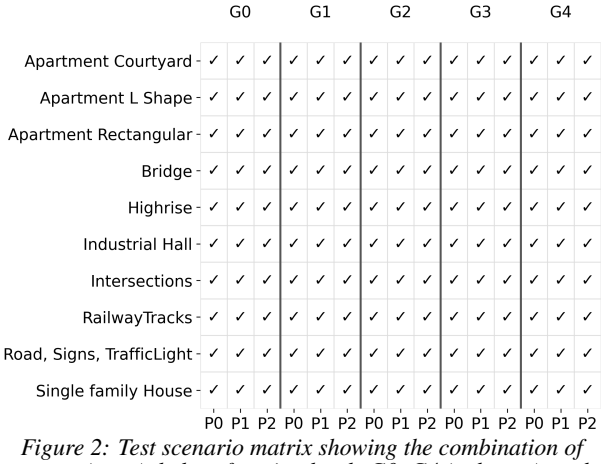

Figure 2: Test scenario matrix showing the combination of scenes (rows), helper function levels G0–G4 (columns), and prompt variations P0–P2 used for evaluation.

we constructed a structured matrix of test scenarios to systematically evaluate the generation process across different

[1] https://github.com/NILSK94/SYN3D-LLM-SYNTHETIC-3D-POINT-CLOUDS-GENERATED-THROUGH-LLM-DISCUSSION

building and infrastructure types in the AECO domain, as illustrated in Figure 2.

Scenes: On the left side of Figure 2 are the scenes we generated, which are described in the code as part of the user input. For example: *A high-rise building with a central core and repeating floors, with an approximate footprint of 18 m × 18 m. It has at least six storeys, with floor levels at z = 0, 3, 6, 9, 12, and 15 m, and a top (roof) level at z = 18 m. The core consists of walls with additional inner walls and columns, windows in the outer walls, and a few corridor doors. Required IFC elements: IfcWall, IfcSlab, IfcColumn, IfcWindow.*

Helper functions G0–G4: At the top of Figure 2, we show the helper functions that are activated during generation. These helper functions act as modular constraints and processing helpers, guiding the LLM by providing code snippets and predefined functions for point cloud generation. The helper functions consist of the objects listed in Table 1.

Table 1: Helper functions for shapes and objects

Helper function	Includes
G0_NoHelper	None
G1_Minimal	Plane Surface
G2_BoxSurface	Rectangle Box
G3_BoxPlusRound	Rectangle Box, Round
G4_Specialized	Rectangle Box, Round, Specialized Objects

Prompt variations P0–P2: In addition, the bottom row of the matrix in Figure 2 shows the prompt variations *P0*, *P1*, and *P2*, which are used to steer the generation and evaluate how prompts influence LLM behavior. While the geometry profiles control which helper functions are available, the prompt variants modify the textual instructions given to the model, ranging from an unconstrained baseline to more specific and robustness-oriented testing. This test is derived from findings on the influence of role allocation in prompt engineering, which can improve LLM performance. The prompt variants are summarized in Table 2.

Table 2: Prompt variants for Apartments as an example

Prompt Variant	Instruction Add-on
P0_Base	None (baseline prompt)
P1_More_Specific	Be explicit: use clear axis-aligned geometry, avoid random noise, and keep openings placed on walls.
P2_Robustness	Robustness: include mild occlusion gaps and slight density variation across elements.

Evaluation metrics

In addition to evaluating the framework, we conducted quantitative analyses, including lightweight checks directly derived from the framework's generated point clouds and log files, to underline the qualitative analysis.

Pass Rate: measures the number of Designer-Critic iterations required until executable Python code is generated. An iteration is considered a pass if the generated code runs without errors and produces valid output. The metric is used across all scenes and configurations.

CountS (Count Successful): verifies each iteration produces a non-empty point cloud, both overall and for required IFC classes where applicable. Reporting the iterations that yield actual point sets rather than empty results.

B–IoU (Bounding-box IoU): measures the overlap between the bounding box of the generated point cloud and the target dimensions specified in the scenario prompt. Values range from 0 to 1, serving as a geometric plausibility indicator for how closely the generated cloud matches the intended dimensions.

Evaluation and Results

For the evaluation, we ran every variation shown in Figure 2. This comprises all scenes and configurations: fifteen runs per scene, each consisting of an initial design step followed by two Designer–Critic iterations. In total, we evaluated more than 300 runs of the framework using an OpenAI GPT-5.2 model, with fixed temperature settings of 0.6 for the designer and 0.4 for the critic. The resulting point clouds were subsequently analyzed. The evaluation starts with a qualitative analysis of the functionality, then moves to the quantitative metrics. To explain the results, we first focus on variations in the helper functions (*G0–G4*) across configurations of the rectangular apartment scene to illustrate how each variation refines the scene design.

Helper function G0–G4 evaluation: Figure 3 shows the result for *G0* (no helper function) and the refinement of the scene across iterations. Over the iterations, the model was able to place doors and windows in plausible positions, so that every room is accessible and has at least one window; The placement of supports remained unreliable. Overall, this highlights the importance of the iterative loop, which progressively refines the design.

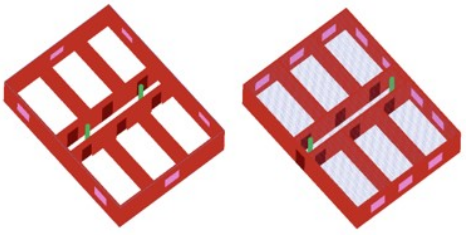

Figure 3: Apartment rectangular layout, prompt variation (P0), helper (G0), iteration 1 (left), iteration 2 (right)

In addition, we analyzed the helper functions provided within the SYN3D-LLM framework by examining their influence when invoked in configurations *G1* through *G4*. For the rectangular apartment layout, this influence was found to be minimal. Nevertheless, the results indicate that the LLM was capable of generating code autonomously without relying on helper functions, and that outputs generated without them tend to exhibit creative variance.

Result pass rate: When considering the pass rate of executable code generation, the results differ across the evalu-

ated helper function variants. Our analysis across all configurations shows that the helper function is crucial for producing executable code in the first iteration. The results are shown in Figure 4. The best pass rate was achieved with the helper function *G2*, which was designed to generate rectangular boxes filled with points on their surfaces. In this case, the function appears to guide the LLM toward producing more structured code output that can be executed directly. In contrast to runs without a helper function (*G0*), the LLM required more iterations to produce executable code.

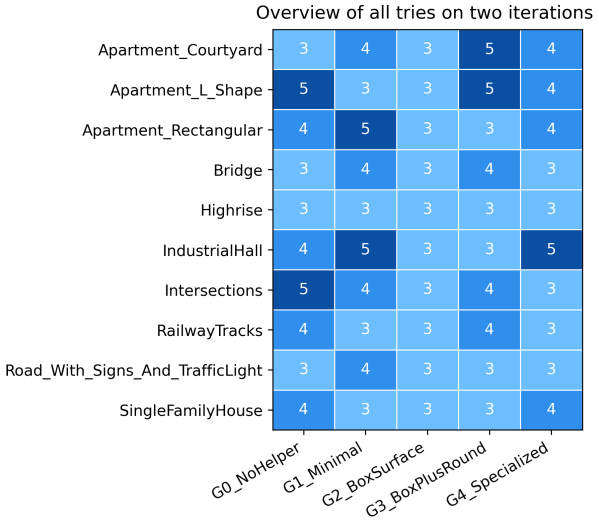

Figure 4: Heatmap of pass rates (two iterations and first design draft required) across scenes and configurations for executable code generation.

CountS: Across all executed iterations in Figure 4, CountS was counted in the Framework, indicating that no empty point cloud outputs occurred in generations because the maximum of 6, by a set default to 3, was not reached.

Prompt variation P0–P2 evaluation: To present the results for prompt variations *P0–P2* (shown for the apartment example in Table 2), we selected the bridge generation scenario to illustrate the influence of prompt variation. The first variant, *P0*, generated the scene shown in Figure 5.

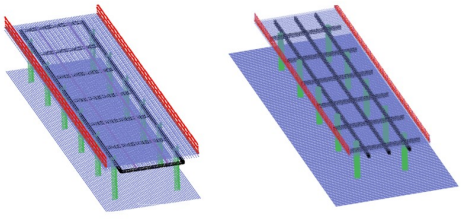

Figure 5: Bridge scene, prompt variation (P0), helper (G0), iteration 1 (left), iteration 2 (right)

Figure 5 shows the baseline prompt *P0* without any additional prompt instructions. While the LLM generates a bridge-like scene, the result is not among the strongest outcomes of the approach, as the geometry remains partially inconsistent and structurally incomplete. In particular, the placement of the supports is not well integrated into a coherent load-bearing bridge structure.

The run with the more specific prompt variant *P1* for the bridge addressed some of the issues observed in *P0*, as shown in Figure 6. The supports are better aligned with the bridge's load-bearing structure, and the LLM generates more detail, particularly in the cut and in the railings or other load-bearing elements. In addition, the model demonstrates the ability to introduce openings in the railings and to incorporate random noise into the generated point clouds. A specific noise setting is also available in the SYN3D-LLM GUI.

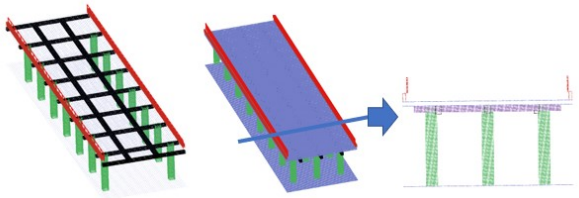

Figure 6: Bridge scene, prompt variation (P1), helper (G0), iteration 1 (left), iteration 2 (middle), cut of iteration 2 (right)

The results obtained with the robustness-oriented prompt variant *P2* are shown in Figure 7. The outcome clearly indicates that the LLM followed the instructions by introducing mild occlusion gaps and slight density variations across elements in the generated point cloud. Beyond improving the baseline prompt's arrangement of supports and load-bearing structure in the generated bridge scenes, *P2* also leads to greater object variation. For example, the LLM attempts to introduce foundations at the ends of the bridge, which are not yet properly connected to the main structure. In addition, the bridge girders beneath the deck are modeled as I-beams, representing substantial structural detail. This can be seen in the cut on the right side of Figure 7. Overall, these results demonstrate that prompt variation can produce meaningful improvements and more plausible outputs within the SYN3D-LLM framework.

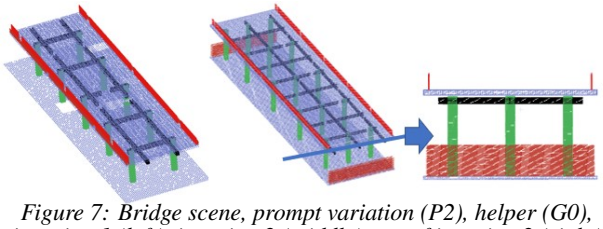

Figure 7: Bridge scene, prompt variation (P2), helper (G0), iteration 1 (left), iteration 2 (middle), cut of iteration 2 (right)

Prompt variant P2 realism effects: Figure 8 presents a qualitative comparison between a synthetic bridge point cloud generated using the prompt variant *P2* (left) and a real-world point cloud acquired with a BLK2GO mobile laser scanner (right). In both cases, mild occlusion gaps and line-like sampling patterns are observable. As illustrated in Figure 7, spatially varying point densities occur across structural elements, particularly along the bridge deck, as well as occlusion-induced shadow regions on the

ground behind supporting columns. In the synthetic example, these effects are generated through the coded point cloud. In real scans, similar characteristics arise from viewpoint dependencies, scanner motion, and the partial occlusions of mobile laser scanning. This visual analysis indicates that SYN3D-LLM generates geometric imperfections like those observed by mobile laser scanners, without explicitly simulating the sensor behavior.

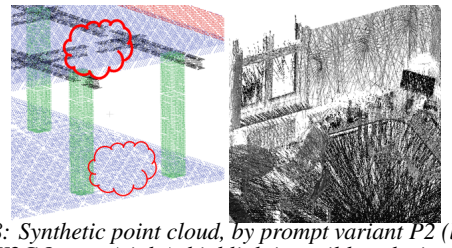

Figure 8: Synthetic point cloud, by prompt variant P2 (left) and a BLK2GO scan (right), highlighting mild occlusion gaps, line-like sampling patterns.

Geometrical check B–IoU: The radar plot in Figure 9 shows how closely the generated synthetic point clouds match the scene dimensions specified in the prompt. Overall, the alignment of the bounding boxes with the target dimensions is minimal.

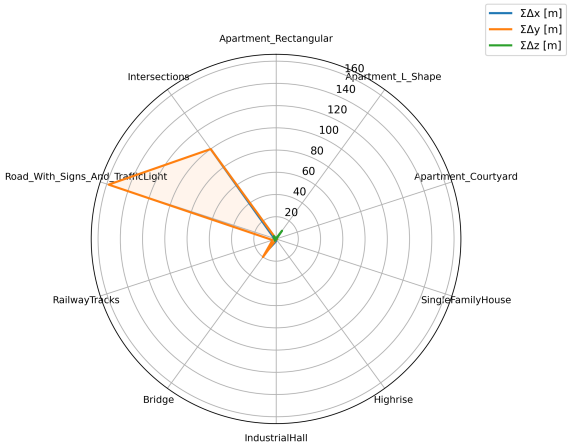

Figure 9: Radar plot showing B-IoU along each axis, comparing generated point clouds to target scene dimensions.

The LLM struggled to generate street scenes with signs and traffic lights, as well as intersection scenes. This can also be observed in the generated data. Figure 10 shows that roads and intersections can be generated, but that there are still major issues in representing these scenes correctly.

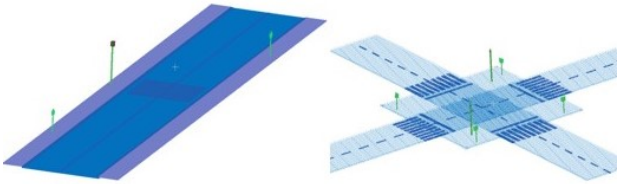

Figure 10: Generated road scene with signs and zebra crossing (left), intersection scene (right).

Semantic labels: The SYN3D-LLM framework stores labels for individual IFC objects as RGB color values in the point cloud. The input scene includes information on the required and permitted IFC classes. The evaluation compares the stored RGB color values in the point cloud with the required and permitted IFC classes specified in the input prompts. The results show a 100 % match for the required and permitted IFC classes explicitly specified in the input prompts. This verifies class presence only and does not assess instance-level correctness or spatial relationships.

Computational cost (Tokens): While the qualitative results demonstrate that iterative refinement substantially improves the structural plausibility and semantic consistency of the generated point clouds, this improvement comes at an increased computational cost.

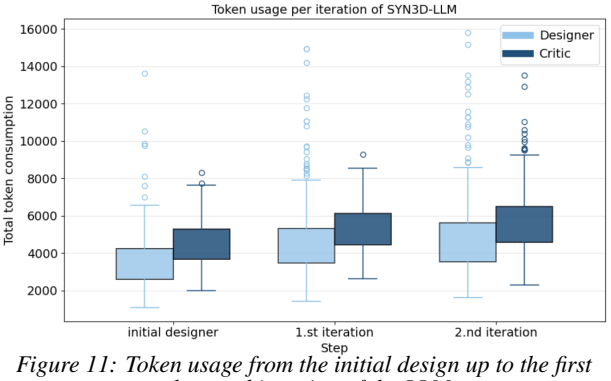

Figure 11: Token usage from the initial design up to the first and second iteration of the LLMs.

Figure 11 shows the token usage per iteration. The results show an increase in the number of tokens required from the initial generation to the first and second iterations. Overall, the Critic needed more tokens to evaluate the design. The round dots in the plot indicate outliers, which are typical for complex tasks.

Discussion

The aim of the paper was to investigate whether an iteration-based, self-discussing framework is capable of generating semantically labeled synthetic point clouds and to examine how reliably the framework follows its input prompts. The results of the proposed SYN3D-LLM framework demonstrate that it successfully generates semantically labeled point clouds. The analysis indicates that the generated point clouds capture the scene's structural elements, but precise geometric alignment is limited in evaluation because the generation is performed without relying on ground-truth data.

The helper functions tested in the framework primarily improve the framework's pass rate and reduce the APIs costs. We can therefore conclude that integrating helper functions is beneficial. But there are limitations, the helper functions may also constrain the LLMs independent creative freedom in generating scenes. Same applies to the predefined input prompts in the framework. Hallucinations are difficult to assess. We should note that the bounding boxes examined using the geometric B-IoU show deviations for certain classes, such as bridges and roads. The

labels indicate that the LLM did not incorporate any new objects into the generated data without being prompted to do so. While semantic hallucinations were not observed, minor geometric deviations in dimensioning cannot be fully ruled out, as they would not be captured by this method. When interpreting the experiments carried out and using the proposed framework, several limitations must be taken into account. The framework was not developed with the aim of generating point cloud data that faithfully reproduces real scan conditions. The absence of an explicit sensor model may introduce a synthetic-to-real gap and limits generalisation to real-world data. The evaluation shows scan patterns that reflect some essential characteristics of real data acquisition, but we need to implement it in future developments. The framework focuses on the variance of point cloud generation. The paper shows that the challenge is not data generation alone, but the controlled, systematic variation of data. Even with model-based approaches, the variance remains in the initial models. In contrast, the variance in SYN3D-LLM is constrained by user prompts, creating a wider variation space.

In particular, for evaluating post-processing steps in point cloud pipelines. Algorithmic methods can be applied to the generated data from SYN3D-LLM and evaluated on constrained data, for example, in the context of ceiling reconstruction.

Outlook

Now we demonstrate our generated data in a short:

Exploratory qualitative case study: that uses the Scan-to-BIM reconstruction approach from Zbirovskỳ and Nežerka (2025) to reconstruct ceilings. We have not yet achieved any results for walls or other components. The SYN3D-LLM framework still needs improvement in this regard. For the Cloud2BIM approach to work, a density of 0.002 meters should be used during generation. The results can be seen in Figure 12. The reconstructed lower ceiling matched the point cloud accurately, but the upper ceiling did not.

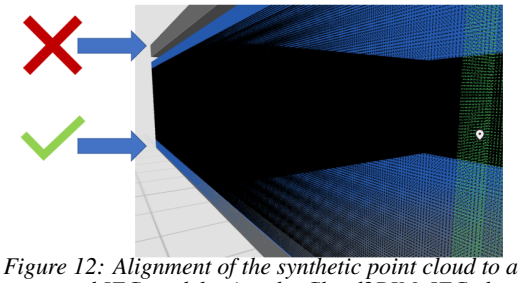

Figure 12: Alignment of the synthetic point cloud to a reconstructed IFC model using the Cloud2BIM. IFC elements shown in grey, point cloud shown in blue, black, and green.

Future work should investigate stopping criteria for controlled refinements in the iteration process and for optimising the computational cost. Furthermore, agent-based approaches are being considered for future development, similar to the Model Context Protocol approach for IFC-based modeling by Nithyanantham et al. (2025). Our next approach could leverage tools that parameterize different point cloud types, enabling more detailed data generation based on user inputs.

Conclusions

This paper presents the SYN3D-LLM framework and demonstrates the potential of synthetic point cloud generation via self-discussing LLMs.

Regarding **RQ1**, the evaluation shows that the framework reliably generates executable code across all tested configurations. The results indicate that helper functions, particularly the G2 configuration, improve first-iteration pass rates. Configurations without helper functions (G0) require additional iterations but still converge to valid outputs within the allowed number of tries.

Regarding **RQ2**, the generated point clouds show plausible structure, but limited geometric precision in complex scenes. Semantic accuracy reached 100% for the required IFC classes specified in the input prompts. But the infrastructure scenes, such as roads and intersections, remain challenging, with larger geometric deviations observed.

Overall, SYN3D-LLM represents a promising approach for generating synthetic point clouds at scale, variations, and for testing reconstruction workflows in the AECO domain. Further optimization is needed, particularly for complex infrastructure scenarios.

Abstract

Large Language Models (LLMs) are emerging as natural-language interfaces for Building Information Modeling (BIM), successfully achieving information retrieval, but no benchmark exists to evaluate their ability to edit Industry Foundation Classes (IFC). We introduce BIBIMBAP, a Text-to-BIM benchmark with 100 curated tasks covering Create-Read-Update-Delete (CRUD) operations across spatial, geometric, topological, numeric, and conceptual categories. Each task includes a natural-language prompt, an IFC model, expected structured outputs, and test scripts for automated evaluation. Baseline results show limited performance (best: 50.2%) and frequent failures in constraint preservation and spatial reasoning, with some correct outputs achieved despite flawed reasoning.

Introduction

Architectural planning can be seen as an iterative process in which design ideas develop through repeated cycles of interpretation and action rather than through linear refinement (Schon and Wiggins, 1992). This process ranges from fundamental conceptual revisions to detailed modifications of façades, individual spaces, or technical components. In BIM-based planning (Building Information Modeling) with computer-aided design (CAD) tools, this is reflected in a dynamic workflow in which individual elements or component groups, such as walls, slabs, and openings, are iteratively created, moved, deleted, or duplicated to explore alternatives of design trade-offs. The resulting solutions aim to satisfy functional and architectural requirements and comply with regulatory constraints.

Several approaches have been proposed to automate the design workflow. More recently, LLM-based approaches have been investigated that enable Text-to-BIM generation, e. g., Du et al. (2024); Deng et al. (2025). These approaches follow an *automated programming* paradigm in which LLMs generate code from a user prompt to create IFC files. While such one-shot approaches may produce simple models, they do not support the iterative refinement process typical of architectural planning. This has changed with the emergence of tool-augmented LLM frameworks, e.g., using the Model Context Protocol (MCP), which define communication interfaces that allow LLMs to access Application Programming Interfaces (APIs) that tools often provide. LLMs thereby understand which functions are available and how to use them. This unlocks LLMs' access to single CAD tools themselves and, more importantly, enables iterative Text-to-BIM workflows.

An example of such a future dialog-oriented assistive workflow is shown in figure 1. Within this agent-based Text-to-BIM workflow, planners can iteratively develop design proposals, refine layouts, or elaborate specific design details through natural language interaction. The LLM can not only provide suggestions but also execute incremental modifications to the building model directly. Over successive design revisions, planners can gradually converge toward a coherent design, reflecting the iterative nature of established architectural planning practices.

However, an iterative design process requires new levels of spatial and contextual understanding by the LLM, because it needs to understand the current design context from the targeted object, design intents, and causal implications. It is debated in the literature whether LLMs exhibit these robust geometric, spatial, topological, and numerical reasoning capabilities required for engineering (Dong et al., 2025; Ploennigs et al., 2025) and architecture concepts (Ching, 2023). Therefore, it is necessary not only to demonstrate what may be possible but also to identify the current limitations of Text-to-BIM systems and to determine whether these limitations stem from the underlying LLMs or from system-level constraints.

Benchmarks are an important instrument for uncovering these limitations and for establishing baselines against which future research can measure improvements. As discussed, end-to-end test do not serve well the iterative refinement approach as they do not ensure to cover all actions, particular update actions. Therefore, we propose to *benchmark the underlying atomic actions*, as their reliable execution is a prerequisite for any iterative Text-to-BIM workflow. Evaluating whether LLMs can execute individual CRUD actions correctly provides: (i) relevant insights into where and why LLMs fail with simple actions; (ii) allow to recombine those actions into iterative workflows; and (iii) avoid instable actions in such workflows.

The state-of-the-art analysis in the next section will show that, to the best of the authors' knowledge, no LLM benchmark exists that systematically evaluates all CRUD actions (Create, Read, Update, and Delete) on IFC models. To address this gap, we present a **B**enchmark for **I**nstructional **BIM**-**B**ased **A**utomated **P**rogramming (**BIBIMBAP**), which is systematically designed to eval-

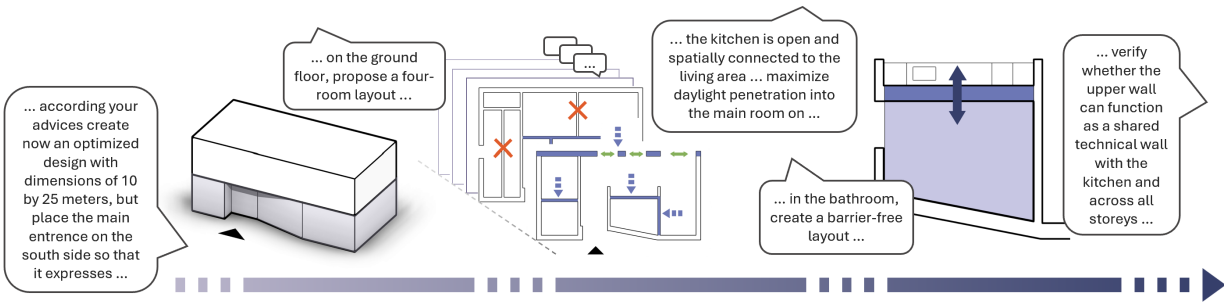

Figure 1: Example of an agentic Text-to-BIM process. Through stepwise interaction with the planner, the LLM provides suggestions, plans changes, and executes the actions in the model, without the planner using the CAD tool itself.

uate Text-to-BIM systems across a curated suite of BIM tasks spanning the full CRUD spectrum. BIBIMBAP emphasizes (i) manipulation tasks that require spatial/geometric and topological reasoning within IFC models, (ii) structured outputs for retrieval tasks that enable direct comparison to ground truth, and (iii) automated tests and evaluation metrics that diagnose where systems fail (e. g., existence, location, dimension, and integrity constraints) without relying on human interpretation. By providing an automated benchmark with tasks, reference IFC models, and executable tests, BIBIMBAP aims to make Text-to-BIM research more reproducible and to support objective comparisons of both language models and the BIM tool interfaces they operate through. Due to its atomic nature, the supported BIM tool interfaces, can be low level frameworks, tool APIs as well as MCPs to test all LLM-based automated programming approaches. Therefore, BIBIMBAP's contributions are:

- A set of Text-to-BIM tasks spanning the full CRUD operations and multiple reasoning categories.
- A prompt grammar (operator/operand/context specifiers) that standardizes task formulation and supports systematic analysis and extensibility.
- An automated pipeline with procedural tests and fine-grained evaluation metrics (existence, location, dimensions, correctness, and IFC integrity constraints).
- Baseline experiments: A validation of the benchmark across different LLMs.

Related Work

This section reviews existing benchmarks and systems for natural-language interaction with BIM, with a focus on how they evaluate retrieval and manipulation tasks. While a growing body of work addresses isolated aspects of Text-to-BIM, like information retrieval, specific generation scenarios, or object recognition, there is currently no widely adopted benchmark that systematically evaluates *all* BIM CRUD operations within a unified framework. Existing benchmarks can be distinguished into: information retrieval benchmarks, datasets related to creation and modification, and end-to-end BIM CRUD approaches. BIBIMBAP is positioned with respect to the remaining gaps across these categories.

Information Retrieval Benchmarks

IFC-Bench-v1 provides curated IFC reference models paired with natural-language queries to assess BIM comprehension and reasoning in an agentic NL-to-IFC retrieval setting, primarily covering the *Read* operation (Hellin et al., 2025). Tasks are grouped according to whether the requested information is directly, indirectly, or insufficiently available in the model. The released dataset lacks explicit class annotations, which requires manual re-categorization, and many tasks rely on open-ended answers evaluated via an LLM-as-a-judge approach, which can be costly and unreliable for free-form responses (Wei et al., 2024). In contrast, our benchmark emphasizes structured outputs, explicit evaluation criteria, and a task taxonomy spanning all CRUD operations and multiple reasoning perspectives (e. g., geometric and topological), enabling finer-grained and reproducible evaluation.
BIMCoder (Liu and Chen, 2025) introduces 1,680 retrieval tasks grouped into object-, location-, and relationship-based queries, which largely correspond to basic retrieval scenarios in our taxonomy. Its evaluation is based on exact matching of generated IFCQL queries and execution accuracy. Other retrieval-focused datasets include *BIN-LQ* (Wang et al., 2022), which contains 2,065 direct questions about element properties or quantities, and *BIM-NLQ* (Yin et al., 2023), which supports ontology-aided querying but lacks explicit ground-truth answers, limiting quantitative evaluation. *BuildingQA* (Mulayim et al., 2025) addresses natural-language question answering over building knowledge graphs represented in RDF/TTL format, but it operates on a different data representation and does not target IFC-based manipulation.

Further AI-Driven BIM Benchmarks and Datasets

Beyond retrieval, several benchmarks address aspects of BIM creation and modification without focusing on Text-to-BIM interaction. *IFCNet* provides single-entity IFC files spanning many IFC classes, enabling controlled evaluation of geometry- and semantics-based methods, but it targets object-level recognition rather than multi-step authoring or manipulation workflows (Emunds et al., 2021). In as-built reconstruction, *BIMNet* offers a scan-to-BIM dataset with metrics that explicitly capture geometric and topological reconstruction quality (Liu et al., 2025). Al-

though it is not driven by natural language, its emphasis on explicit constraint checking aligns with the requirements of reliable IFC editing. *ResBIM* contributes a synthetic paired dataset of 2D floor plans and corresponding BIM models for reference-based generation (Liang et al., 2026).

BIM CRUD Approaches

Text-to-BIM systems translate natural-language intent into executable modeling actions, often via multi-agent decomposition and tool or API calling, enabling the generation of editable, semantically rich building models (Du et al., 2024; Dong et al., 2025). Recent work frames BIM authoring as a computer-use problem: BIMgent employs multimodal LLM agents to plan and execute GUI-level actions in BIM software (Deng et al., 2025). More recently, MCP-based approaches aim to standardize tool access for LLMs to query and edit IFC models directly, as exemplified by *MCP4IFC* (Nithyanantham et al., 2025).

Despite increasing capabilities across Create, Update, and Delete operations, evaluation remains fragmented. Existing studies typically report task-specific success rates or qualitative outcomes, but provide limited standardized, fine-grained diagnostics of geometric correctness, topological validity, and constraint integrity across the full CRUD spectrum, motivating the need for a dedicated benchmark.

Benchmark

We introduce **BIBIMBAP**, a benchmark of 100 tasks for evaluating Text-to-BIM systems on both information retrieval and BIM model manipulation. Tasks are organized along two dimensions: CRUD operation (Create, Read, Update, Delete) to reflect practical BIM workflows, and reasoning requirement, including direct, spatial-geometrical, topological, numeric-calculative, and conceptual tasks. Beyond evaluating LLM capability, BIBIMBAP also evaluates the Text-to-BIM system itself by checking whether the required BIM operations are available and exposed in a way that models can use reliably. To support broad adoption, the benchmark framework provides a unified interface that allows easy integration of different system backends, including direct code-generation pipelines, MCP-based tool interfaces, and custom implementations. The evaluation operates on native IFC, for both input and output, as it is an open standard that most proprietary BIM systems can import and export, making BIBIMBAP applicable to any Text-to-BIM system regardless of implementation details.

Benchmark Architecture

Each task consists of (i) a natural-language prompt, (ii) a task-specific IFC file containing only the elements needed for the task, (iii) a Python test script that computes evaluation metrics, and (iv) for retrieval tasks, a structured output schema. The IFC files were created specifically for individual tasks and include only the information needed to solve them. At the same time, they are designed so that the task is not trivial; for example, retrieval tasks may include multiple competing candidate objects. Figure 2 illustrates the execution flow. Tasks are executed independently by design, as they represent atomic steps within an iterative design process, such as creating a single wall, inserting a door, moving one element, or retrieving one quantity. This is a deliberate methodological choice: the benchmark does not aim to evaluate the solving of complete multi-step design objectives, such as generating an entire house from a single prompt, but rather the model's ability to reliably perform individual, well-defined atomic actions that are prerequisites to reliably fulfill multi-step objectives.

For automated evaluation, the system prompt discourages the LLM from asking clarification questions. The benchmark framework allows users to configure both the evaluated LLM and the number of samples per task. All model outputs are logged, and modified IFC files are stored for Create, Update, and Delete tasks. Evaluation is deterministic and depends on the task type: retrieval tasks expect structured outputs from the LLM with explicit schemas for direct comparison with ground truth, avoiding LLM-as-a-judge evaluation Hellin et al. (2025). Create, Update, and Delete tasks use task-specific test scripts written in Python, using IfcOpenShell, which analyze the original and modified IFC files to compute the metrics. Each test script was validated by a second person to assure correctness.

Task Categorization

As Text-to-BIM systems do not fail uniformly across different tasks, we use distinct categories to systematically separate different error modes, enabling not only to diagnose that tasks fail, but rather understand failure origins. The benchmark is therefore structured into five main categories: direct tasks, spatial-geometrical reasoning, topological reasoning, numeric-calculative reasoning, and conceptual understanding. Each category contains a total of 20 tasks. The first three categories are subdivided according to the four CRUD operations, with five tasks assigned to each one, while the numeric-calculative and conceptual understanding categories consist of 20 retrieval tasks each. By structuring the benchmark along these categories, we make explicit which aspects of BIM understanding current LLM-based systems struggle with, rather than reporting a single aggregated performance score, thereby enabling to assess a models specific strengths and limitations.

Task Complexity

The general difficulty of individual task categories results from the information provided in the prompt. Direct tasks contain explicit information about the targeted elements, so that the LLM can identify them concretely by their ID. Geometric-spatial, topological, numeric-calculative and conceptual tasks contain a prompt component with implicit information about the targeted elements. Based on a contextualized description (e.g. "element that is enclosed by"), the LLM has to derive the targeted elements through model properties and spatial relation-

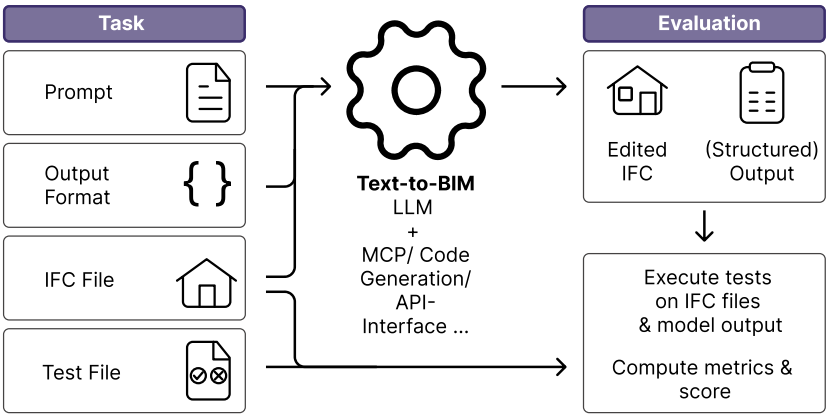

Figure 2: Benchmark architecture: the Text-to-BIM (LLM) takes a prompt and an IFC file (with an output structure for retrieval tasks) and produces an edited IFC file and optional structured output, which are evaluated using the test file and the original IFC model.

ships. Across all CRUD operations, domain-specific contexts, properties and expressions are applied to address realistic and practice-oriented tasks. This is particularly evident in numeric-calculative and conceptual tasks: Numeric-calculative tasks require mathematical reasoning and domain-specific knowledge for their solution, while conceptual tasks require the capacity to assess abstract architectural relationships.

Direct Tasks

These tasks test LLM capabilities for basic BIM operations and examine whether fundamental planner intentions can be understood and correctly executed without requiring complex reasoning. Each prompt includes all required details (e. g., element IDs, coordinates, and dimensions), so the task can be solved directly, as all information for understanding the scene is explicitly provided in the prompt. Examples include moving objects within a local coordinate system, deleting objects specified by explicit element IDs, and adding objects with numerically defined dimensions, placement, and orientation (e. g., ‘‘Add a wall of length 15 m starting at (0, −10)‘‘).

Spatial-Geometrical Tasks

Spaces are configurations of surfaces, volumes, and openings whose effects emerge through placement, orientation, scale, and angular relations, and in building design these configurations determine how spaces, functionality, and spatial perception are produced. Spatial-geometrical tasks therefore test whether an LLM can reason about such spatial and geometric relationships. The model must identify the correct elements based on shape cues (e. g., ‘‘the room that is not a perfect square‘‘) by computing properties such as lengths, perimeters, or bounding-box dimensions. It should also follow spatial instructions (e. g., ‘‘the door between doors X and Y‘‘) by understanding relations such as between, next to, or opposite. These tasks assess whether an LLM actually reasons about the spatial alignment and require the model to construct an internal spatial representation and derive properties such as relative position, betweenness, and shape characteristics.

Topological Tasks

Topological reasoning tasks test whether an LLM can understand functional and technical relationships such as adjacency, enclosure, openings, connectivity, and contact. In building design, these topological relations generate functionality and spatial organization, for example, whether a wall fully separates a kitchen from a living room or defines a shared space. While some relations are explicitly stored in IFC (e. g., a column assigned to the space it belongs to), many important relations are not represented directly and must be inferred through higher-level topological reasoning. These tasks, therefore, require the model to reason over collections of elements, such as identifying how multiple walls jointly form an enclosure or determining which walls separate interior from exterior. Examples include creating a connection between an interior space and the outside by adding a window.

Numeric-Calculative Tasks

In building design and planning, a robust understanding and mathematically correct handling of quantities, areas, volumes, and perimeters is essential, as building regulations frequently specify numerical constraints, and such quantities form the basis for cost estimation, and rentable area calculations used in economic evaluations. These tasks require the LLM to retrieve numeric properties from IFC elements and perform multi-step calculations to produce a final result. They often involve selecting the correct elements (by ID or filter), choosing the appropriate measurement (net vs. gross), aggregating across multiple elements, and applying deductions such as subtracting openings from wall surface areas. As such, they test multi-step reasoning rather than direct value lookup. For example, ‘‘Provide the total net wall area of walls A, B, and C‘‘ requires extracting each wall’s surface area after accounting for openings and then summing the values.

Conceptual Tasks

Architectural design builds on an understanding of how architectural concepts emerge from the interplay of spatial, geometric, and topological properties. For example,

functionality is often produced through the organization and hierarchization of spaces, while spatial perception can arise from geometric form, placement, and light. These tasks, therefore, require an understanding of formal and functional architectural concepts that emerge from spatial configuration rather than from explicitly stored properties. Guided by principles of architectural perception and design (Ching, 2023), we distinguish four categories: spatial–geometric relationships, organizational structures, openings and light, and ordering principles. Solving these tasks often requires combining multiple types of reasoning described earlier. For instance, identifying a corridor requires understanding orientation, proportion, and connectivity patterns, even if the space is not explicitly labeled.

Prompt Construction

To ensure a high CRUD task coverage and systematic testing of LLM reasoning capabilities, all prompts follow a structured grammar (figure 3) that allows to create variants of prompts. Each prompt includes an *operator* that denotes the intended operation (e. g., create, rotate, provide); an *operand* that denotes the target building elements or the desired information subject to the task; *operation specifiers* that constrain the request (e. g., required properties, relations, or filters), and *context specifiers* that specify the relevant context elements either implicitly or explicitly. This allows similar tasks to address different reasoning categories by replacing or omitting individual parts of the prompt. For example, a task could be direct with the explicit context specifier "with <id>", while by using the context specifier "which is parallel to wall with <id>", the task would be a spatial-geometrical one.

Evaluation Metrics

To quantify performance, we define evaluation metrics. Because tasks differ, it is impractical to define a fixed set of metrics for all of them. Therefore, we define a set of metrics for each CRUD category. The set of metrics and their assignment to task categories is described in table 1. For each task t, we calculate $\mathrm{score}(t)$, and the overall benchmark score is the average of $\mathrm{score}(t)$ over all tasks.

$$\mathrm{score}(t) = \frac{\text{no. of metrics satisfied for } t}{\text{no. of metrics evaluated for } t}.$$

These metrics provide more insights into where an LLM fails, rather than simply determining whether a task was completed correctly. For example, the task "Create a door with the size of 2 by 1 meters in the wall" is evaluated using the metrics *Object exists*, *Correct location*, *Correct dimension*, and *Integrity assured* (a corresponding opening must exist that voids the wall and is filled by the door). The integrity metric is task-specific. For example, inserting a wall to enclose a room requires topological relationships to the other walls. Deleting an element requires that IFC relationships (e. g., *IfcRelContainedInSpatialStructure*) are also removed. Furthermore, the integrity metric verifies that no clashes are introduced, the spatial hierarchy is preserved, and non-target elements remain unchanged. Retrieval tasks use *Correct answer*, comparing the structured output against ground truth.

Table 1: Evaluation metrics and applicable task categories.

Metric	Description	Categories
Object exists	Required object exists in the edited IFC file	Create
Object does not exist	Referenced object does not exist in the edited IFC file	Delete
Correct location	Object of interest is in the correct location	Create, Update
Correct dimension	Object of interest has the correct size	Create, Update
Integrity assured	No constraints are violated	Create, Update, Delete
Correct answer	Model provided the correct answer	Retrieval

Experiments

We evaluate Claude Opus 4.6, GPT-5.4, Gemini 3 Flash, GPT-5.2, GPT-5 Mini, and GPT-4.1 in a minimal tool-based setup implemented with the LangChain framework. Each model is given access to a single tool, `execute_ifc_code`, which runs Python code with IfcOpenShell in a sandboxed environment. The models may call this tool multiple times to solve a task. To prevent infinite loops, we limit the number of tool calls at 25 per task. No task-specific examples or hints are provided, which ensures a fair baseline setting. All models use the same system prompt, agent framework, and tool access. To demonstrate that the top-performing models produce consistent results across runs, we run the three newest models (Claude Opus 4.6, GPT-5.4, and Gemini 3 Flash) three times each and report mean scores with standard deviations. The remaining three models (GPT-5.2, GPT-5 Mini, and GPT-4.1) are evaluated with a single run.

Code-Execution Pipeline

The benchmark evaluates LLMs through a code-execution pipeline rather than direct IFC text editing. When the LLM receives a task prompt, it generates Python code that uses the IfcOpenShell library. This code is then passed to the `execute_ifc_code` tool, which runs it in a sandboxed subprocess with the IFC file already loaded as the variable `ifc`. For editing tasks, the LLM must call `commit()` to save the changes. Geometry is modified through the IfcOpenShell API, for example by creating representations with `ifcopenshell.api.run()`. The LLM may make several tool calls in sequence, first to inspect the model and then to apply the required changes. For example, consider the prompt: *''Delete all doors on the first floor.''* The LLM may first generate code to inspect the IFC model and find which storey corresponds to the first floor and which doors belong to it. After receiving the result, it then gener-

Operator	Operand	Operation Specifiers	Context Specifiers	
Create	Door	with the size 2 by 1 meters	in the wall	with id <id>
Rotate	Wall	by +45° around its center	which is parallel	to wall with id <id>
Provide	net floor area	of the room	with id <id>	

Figure 3: Visualization of the prompt structure using the grammar with three examples.

ates a second code snippet to delete those doors and calls `commit()` to save the changes. All the generated code is executed through the `execute_ifc_code` tool.

Our goal is to establish strong baseline results that can serve as a reference point for future improvements. Failures on particular task types highlight open challenges (e. g., geometric reasoning, IFC relationship handling, and BIM-aware representations), while strong performance indicates tasks that current LLMs already support reliably.

Results

Table 2 summarizes the overall model performance with a breakdown by category. Overall, the newer models achieve higher scores; however, the performance still remains low, which shows that Text-to-BIM manipulation is still challenging for an LLM. Claude Opus 4.6 achieves the best overall average score (50.2%), followed by GPT-5.4 (31.3%), Gemini 3 Flash (30.8%), GPT-5.2 (30.5%), GPT-5 Mini (25.0%), and GPT-4.1 (23.9%). The top three models show consistent results across repeated runs. Even the best model solved only about half the tasks on average, which highlights the difficulty of reliably using LLMs for CRUD and fulfilling all evaluation criteria.

Performance differences across categories show clear trends. Direct tasks are relatively easy because they often provide explicit identifiers, coordinates, or dimensions. Spatial-geometrical and topological tasks are harder because they require selecting the correct target elements from context and reasoning about relationships or placements. Numeric-calculative tasks are the most difficult for all models, with consistently low scores. These tasks typically require aggregating information across multiple elements and computing quantities from geometry (e. g., areas, volumes, and totals). Models often produce partially correct code but miss elements, apply an incorrect quantity definition, use wrong unit scale or return an incorrect value. The consistently low scores on numeric-calculative tasks suggest that BIM reasoning remains a major limitation for the used LLMs.

Tool usage patterns differ across models. All models rely heavily on the tool interface to solve tasks. Claude Opus 4.6 makes the most tool calls, averaging around 4.9 per task, followed by Gemini 3 Flash with about 3.5 calls, GPT-4.1 with 2.7 calls, GPT-5 Mini with 2.5 calls, GPT-5.2 with 2.2 calls, and GPT-5.4 with only 1.67 calls. Notably, Claude Opus 4.6 achieves the highest overall score while also using the most tool calls, suggesting that its iterative strategy contributes to its stronger performance.

Table 3 shows the performance of the LLMs by CRUD operation. Create is the easiest operation in the current benchmark, since most creation tasks focus on simple building elements with explicit parameters. Claude Opus 4.6 reaches 81.1% on Create tasks. Retrieve is the most difficult because it requires both reliably identifying the correct target elements and computing or formatting the answer. Update tasks require precise geometric modifications, while Delete tasks can appear easy, but many failures arise from integrity requirements: deleting an element often requires removing related relationships or associated elements (e. g., when a door is deleted, its associated opening also needs to be deleted). As a result, a model may remove the main element but still fail the task if the IFC remains inconsistent.

Figure 4 plots the accuracy across the evaluation metrics and highlights a consistent limitation: *integrity_constraint* is the most challenging criterion for all models. In contrast, the *object_exists* and *object_not_exists* constraints achieve higher scores, indicating that models can often create or delete an entity but still struggle to maintain correct IFC relationships and constraints. Similarly, *correct_location* and *correct_dimensions* remain low for most models, which is critical for practical BIM authoring because a created element is only useful if it is placed correctly and has the correct dimensions. For retrieval tasks, *correct_answer* remains low, suggesting that even when the model can access the relevant elements, it often fails to compute or properly format the final answer.

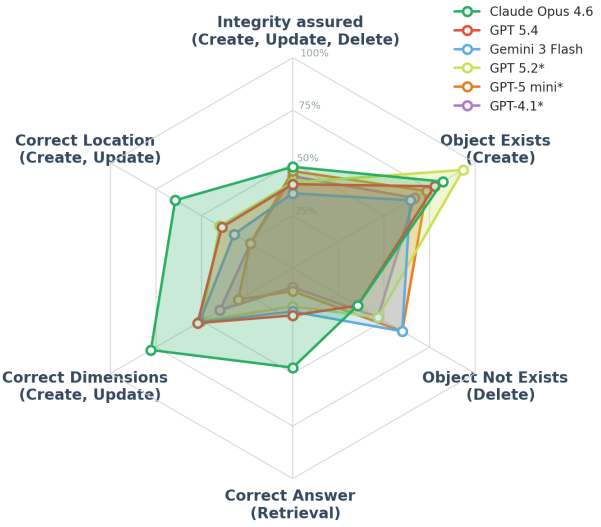

Figure 4: Each model's performance across the six evaluation criteria.

Overall, these results highlight both the promise and the limitations of current LLMs. Current models can of-

*Table 2: Model performance by category and overall average score (%). The top three models are averaged over three runs (± std. dev.). Models marked with * are single-run results.*

Model	Direct (20)	Spatial (20)	Topological (20)	Numeric (20)	Conceptual (20)	Overall Score
Claude Opus 4.6	65.83 ± 0.16	63.89 ± 0.22	53.06 ± 0.19	38.33 ± 0.24	30.0 ± 0.21	**50.22 ± 0.22**

Gemini 3 Flash	65.42 ± 10.4	40.97 ± 1.73	21.11 ± 3.37	20.00 ± 5.00	6.67 ± 2.33	30.83 ± 1.91
GPT-5.2*	52.50	34.58	35.42	5.0	25.0	30.50
GPT-5 Mini*	50.94	25.83	25.83	0.0	25.0	25.00
GPT-4.1*	38.33	30.00	31.25	0.0	20.0	23.92

Table 3: CRUD success rate by model (%).

Model	Create	Read	Update	Delete
Claude Opus 4.6	81.1±0.2	47.3±0.3	61.5±0.2	18.9±0.1
GPT-5.4	56.0±0.3	22.4±0.0	50.4±0.3	20.0±0.2
Gemini 3 Flash	45.6±8.4	20.6±1.1	46.7±2.2	37.8±6.9
GPT 5.2*	58.9	18.2	51.1	26.7
GPT-5 Mini*	31.2	10.9	55.5	43.3
GPT 4.1*	29.4	9.0	60.0	36.6

ten perform basic Create and Delete actions, and larger, stronger models benefit from iterative tool use. However, robust BIM manipulation requires more than producing valid code: it also requires correct element selection, correct computations, and consistent IFC integrity constraints. The results show, that no model manages to address all those aspects.

Examples

To illustrate task complexity, we give one example each for success and failure cases. For each, we show the IFC models alongside the corresponding prompts, as well as the resulting IFC models.

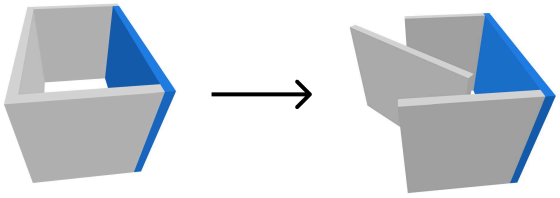

Figure 5: Successfully solved spatial-geometrical task of Claude Opus 4.6

Figure 5 shows a spatial-geometrical task that was successfully solved by Claude Sonnet 4.5. The main challenges are identifying the correct wall to rotate and rotating it about its center while ensuring the correct placement after rotation. The LLM first extracted the direction of the reference wall. It then extracted the directions of the other walls to find the one with the same direction, computed its rotation center, and finally derived the new direction and location. This process required six tool calls in total.

Figure 6 shows an example of a conceptual task. The task is to identify the door that is perceived as the entrance only by reasoning about the architectural concept. GPT-5.4 tried to find keywords in door objects that indicate their

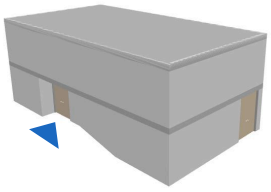

Figure 6: Example of a conceptual task. GPT-5.4 solved it by choosing the right door randomly.

use as the entrance. Because no such keyword was present, the model selected the first door as the answer, which happened to be correct by chance, even though the model was not able to solve the task in a principled way. In other tasks in this category, the LLMs exhibited similar issues and produced errors after making too many tool calls.

Another common failure was incorrect unit handling: models sometimes used wrong units or returned incorrect results despite explicit unit specifications.

Limitations

The current version of the benchmark consists of a limited number of 100 prompts. Future versions aim to expand the task pool to improve statistical robustness and broader coverage. Although the benchmark covers all four CRUD operations, retrieval tasks represent the largest share. This is partly by design: the numeric-calculative and conceptual understanding categories consist exclusively of retrieval tasks, and providing quantifiable, directly evaluable answers for these is itself a contribution of this work. Future versions of the benchmark will increase the proportion of Create, Update, and Delete tasks to achieve a more balanced distribution across operation types.

The IFC files used in the evaluation are generally applicable to other tasks, but they primarily serve as task-specific test environments that include only the elements required for the respective task. We therefore selected small models to keep the benchmark focused on individual tasks and to ensure a clear evaluation. However, this also means the benchmark does not fully reflect realistic BIM authoring settings, which are typically larger and noisier and exhibit higher structural complexity (e. g., more storeys and a wider variety of building elements).

Our tasks are instructions for atomic operations. In real use, users often interact with an AI system over multiple turns to refine requests and refer to earlier actions

(e. g., "Undo the last change" or "Now make that window larger"). Those interaction sequences are not part of this work, as models already fail on simple steps.
The evaluation metrics are detailed, but they do not cover all aspects of the BIM authoring standards. The benchmark focuses on hard constraints (geometry, existence, and relationships), but does not evaluate, e.g. whether element naming conventions are followed. We also do not test whether non-geometric properties are preserved in Update tasks; for example, deleting an element and recreating it can count as a correct update even if properties are lost.

Conclusion

This paper introduces BIBIMBAP[1], a benchmark for evaluating Text-to-BIM systems on IFC-based tasks spanning the full CRUD spectrum (Create, Read, Update, Delete) across multiple reasoning categories (direct, spatial-geometrical, topological, numeric-calculative, and conceptual). We report baseline results for several state-of-the-art LLMs in a tool-based setup. Our results indicate that current models can often complete simple actions when parameters are explicit, but they frequently fail on tasks that require geometric or topological reasoning, multi-step computation, or preserving IFC relationships and constraints. These findings highlight that reliable BIM manipulation remains challenging and that progress should be measured with reproducible tests. Overall, BIBIMBAP provides an automated evaluation framework for Text-to-BIM approaches, identifying failure modes and tracking progress over time. We hope it supports both researchers and practitioners in developing more reliable BIM assistants and motivates future work on BIM-aware LLMs and domain-specific training.

A Semantic Framework for Formalizing Stakeholder Information Requests in Construction

Timur Weilbach-Eyüboglu, Cornelius Preidel, and Simon Vilgertshofer
Hochschule München University of Applied Sciences, Munich, Germany

Abstract

The construction industry relies on answering recurring questions, but required information is fragmented across heterogeneous data sources, including digital models, schedules, and documentation. This paper introduces a semantic request framework implementing stakeholder questions as information objects that capture templates, bindings, constraints, and provenance for re-execution and diagnostics. Reusable question templates derived from an exemplar construction process are aligned with established domain ontologies such as *DiCon*, *ifcOWL*, and *BOT*, then operationalized through parameterized graph query patterns over federated knowledge graphs. Instantiated requests bind templates to project instances, enabling evidence-based evaluation of readiness, approvals, constraints, and resource availability.

Introduction

Construction projects require stakeholders to obtain situation-specific information on demand to make informed decisions. Such information needs arise dynamically, depending on the current project state, the actor's role, and the decision context. Typical questions include *"Is this area ready for the next activity?"*, *"Are the required approvals available?"*, or *"Can this task be released under the current conditions?"*. While their wording varies, the underlying intent of these questions is highly recurrent: across projects and roles, stakeholders repeatedly ask structurally similar questions but expect context-specific, evidence-based answers.

These questions are central to production coordination and decision-making. In Lean Construction, they directly relate to constraint analysis, work packaging, and reliable promise-making (Ballard, 2020; Koskela, 2000). From a situation awareness perspective, they express the information required to perceive, comprehend, and anticipate the state of the work system (Endsley, 1995). As such, they determine whether work can be executed safely, correctly, and without disruption. Despite their importance, answering such questions remains difficult in practice. Applied research and industry-informed studies consistently report that the evidence required to assess process readiness or approval conditions is distributed across heterogeneous systems, maintained by different stakeholders, and represented in various formats (Sacks et al., 2020; Čustović et al., 2025). This observation is further reinforced by practice-driven analyses that we conducted in preparation for this paper in close collaboration with industrial partners, based on structured workshops and expert interviews, in which even routine operational inquiries were found to require manual coordination across BIM models, schedules, quality assurance records, safety documentation, and domain-specific planning tools. As no single system provides a unified representation of process dependencies and current states, situational awareness is fragmented, and decision-making becomes time-consuming and error-prone. The core challenge is therefore not a lack of data, but the absence of a mechanism that consistently translates recurring operational questions into verifiable, cross-system information requests. Although construction projects repeatedly pose the same types of questions, these questions are reformulated anew for each system and context, preventing systematic reuse and comparability of answers.

This paper addresses this gap by proposing a semantic request layer for recurring operational information needs in construction. The approach separates stable question semantics from project-specific bindings, allowing the same underlying request structure to be specified consistently across heterogeneous systems and reused across projects. Three contributions are made: first, a formal representation of recurring stakeholder questions as reusable request templates; second, a binding and constraint mechanism that links these templates to project-specific entities and evidence requirements; and third, a prototype design for operationalizing such requests over federated graph-based project data. Execution-time readiness and work-release decisions serve as the exemplar application. Automated natural-language interpretation is discussed as a prospective interface to this layer, but is treated as future work rather than part of the present evaluation.

Related Work

From a lean production-control perspective, questions such as whether work can be released or whether an area is ready for the next task belong to make-ready planning, constraint analysis, and reliable promise-making (Ballard, 2020; Ballard and Howell, 1998; Koskela, 2000). These decision situations depend on multiple prerequisites spanning workforce, information, materials, equipment, prerequisite work, safety, and external conditions.

At the same time, BIM and construction digital twin research consistently reports that the required evidence is distributed across domain tools, making the problem one of information access rather than data availability (Sacks et al., 2018, 2020; Čustović et al., 2025). Ontology-based approaches address this fragmentation by providing shared semantic foundations. Foundational ontologies such as *ifcOWL* (buildingSMART International, 2025) and the *Building Topology Ontology (BOT)* (Rasmussen et al., 2020) support graph-based representations of building elements and spatial structures. Workflow-oriented ontologies extend this scope toward construction processes, resources, states, and information objects, most notably the *DiCon* ontology suite (Zheng et al., 2021). Related work further specializes these ideas for production control, safety, and digital twin integration (Farghaly et al., 2024; Speiser et al., 2025; Schlenger et al., 2025). While these ontologies provide rich, machine-interpretable models of construction entities, processes, and states, their focus remains on the supply side of information modeling. They describe what data exists and how it can be linked. However, they are not designed to explicitly represent the structure of stakeholder questions or the decision logic for combining evidence from different domains. Competency questions used in ontology development primarily serve validation and illustrative purposes, but they are not formalized as reusable models of operational information needs (Zheng et al., 2021; Sacks et al., 2020). As a result, recurring process-oriented inquiries, such as readiness or approval checks, remain implicit and system-specific. In parallel, significant research has focused on improving information retrieval from BIM models. Early approaches introduced domain-specific query languages and visual query tools that operate directly on IFC or *ifcOWL* schemas, such as *BIMQL* (Mazairac and Beetz, 2013) and *QL4BIM* (Daum and Borrmann, 2014). These languages enable expressive, schema-aware queries for building models. However, they require users to be familiar with underlying data schemas and primarily address model-internal structures, geometric properties, and element relationships. More recent work increasingly uses natural language processing to translate user queries into formal graph queries. Ontology-aided semantic parsers and question-answering systems enable multi-constraint queries over BIM models for non-expert users (Yin et al., 2023; Nabavi et al., 2023). Recent work also explores LLM-based natural-language retrieval directly over IFC-encoded BIM models through agentic workflows (Hellin et al., 2025). These approaches improve access to BIM-centered information, but they generally focus on individual questions rather than on model data or closely related semantic extensions. By contrast, the present work formalizes recurring operational question types as reusable semantic request templates that can be instantiated across project contexts and resolved against federated cross-domain evidence. Thus, the contribution is not a direct NL-to-query interface, but an intermediate semantic request layer that such interfaces could use. To enable cross-system access, research on federated knowledge graphs proposes technical architectures for linking and querying heterogeneous, domain-specific graphs (Teclaw et al., 2024; Pauwels, 2014). Such federated approaches provide a robust infrastructure for cross-domain querying and align well with the digital twin vision. Nevertheless, they primarily address schema alignment and data availability. They do not specify how operational questions should be represented, nor how complex dependencies across federated sources can be captured in a reusable and decision-oriented manner. Users are still required to formulate explicit queries or rely on system-specific interfaces. Across these research streams, a common limitation becomes apparent. Existing ontologies, query systems, and federated graph architectures excel at modeling and accessing construction data, but they do not provide a structured semantic layer for representing recurring stakeholder questions. In particular, operational inquiries that combine spatial, temporal, procedural, and administrative dependencies, such as readiness to release work in lean production systems (Ballard and Howell, 1998), are not supported at this stage. This gap motivates the present work, which introduces a semantic request layer that formalizes recurring operational questions as reusable request templates, links them explicitly to distributed information dependencies, and connects lean work-release logic with existing ontologies and query infrastructures.

Methodology

We objectify stakeholder information needs by representing them as explicit *InformationRequest* entities in a semantic request layer, rather than ad-hoc *queries* across heterogeneous systems. Each request is a persistent, addressable object with an identifier and links to its *RequestTemplate*, bindings, constraints, and provenance, supporting reproducibility and auditability. We refer to (i) the natural-language question, (ii) its formal representation as an *InformationRequest*, and (iii) the corresponding graph-based retrieval specification (e.g., federated SPARQL). Because such questions recur in specific process situations (readiness, approval, compliance, coordination), we elicit reusable request types and associated constraints using an exemplar foundation process chain while keeping the framework process-agnostic; the foundation and readiness examples serve to instantiate the method, not to define its full scope. The methodology therefore proceeds from observed execution-time questions and process checkpoints to formal representations in a request layer that can be aligned with existing ontologies, such as *DiCon*, *ifcOWL*, *BOT*, and digital twin information models. Figure 1 summarizes how an *execution-time question* is mapped to a template, instantiated via placeholder bindings, and specified for graph-based retrieval over federated project data. Unlike NL-to-query approaches, the request layer specifies the decision condition and admissible evidence paths, not a single system-specific retrieval proce-

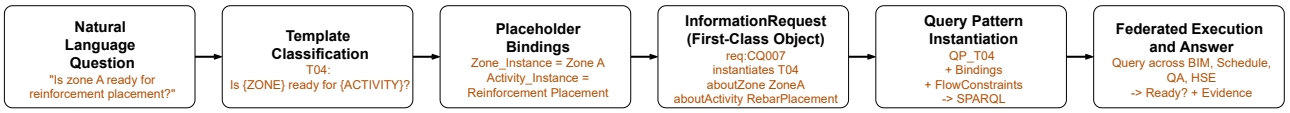

Figure 1: From a natural-language question to an operationalizable graph-based request via the proposed request framework

dure. A future natural-language front-end is envisioned as a candidate-generation layer rather than the locus of semantic interpretation itself. Its role is to rank likely request templates and propose bindings for typed placeholders (e.g., {Zone}, {Activity}, {Entity}) based on the user's utterance and the project context. The semantic request layer defined here then validates these candidates against ontology-based type constraints and admissible relation patterns before execution. Where multiple interpretations remain plausible, the system is intended to request clarification rather than execute an underspecified request.

At the core of the approach is the notion of a *RequestTemplate* (a controlled-natural-language question template). Practitioners may ask many different *execution-time questions* in natural language, but many of these can be understood as instances of a compact set of underlying question types. For example, *"Has the excavation been completed?"*, *"Has the blinding layer been completed?"* and *"Has the reinforcement placement been completed?"* are phrased differently but share the same underlying structure: asking whether a given activity has reached a state of completion. Similarly, *"Has the blinding layer been inspected and approved?"*, *"Has the reinforcement for Footing "F1" been inspected and approved for concreting?"* and *"Has the formwork been inspected and approved?"* conform to a pattern that inquires whether an entity has passed through an approval process in a specific execution context. The methodology, therefore, begins by abstracting from individual wordings to generic question types.

In four workshops with two industry partners (design–build and general contracting), we collected execution-time questions along an exemplar foundation process, clustered them into request types, and iteratively refined template formulations and argument roles with practitioner feedback. The outcome is an initial template library covering completion, approval, readiness, and selected cross-domain request types, designed to be extended through additional templates, mappings, and query patterns. These workshops supported template elicitation and refinement, but they do not constitute a performance validation of the framework.

Each recurring execution-time question type is expressed as a *RequestTemplate*; each template references one or more query patterns (*QP_**) that are intended to become executable after placeholder binding. A template is written in a controlled natural language form with explicit placeholders for variable elements. For instance, a completion template may have the form *"Has **{Activity}** been completed?"*, a tolerance template may be written as *"Is the **{Property}** of **{Component}** within **{Requirement}**?"*, and a readiness template takes the form *"Is **{Zone}** ready for **{Activity}**?"*. The placeholders denote the template's arguments. They are not mere textual gaps but correspond to semantic roles that must be bound to specific project instances, such as activities, components, zones, requirements, or documents. Templates may introduce additional roles where required (e.g., resources, suppliers, time windows, hazards), each of which is typed and described as part of the template metadata. Each template is enriched with an explicit description of its arguments, specifying for each placeholder the type of entity it refers to.

Table 1 shows the resulting *RequestTemplate* representation for a readiness question type (T34), including typed arguments, ontology mappings, and selected template metadata such as flow type and target state.

Table 1: Request template T34 for readiness checking.

Request Template	
Context	Template_ID: T34
Question_Template	*Is {Entity} ready for {Activity}?*
Arguments	Entity: Entity Activity: Activity
Mapping	Entity: `ifcowl:IfcProduct` → `dice:Object` Activity: `dicp:Activity`
Flow_Type	Safety / Workspace; Prerequisite Work; Material; Equipment; External Condition
Target_State	Ready; Approved

Decision logic is captured in a configurable *FlowConstraint* profile linked to each template/request. At runtime, an *InformationRequest* instantiates the template by binding argument roles to project instances, e.g., CQ013 binds Entity=FootingF1, Activity=Concreting, Zone=Zone_FootingF1. Argument types are anchored in shared semantic representations through ontological mapping: activities to *DiCon* Processes (dicp:); components to *DiCon* Entities (dice:) or ifcOWL products (ifc:); and zones to BOT spaces (bot:) or *DiCon* locations (dice:). Similarly, documents map to *DiCon* Information (dici:), resources to equipment/material concepts (dice/dicp:), and actors to *DiCon* Agents (dica:). This structure enables binding placeholders to project-specific instances, such as schedule tasks, model identifiers, zone definitions, or supplier records.

In addition to the argument structure, each template is associated with a characterization of the dependency it addresses and the state being checked. The methodology employs a concise vocabulary of flow types and target states, informed by lean construction practice and represented us-

ing *DiCon* constraint and state constructs (dicv:, dice:). In particular, the flow vocabulary is derived from the eight main flows used in Lean Construction constraint analysis: people, information, shared understanding, equipment, materials, prerequisite work, safe workplace, and external conditions (buildingSMART Deutschland, Fachgruppe BIM und Lean Construction, 2025). In the present paper, this flow vocabulary serves as an exemplar structuring device for one important class of operational requests, rather than as a restriction on the generality of the request layer itself. Target states specify whether the required condition is completion, approval, conformity, cleanliness, safety, availability, confirmed booking, or acceptable external conditions. For approval *requests*, the template semantics reflect that approvals are often granted for a subsequent activity, for example, "approved for concreting", rather than representing a context-free approval status. This improves alignment with work-release decisions, in which the relevant interpretation of an approval is tied to the next planned operation.

These elements are formalized in a request ontology. In this ontology, *RequestTemplates* are represented as instances of a *RequestTemplate* class, with properties that capture argument roles, associated flow types, and target states, as well as links to the corresponding classes in *DiCon*, *ifcOWL*, and *BOT*. The request ontology sits on top of the existing domain ontologies and defines the structure of information requests independently from the particular data instances of a project. It does not introduce new construction entities but explicitly represents the demand side. This allows the framework to refer to question types in the same way that *DiCon* relates to activity or entity types, and it enables reasoning about which data and states must exist to answer a given question type.

A second element of the methodology is to define graph-based query patterns for each template. While the request ontology defines the semantic structure of the *InformationRequest*, the query pattern describes how an instance of that *template type* is intended to be resolved over a set of federated knowledge graphs. For each template, the methodology identifies the relevant paths through the *DiCon* modules and related ontologies that correspond to the flows and states referenced by the template. For a completion *template*, the pattern follows the link from a process to its state and checks whether it is *Completed*. For a tolerance *template*, it follows from a component to a variable representing a measured property. It compares it to a constraint that encodes an allowed range and provides traceability to the originating requirement or specification reference. For booking and availability queries, patterns integrate process time windows with resource allocation or booking states and verify that commitments cover the relevant period.

For readiness *requests*, the pattern becomes more complex because readiness is defined as a conjunction of multiple flow conditions. In the framework, readiness is operationalized as an explicit set of constraints attached to a request, each specifying a flow type, a required target state, and the topic it concerns. The readiness query pattern evaluates these constraints by searching for evidence paths in the federated graph. This supports evidence-based assessment of work release and enables identification of which constraint lacks supporting evidence when a request cannot be satisfied.

These query patterns are defined as reusable graph-traversal templates and, for selected question types, are specified in SPARQL. They specify which node and relationship types must be traversed in the graph, but they do not hard-code project-specific identifiers. Instead, they are designed so that, once a concrete information request binds the template placeholders to specific project entities, the pattern can be instantiated into a graph query specification in SPARQL or another query language.

Scope and limitations. The methodology targets *execution-time* decision support in construction, where stakeholders assess readiness, approvals, constraints, resource commitments, and safety/compliance conditions under short-horizon operational planning. While the request layer is process-agnostic by design, the elicitation and exemplar instantiations in this study focus on foundation construction; extending coverage to additional project phases (e.g., design), trades, or process types primarily requires adding further templates, mappings, and query patterns.

The methodology stops short of implementing the full machinery for automatically translating arbitrary natural-language questions into template instances and for extracting evidence from all operational systems. Instead, it focuses on defining the semantic structure and logical content of templates and patterns, demonstrating how they can be aligned with existing ontologies and support cross-system reasoning about readiness, approvals, constraints, and resource availability.

By proceeding from observed questions in practice through abstraction into templates, formalization in a request ontology, and definition of graph-based query patterns, the methodology provides a coherent framework for representing stakeholder information needs in a manner compatible with ontology-based data integration efforts. It establishes a layer between human questions and machine-interpretable models, serving as a foundation for subsequent work on natural language interfaces, interactive disambiguation of underspecified requests, automated query generation, and integration with digital twin platforms.

Prototype Design and Illustrative Instantiation

This section outlines the current prototype design for operationalizing *InformationRequest*s over federated construction knowledge graphs and illustrates how selected request types are intended to be instantiated. The companion repository (see Data Availability) provides the request ontology, template library, example request instances, and

an evolving query-pattern collection that together specify the proposed execution logic. At the current stage, these artifacts demonstrate how recurring operational questions can be formalized, bound to project-specific entities, and linked to graph-based evidence paths, but they do not yet constitute a fully implemented end-to-end demonstrator. In particular, automated execution across multiple distributed sources, persistence of intermediate check results, and comparative evaluation against manual information retrieval remain future work. Accordingly, the contribution of this section is to make the proposed operationalization concrete and inspectable rather than to report a completed system evaluation. The examples that follow are therefore intended as illustrative instantiations of the request logic, not as an empirical evaluation of end-to-end system performance.

A central design choice is that the framework does not assume universal, one-size-fits-all definitions of readiness, approvals, constraints, and resource availability. Instead, each template is paired with a *constraint profile* derived from decision checkpoints in an exemplar process chain, as described in the Methodology. This keeps request semantics stable across projects while allowing project-specific specialization of what counts as sufficient evidence (e.g., adding/removing constraints or tightening evidence requirements).

Consider the natural language question *''Is zone A ready for reinforcement placement?''*. The framework does not treat *ready* as a literal attribute to retrieve. Instead, the utterance is mapped to template T04, *''Is {Zone} ready for {Activity}?''*. This readiness mechanism is defined for multiple scopes, including zone-level readiness (T04) and entity-level readiness (T34, Figure 2). In the current repository state, zone-level readiness (T04) is specified more concretely than the entity-level readiness pattern (T34), whereas the latter currently remains illustrative. The request ontology constrains this mapping by typing the placeholders: *{Zone}* must resolve to a spatial entity, for example a *BOT* space or an aligned spatial entity concept, and *{Activity}* must resolve to a process concept in the workflow model, for example a *DiCon* process instance or type. These types act as semantic guardrails. They ensure that query construction relies on relations and states that exist in the aligned graph model, rather than producing queries that are formally valid but semantically ungrounded.

The template becomes operationalizable through bindings. For the corresponding request instance, *Zone_Instance = Zone A* and *Activity_Instance = Reinforcement Placement* are bound to concrete graph nodes such as *ex:ZoneA* and *ex:RebarPlacement_ZoneA*. The binding step links the domain language to project identifiers, including schedule IDs, identifiers from digital building models (for example, IFC GUIDs or curated element sets), and document references. In practice, this does not require authoring each request by hand: zones can be resolved from a location breakdown structure or spatial definitions, while activities can be resolved from schedule activities, work packages, or Last Planner tasks. What matters is that bindings persist as explicit links, preserving traceability from the question text to the graph entities used in execution. Operationally, readiness is evaluated as a *set of prerequisites* rather than a single status value: an *InformationRequest* is satisfied only if each required prerequisite can be justified by an evidence path in the federated graph. Accordingly, each prerequisite presupposes that corresponding evidence objects (e.g., inspection records, delivery confirmations, reservations, or safety documents) are maintained in the relevant source systems with sufficient identifier quality and timeliness to support decision-making. In Lean Construction constraint analysis, such prerequisites are commonly organized into recurring flow categories (often referred to as the ''eight flows''): *People* (qualified workforce), *Information* (execution documents), *Shared Understanding* (aligned interpretation and commitments), *Equipment*, *Materials*, *Prerequisite Work* (prerequisite work and trade interfaces), *Safe Workplace* (space availability and safety measures), and *External Conditions*. Table 2 summarizes the mapping from these flow categories to *FlowConstraint* types and typical evidence objects in a federated graph. Within

Table 2: Mapping of Lean ''8 main flows'' to controlled FlowConstraint types and typical evidence objects.

8 main flows	**Flow Constraint Type**	**Evidence Object Types (examples)**
People	Staffing	Crew allocation; Shift record
Information	Information	Latest drawings; Permits
Shared Understanding	Commitment	Weekly plan promise; Handover criteria
Equipment	Equipment	Reservation; Availability confirmation
Materials	Material	Delivery confirmation; On-site stock record
Prerequisite Work	Prerequisite Work	Completion state; Predecessor handover
Safe Workplace	Safety / Workspace	Risk assessment; Traffic setup
External Conditions	External Condition	Weather check; Site restrictions

Note: Flow types and target states are controlled vocabulary terms; labels shown here are human-readable.

the request ontology, these flow categories are encoded via *FlowConstraint* objects attached to an *InformationRequest*. Each *FlowConstraint* specifies a flow type, a target state, and the topic it concerns, with approvals modeled

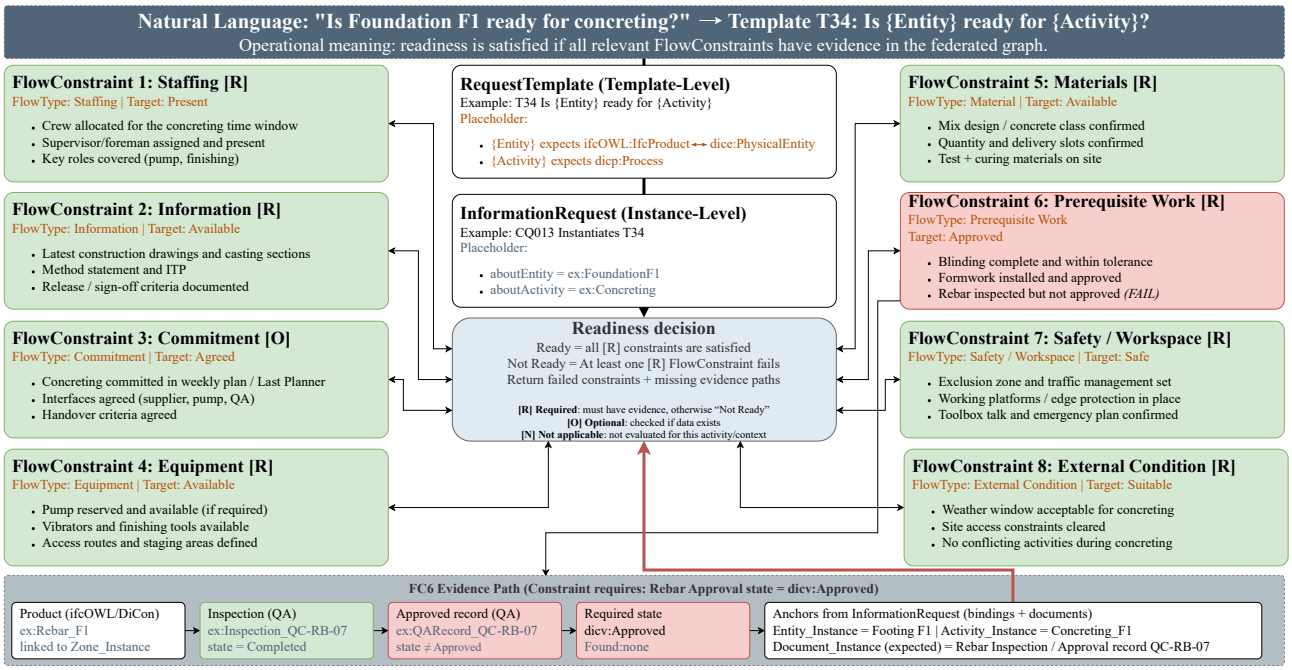

Figure 2: Illustrative template-driven readiness specification with evidence-path diagnostics at object level.

as required target states of the relevant evidence objects (e.g., inspection records) rather than as a separate flow type. For reinforcement placement in a foundation zone, this can include (i) the completion state of prerequisite work (e.g., blinding), (ii) an approval state for the relevant inspection record, and (iii) an implemented state for required safety measures. In this design, a *constraint profile* serves as a reusable default for a given template, specifying which flow constraints are required at a particular checkpoint. An *InformationRequest* then references the applicable profile and materializes the corresponding *FlowConstraint* instances for request-specific evaluation logic; project-specific specialization is expressed by adding, removing, or tightening these constraints at the request level (while keeping the template semantics stable). The key point is that the constraint profile is not constructed at query time; it is derived from the exemplar process checkpoints and refined based on partner feedback, so that the template encodes reusable readiness logic while remaining adaptable to project-specific requirements.

To make evaluation and diagnostics explicit, Figure 2 illustrates the same mechanism as shown in Figure 1, but on an object-level readiness request for concreting (T34) instead of zone-level readiness (T04), in which a single failing constraint can be traced to missing evidence that should justify work release. This highlights a practical requirement of operational question answering: a negative outcome should be explainable in terms of identifiable blockers rather than an undifferentiated ‘‘not ready’’ label.

In the intended execution logic, the bound request is evaluated against the attached constraint set. A readiness request is satisfied only if each required constraint can be justified by a matching evidence path in the federated graph; otherwise, the corresponding unsatisfied constraint and expected evidence type are identified. In this way, negative outcomes remain actionable by exposing specific blockers rather than an undifferentiated ‘‘not ready’’ label.

In the pattern library, analogous blocks are specified to resolve state checks (e.g., approved inspections), safe workplace, information, and logistics constraints through the corresponding document, resource, and process links in the aligned ontologies. Because constraints are explicit objects, the same request can, in principle, return diagnostics by selecting the constraints that fail and exposing missing evidence paths. Conceptually, a response can therefore be treated as a structured answer object that includes (i) the boolean result (ready / not ready), (ii) the constraint set evaluated, (iii) minimal evidence paths for satisfied constraints, and (iv) for unsatisfied constraints an expected path signature indicating what evidence type is missing (e.g., an inspection record in state *Approved* for a specific object and checkpoint). This turns negative outcomes into actionable blockers and preserves traceability back to the originating question, bindings, and sources.

Bindings determine which concrete project instances a request refers to (e.g., which zone, activity, object, or document). In practice, bindings can be obtained through three complementary mechanisms: (i) user-assigned bindings, for example by selecting a zone, activity, and checkpoint in an interface; (ii) context- or rule-derived bindings from existing project structures, such as linking scheduled activities to locations via a location breakdown structure, mapping work packages to curated element sets, or resolving document instances from metadata (e.g., inspection type and revision); and (iii) language-assisted proposals that extract candidate entities from the utterance and surrounding

context. In ambiguous cases, proposed bindings are expected to be confirmed or clarified by the user.

To preserve traceability and support evidence-based diagnostics, each binding is explicitly stored in the *InformationRequest* and annotated with provenance metadata that capture its origin and creation context (source system/-dataset, timestamp, and confirmer). At minimum, this includes the source system or dataset from which the binding was obtained, the identifier/URI used in the graph, a timestamp, and (if applicable) the role or actor who confirmed the binding. Thereby, the provenance metadata supports reproducibility and auditing of decision-relevant answers, and helps distinguish missing evidence in the data from underspecified or incorrectly bound requests. Beyond readiness, the same request semantics covers other execution-time decision questions across the eight flows. The template library includes approval and release checks (linking components or activities to inspection records and release documents), tolerance and requirement conformance queries (linking measured variables to specification constraints with traceability to the originating document), and logistics and resource commitment requests (linking activities and time windows to bookings for equipment, deliveries, or crews). These requests follow the same operational pattern: placeholders are bound to project instances, and the corresponding query pattern searches for satisfiable evidence paths, potentially across federated sources such as scheduling systems, Quality Assurance (QA) tools, health-and-safety management systems, procurement, or supplier dispatch data. When evidence is missing or inconsistent, the request returns unsatisfied constraints and their missing paths, enabling targeted follow-up actions rather than manual, system-by-system search.

Discussion and Future Work

The proposed framework highlights that many execution-time questions are fundamentally representation problems: decision-level inquiries require combining evidence across domain systems. The framework addresses these information needs through reusable requests: templates capture stable semantics, while bindings link them to project-specific instances, and the intended response structure exposes evidence-grounded blockers.

The readiness example illustrates why this separation is useful. A question such as *"Is zone A ready for reinforcement placement?"* cannot be reliably answered by searching a single system or treating readiness as a single status value. It requires explicit aggregation of prerequisite conditions aligned with lean constraint analysis flows, and it benefits from diagnostics that expose which prerequisites lack supporting evidence. Representing prerequisites as typed constraints and evaluating them via evidence paths enables the system to return actionable blocker traces, rather than undifferentiated negative answers. At the same time, the approach is compatible with federated settings, where evidence remains in its native systems, while requests provide a uniform mechanism to verify whether the required information is present and consistent.

The current scope also implies limitations. Templates and query patterns were derived from an exemplar process chain and refined with partner feedback, but broader generalization requires validation across additional trades, contracting arrangements, and delivery settings. Practical deployment depends not only on semantic formalization but also on data governance: binding resolution requires sufficiently stable identifiers, classifications, and contextual cues across tools, and missing records must not be conflated with negative evidence. In federated settings, evaluation must also account for access constraints, latency, and conflicting versions across sources. We have not yet evaluated the approach through end-to-end execution on noisy real-world project data; current validation is limited to curated example graphs and synthetic instances in the companion repository. Robustness under missing, conflicting, or partially linked evidence across sources remains future work. The intended behavior under such conditions is to return explicit blockers (missing evidence paths) rather than produce ungrounded answers silently.

In this sense, the framework can also be understood as an explicit specification of project information obligations: it makes visible which evidence must be available, from which source, and at what level of reliability to support a given operational decision.

Future work will focus on closing the loop from natural language to operationalizable, evidence-grounded requests. This includes template selection and placeholder binding from user utterances and project context, clarification of underspecified requests, and connectors for retrieving and linking evidence from real project systems. Evaluation across multiple projects will assess the correctness of answers, time-to-answer, and the practical usefulness of diagnostics for resolving blockers.

Conclusion

This paper addressed the persistent difficulty of formalizing execution-time process questions in construction when relevant evidence is distributed across heterogeneous systems. It introduced a semantic request layer that represents recurring operational information needs as reusable request templates, separates stable request semantics from project-specific bindings, and links these requests to graph-based evidence structures across federated sources. Lean work-release and readiness questions served as an exemplar application domain for eliciting and structuring the required dependencies.

The proposed request layer complements supply-side ontologies such as *DiCon*, *ifcOWL*, and *BOT* by explicitly representing the demand side of project information: which question is being asked, which entities and constraints it refers to, and which evidence paths would be required to support an answer. The illustrative examples show how natural-language questions can be grounded in explicit bindings and operationalized as evidence-oriented request specifications, providing a more transparent and

traceable basis for decision support. Automated natural-language interpretation and end-to-end execution over live project systems remain future work.

Data availability statement

The data supporting this study's findings are available at `https://gitlab.lrz.de/tweilbach/semantic_request_framework`,
ensuring that they are Findable, Accessible, Interoperable, and Reusable (FAIR).

EXPLORING THE APPLICABILITY OF COMPUTER VISION MODELS FOR AUTOMATED CODE COMPLIANCE CHECKING

Asaf Talor Shnay[1], Guy Austern[2], Tanya Bloch[1]
[1]Faculty of Civil and Environmental Engineering, Technion-Israel Institute of Technology, Haifa, Israel

Abstract

Automated Compliance Checking (ACC) traditionally relies on rule-based systems operating on fully parametric Building Information Models (BIM). In practice, 2D drawings remain dominant for communicating building information. Recent advances in Computer Vision (CV) enable reliable detection and segmentation of 2D drawings, but remain largely unexplored for ACC. We propose a CV-based ACC framework for 2D drawings. Through a case study focusing on the instructions for sanitary installations, we describe the full computational pipeline, from drawing preprocessing and detection to compliance checking. Results indicate that CV technology is a viable computational bridge between traditional drawing-based engineering practices and ACC.

Introduction

Design review is a time-consuming task that requires high attention to detail and extensive domain knowledge. Automating design review has been a subject of research for many years. Significant efforts have focused on formalizing regulations into a computer readable format (Preidel and Borrmann, 2016; Wang et al, 2023; Fuchs et al, 2024), as well as on processing BIM files so that they contain the needed information for regulatory checks (Bueno and Bosché, 2024). Despite their potential, existing ACC systems such as Solibri (Solibri, 2024) face several limitations. These tools are BIM based, require adherence to standardized modeling practices, often involve a steep learning curve, and are cumbersome to use. These poses substantial barriers to the adoption of advanced ACC workflows. While overall BIM adoption is increasing, it is unevenly adopted across regions and organizations (Chowdhury et al., 2024). BIM adoption is considerably low in the global south, with the Middle east and Africa typically showing very low scores at the end of the previous decade (Zahedi et al., 2022). Furthermore, BIM use is notably limited within municipalities and local planning authorities (Ullah et al., 2022), where design review still mostly relies on traditional 2D documentation and manual work. Recent advances in computer vision (CV) provide an opportunity to revisit the role of 2D drawings in ACC. Recent image segmentation and recognition methods have reached a level of accuracy that enables the extraction of meaningful geometric information from floor plans. Since 2D floor plans are heavily embedded in the construction culture, leveraging them for an ACC system can offer several advantages. In this paper, we demonstrate how these advances can be used to analyze 2D floorplans with sufficient accuracy to support compliance checking.

We propose a CV approach that treats visual recognition as an enabling step toward regulatory verification, which is performed using traditional, heuristic algorithms. This approach can serve as an intermediate solution for organizations transitioning toward more advanced digital workflows, or a potential alternative to BIM-based ACC systems in contexts where BIM adoption is limited. This will also allow designers to continue working within the familiar environments and workflows they are accustomed to. Alternatively, it may function as a complementary subsystem within predominantly BIM-based environments, supporting compliance checks that do not require fully structured data.

Given the extensive regulatory landscape governing floor plan design and code compliance, we narrow the scope to architectural spatial regulations related to bathroom design. By addressing a well-defined subset of rules that are both spatially complex and critical for compliance checking, we demonstrate the applicability and potential of CV algorithms to support ACC.

Following a review of related work in ACC and floor plan analysis, we describe our computational pipeline, including data processing, object detection, and rule formulation. The proposed approach is then validated through a case study focused on sanitary regulations, analyzing the system's ability to bridge the gap between 2D documentation and automated verification. The study concludes with a discussion of the results and the potential for scaling this technology to broader regulatory contexts.

Background

ACC requires two fundamental components: the design and building regulations. To enable an automated evaluation, both need to be translated into a machine-readable format. A significant body of research has been focused on the interpretation of regulations. Particularly rule formalization, Natural Language Processing (NLP) and Machine Learning (ML) techniques for extracting computable rules from regulatory documents (Ullah et al. 2022; Alnuzha and Bloch, 2025; Zheng et al. 2024). As for the design, one of the most significant enablers of

ACC tools is BIM, which provides a computer readable representation of the design information through explicit geometric and semantic descriptions of building elements. However, BIM has not yet been fully adopted by the AEC industry, especially in the public sector (Yusuf et al., 2024). As a result, the design review process continues to rely on two-dimensional drawings as the primary source of information. Despite the volume of research in the area of ACC, using rule based approaches (Aydin, 2022), graph based approaches (Bloch et al, 2023), ML based approaches (Alnuzha and Bloch, 2025), and more recently, LLM based workflows (Ying and Sacks, 2024), to the best of the author's knowledge, implementation of CV has not been explored for supporting the ACC workflow.

The use of computer vision to process 2D floorplans

Machine Learning is a subset of Artificial Intelligence (AI) that learns to make decisions from a given detailed data set without being explicitly programmed for every decision (Russell and Norvig, 2020; Datta et al, 2024). ML is extensively researched, and applied for real world applications, including in the AEC sector. CV is a branch of ML that involves training algorithms to interpret and classify visual data, such as images and videos. In recent years, Convolutional Neural Networks (CNNs) became a pivotal CV technique, used for image classification, object detection, and segmentation (Chen et al., 2021). CNNs are a deep learning architecture designed to process images by utilizing mathematical convolution operators on their grid data structure. They are designed with specific layers that aid in shape and texture detection and edges. YOLO (Jocher et al., 2023) is a good example for this type of model and is utilized here as an object detection model. Previous research has demonstrated the potential of CV and image processing techniques for extracting meaningful architectural information from 2D floor plan images.

Early work by Ahmed et al. (Ahmed et al., 2012) applied traditional image processing to rasterized floor plans, achieving 82% accuracy in generating structured, computer-readable data. Other studies focused on drawings derived from CAD files (Huang et al., 2008) bridging the gap between architectural drawings and automated analysis. Lv et al. (2021) used DeepLabv3+ combined with specialized loss functions and OCR-based text detection to generate 3D reconstructions from 2D floor plans with over 90% accuracy. Zeng et al. (2019) introduced a dual-decoder network to simultaneously predict room boundaries and types, effectively handling complex wall topologies with an 89% accuracy rate. More recent advancements leverage multi-task learning and deep structural understanding. MuraNet (Huang et al, 2023), for instance, uses relation attention mechanisms to enhance both object detection and segmentation performance, treating rooms and fixtures as interrelated components.

Despite these advancements, the majority of efforts have focused on using the extracted information to generate 3D models or BIM-style reconstructions (Lv et al, 2021; Zeng et al, 2019). However, the data extracted from 2D floorplans has not been leveraged for regulatory code compliance. While floor plan parsing has matured, the downstream use of this information, particularly in evaluating spatial relationships or conformance to design rules, remains underexplored.

Aims and methods

The primary aim of this work is to assess whether information extracted from 2D floor plans using CV techniques can support reliable regulatory compliance checking. To achieve this, we follow a structured methodological pipeline, as illustrated in Figure 1. First, we collect a scale-consistent dataset of relevant 2D floor plans, focusing on the design of bathrooms in both residential and public buildings. Next, we develop a scalable and standardized data tagging and processing pipeline to prepare the data for downstream analysis. Object detection techniques are then applied to identify building elements relevant to compliance checking such as walls, toilets, and sinks. Finally, to demonstrate the viability of integrating CV-based methods into ACC workflow, selected local regulatory rules are translated into machine-readable logic and applied to the information extracted from the floor plans.

Data collection

As this study is focused on regulatory architectural spatial constraints, the floor plans must be at scale to enable the extraction of true geometric dimensions. In addition,

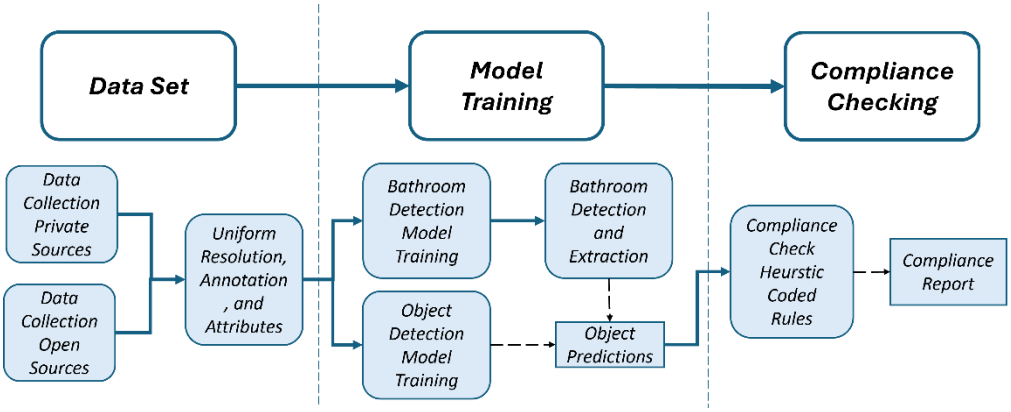

Figure 1: Proposed workflow

having focused specifically on bathrooms, any plans that did not have sanitary fixtures were deemed unusable. Several publicly available data sets were considered. The RPlan dataset (Wu et al., 2019) focuses on room division and doesn't contain sanitary fixtures, hence it was excluded. The Swiss Dwellings data set (Standfest et al., 2022) is too abstract as to train a vision-based model without significant adaptation. Lastly, the CubiCasa5k (Kalervo et al., 2019) data set was also dismissed because the rasterization processes removed any usable scale information. Once the open datasets were excluded, we also explored data sources accessible through the annotation platform used for this research, Roboflow (Alexandrova et al., 2015). Unfortunately, similar limitations persisted, including lack of consistent scale information, and absence of sanitary fixtures. Currently, our work is based on 182 distinct floorplan images collected from our partnership with private companies and public offices. Although the data set used in this study is relatively small, it is sufficient to demonstrate the feasibility of the proposed workflow. Expanding the data set is expected to further improve the results.

Data processing

Given the central role of data representation, we have developed a systematic data processing workflow which was documented in a detailed annotation guide. This guide defines the regulatory constraints addressed in the study, the data processing steps, and the annotation conventions, ensuring tagging consistency. First, each floor plan was assigned with a unique identifier and some descriptive metadata, such as bathroom type, multiuser (for public buildings) or single user (for residential buildings), and the number of bathrooms included in that plan. The goal of this step was to support data management and to establish a common language through the annotation process and team. Afterwards, all the collected floorplans were converted to a uniform resolution of one pixel per two centimeters using GIMP (The GIMP Development Team, 2025), a free image editing tool. The selected scale provides a balance between the image size and its detail, avoiding excessively large images that take a long time to process, while maintaining readability. Thus, a large, 3 meters long bathroom, easily fits within a standard, 256 pixels image. While a 10 cm wide wall occupies 5 pixels in the image and its features are clearly identifiable, as can be seen in Figure 2. The data was then uploaded to Roboflow, an online data management and annotations tool, for further processing. Roboflow was chosen for both its collaborative nature and for the added feature of nested annotations called attributes, which enabled us to tag relevant elements if they passed a compliance check. The images were annotated using 27 classes covering rooms, walls, windows, doors, and sanitary fixtures.

In addition to object classes, each of the objects in the bathrooms of the designs was annotated with an additional attribute according to the compliance rules. Each rule which was to be tested was represented using an attribute indicating whether the corresponding requirement was satisfied or violated. This enabled the annotated data to serve as training data for object detection, as well as a ground truth for downstream compliance checking.

The data was then split into three groups Train/ Validate/ Test, at 76%, 12%, 12% respectively, resulting in 140 images for training, 21 for validation and 21 for testing all in all 182 distinct floorplan images. To overcome the limitations of a small training set, the training data was augmented in the following ways: flipped horizontally and vertically, rotated 90 degrees clockwise and counter clockwise, and finally blurred by 2 pixels, resulting in 694 training images. We kept the validation and test sets without augmentation, giving us a total of 736 floorplans.

To improve detection of small objects, we decided to tile the large architectural drawings into smaller tiles of 640 pixels. To prevent missing essential elements because of tile cutoff, images exceeding 640 pixels in either dimension were tiled into 416X416 pixel images with 150-pixel overlap, as illustrated in Figure 3. The tiling process resulted in 2,410 distinct image patches used for training and evaluation.

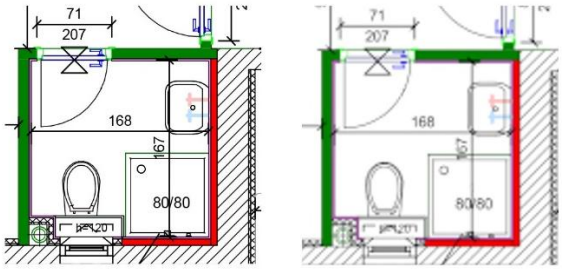

Figure 2: Results of processing with one pixel per two centimeters ratio

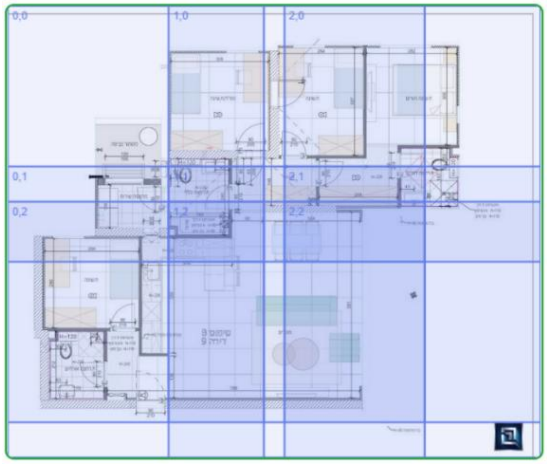

Figure 3: Tiling Example

The size and overlap of the tiling were chosen iteratively, as smaller tile sizes and overlap amounts resulted in degraded detection performance. All the annotations were processed to match the new, tiled images. Annotations corresponding to objects that were partially cut by tile boundaries were discarded if less than 70% of the object area remained visible within the tiled image. For our experiment, a subset of 11 from the 27 original classes was used. The distribution of annotated instances across

classes is provided in Table 1. Table 2 presents a breakdown of the objects involved in the regulatory compliance check within the test set.

Table 1: Description of the final data set

Class	Total	Class	Total
Bathroom	2,391	Opening	8,793
Stall	793	Window	6,803
Wall	44,309	Door Direction	8,976
Toilet	2,873	Sinks Row	204
Sink	3,139	Partition	1,172
Shower	965	Bath	983

This table also presents the proportion of compliant instances per object class, providing insight into the distribution of regulatory outcomes in the data set aside for testing. As non-compliant elements were rare in the original dataset, selected floor plans were modified to introduce additional non-compliant cases, enabling a more balanced and controlled evaluation of the compliance checks.

Table 2: Description of the test set

Class	Accepted	Rejected	Ratio
Opening	43	64	40.2%
Stall	21	20	51.2%
Sink	13	9	59.1%
Door Direction	48	32	60.0%
Toilet	40	26	60.6%
Shower	15	8	65.2%
Bathroom	23	11	67.6%

Object detection

Object detection was performed using YOLOv11 (Jocher and Qiu, 2024). YOLO was selected for both its strong detection performance and its intuitive, easy-to-use nature. YOLOv11 has demonstrated superior accuracy over other versions detecting small and medium-sized symbols (Khanam and Hussein, 2024). The architectural improvements in YOLOv11, particularly its attention module, allow the model to focus on both spatial and channel dimensions making it excellent for the repetitive nature of floorplans. As demonstrated in He et al (2024), YOLOv11 outperforms older YOLO versions and other object detectors like DeepLabv3 +.

To reflect a realistic code checking process, our process was divided between two models. The first model identifies bathroom regions within complete floorplans, enabling the exclusion of images without relevant spaces. After the bathrooms are detected, they are extracted from the full floorplan, then the second model focuses on detecting architectural elements and sanitary fixtures within extracted bathroom regions. This two-stage detection strategy was chosen to improve performance on small objects while reducing unnecessary computation in irrelevant areas.

Model training was initialized using a pre-trained Yolo11m running for 300 epochs with early stopping applied if no improvement was observed in over 30 consecutive epochs. Optimization parameters, including the optimizer and learning rate, were selected automatically by the model. The batch size was set to 16 and the image size chosen was 640x640 to fit our tiling results. This has the added advantage of not compressing the images for training, which would have caused small objects like sinks to become skewed. Validation was performed during training on a withheld validation set. Following the training, the ensembled object detection model was applied to previously unseen 2D floorplans to identify all objects relevant to compliance checking.

Compliance checking

To demonstrate the applicability of CV workflows to support ACC, this study focuses on six regulatory requirements: door opening direction, and minimal sizes of bathroom, shower, opening, sink usage area, and toilet usage area, as defined in the Israeli sanitary installations code (Ministry of the Interior, 2007).

The first requirement we checked was that all bathroom doors must swing inward, opening into the bathroom or stalls. Minimum dimensions for stalls as defined in the regulations are illustrated in Figure 4 (a).

Showers are required to have both a minimum area and minimal dimensions as described in Figure 4 (b). The most complex regulatory checks addressed in this work concern the usage areas of toilets and sinks. As per regulations, a clearance of 40 cm on each side of the fixture centerline and 75 cm in front of the fixture are required, as illustrated in Figure 3(c). And finally, all openings must be at least 80 cm. All regulatory checks were implemented using a rule-based, conditional logic operating on the geometrical information detected and extracted from the floor plans through the CV pipeline. An example of such a computational procedure used to evaluate the shower size is formalized in Algorithm 1.

Algorithm 1: Check Shower Compliance

    FOR EACH s IN Showers:
        // Convert bounding box to calculation units

        w = s.bbox_width  * W_img
        h = s.bbox_height * H_img
        // 1. Validate Area
        CalculatedArea = (w / 100) * (h / 100) * 2
        PassArea =
(CalculatedArea + AREA_TOL >= MIN_AREA)
        // 2. Validate Dimensions (Width/Length)
        PassDims = CheckDimensions(w, h)
        // 3. Determine Result
        Status , Reason
        IF PassArea AND PassDims:
            Status , Reason
        ELSE IF PassArea AND NOT PassDims:
            Status , Reason
        // Store Result
        ADD TO R
    RETURN R
```

Since all the floor plans were scaled at 1 pixel per 2 centimeters, object detection results produced by the YOLO models could be directly converted to real-world dimensions by scaling bounding box coordinates accordingly. This allowed us to translate the object detection box sizes to centimeters, consistent with regulatory requirements. However, since predictions are also not as geometrically accurate as our tagging, a tolerance of 1.5 pixels was used in all algorithms.

Each compliance check was structured to yield a clear pass or fail outcome for every relevant element in the floor plan. For instance, in a multi-user bathroom (public buildings), each toilet's coordinates were assessed individually for the Toilet Usage Area rule, resulting in either a pass or fail for both that object and for the entire room. When an object fails a compliance test, the corresponding reason for non-compliance is reported.

Each image was evaluated against the full set of applicable regulations, and the results were recorded in a structured library indexed by image identifier and regulation type. This library was subsequently compared against the annotated ground truth.

Experiments and results

The object detection model achieved an overall F1 of 0.9059 effectively generalizing the features of the floor plans despite the limited dataset size. As for the second model, performance varied across classes, as detailed in Table 4, with higher precision for recognition of toilets, sinks, and door direction (99.16%, 96.15%, and 95.11% respectively). Lower performance was observed for visually ambiguous classes such as partitions, reflecting the greater variability in their graphical representation within the dataset.

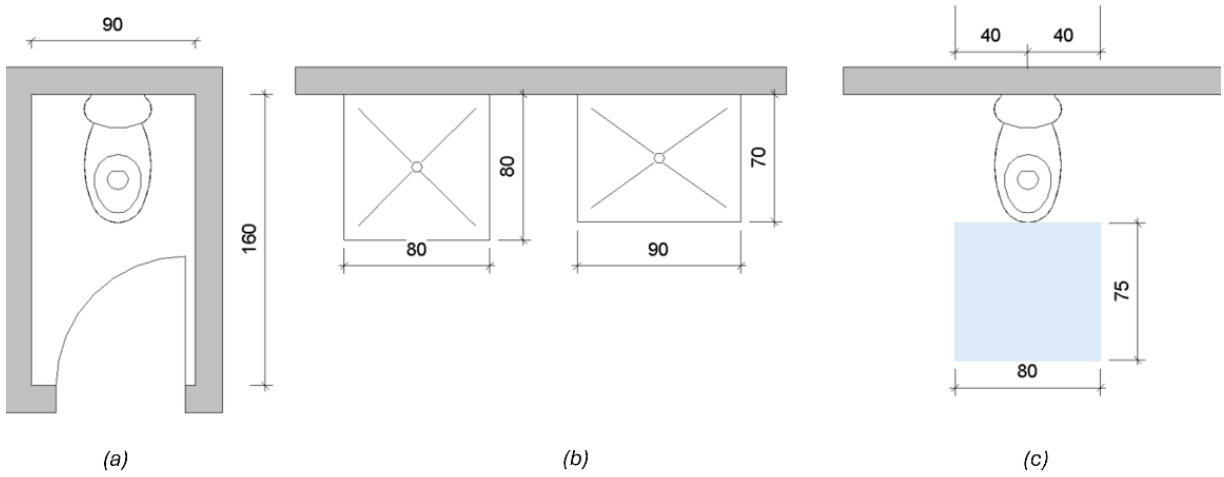

Figure 4: Requirements for (a) stall size (b) shower size (c) toilet fixture usage area

Table 4: YOLO detection Metrics

Class	Precision	Recall	F1-Score
Bathroom	0.8519	08421	0.8470
Door Direction	0.9511	0.9435	0.9473
Opening	0.8995	0.8609	0.8798
Partition	0.8259	0.3250	0.4664
Shower	0.9475	0.8889	0.9173
Sink	0.9615	0.8659	0.9112
Sinks Row	0.8900	1.0000	0.9418
Stall	0.8331	1.0000	0.9090
Toilet	0.9916	0.9041	0.9459
Wall	0.7611	0.8112	0.7854
Window	0.9190	0.9247	0.9218
OVERALL (Mean)	**0.8932**	**0.8700**	**0.9059 (mAP50)**

In order to assess the correctness of the developed regulatory checks independently of the object detection results, they were first evaluated using the ground truth annotations. All heuristic tests yielded 100% precision and recall, except for the toilet usage area which produced one false negative, resulting in 97.4% recall. This error was caused by the algorithm assigning an incorrect toilet orientation affecting the evaluation of the corresponding spatial constraint. Next, the extracted bathroom regions were processed using the trained YOLO model to predict the different elements in our floorplans. Based on these predictions, 296 compliance checks were performed.

Table 5: Compliance tests YOLO prediction results metrics

Category	Precision	Recall	F1
Door Swing	94.7%	100.0%	97.3%
Shower Size	78.3%	85.7%	81.8%
Opening Size	85.0%	100.0%	91.9%
Sink Usage Area	81.8%	75.0%	78.3%
Bathroom Size	70.6%	100.0%	82.8%
Toilet Usage Area	82.1%	74.2%	78.0%
Total	**82.2%**	**87.4%**	**84.7%**

Table 6: YOLO prediction compliance results breakdown

Category	TP	TN	FP	FN
Door Swing	18	14	1	0
Shower Size	18	6	5	3
Opening Size	17	49	3	0
Sink Usage Area	9	10	2	3
Bathroom Size	12	51	5	0
Toilet Usage Area	23	27	5	8
Overall	**97**	**157**	**21**	**14**

Of these, 97 elements were classified as compliant to the code (Approved) and 157 as not compliant (Rejected). The results of the heuristic compliance checks applied to the YOLO-based predictions are presented in Table 5. As shown in Table 6, 21 False Positives (FP) and 14 False Negatives (FN) were observed. As the compliance evaluation relies directly on the detected objects and their bounding box geometries, errors in object detection propagate to the compliance checking stage and affect the resulting classifications.

Conclusions

This study demonstrates the feasibility of using a CV-based workflow for compliance checking, providing a practical and accessible alternative to BIM-based systems. We developed an end-to-end, 2D based workflow that uses conventional architectural drawings. The workflow integrates object detection ML models with algorithmic compliance checking, without requiring structured building information or standardized naming conventions. By focusing on the regulatory requirements for bathroom design, the study provides a demonstration of how CV can support automated compliance checking. Our findings support the potential of this approach in three key areas. First is the robustness of YOLO object detection in floorplans. The YOLOv11 model achieved high precision and recall for key classes, including toilets (99.16% precision), showers (94.75% precision), and door directions (95.11% precision). This indicates that modern vision models can successfully interpret the semantic content of technical 2D drawings without relying on standardized naming conventions, even when trained on small datasets. Second is integration of CV with compliance checks. The heuristic algorithms developed for six specific regulatory clauses (e.g., door swing, fixture usage areas, and room dimensions) proved highly effective. When applied to the model-predicted

data, the system maintained strong performance, identifying compliant and non-compliant elements with an overall precision of 82.2%, and recall of 87.4%. Lastly, we established a scalable data processing pipeline, from scale normalization to attribute-rich annotation, that directly addresses the industry's reliance on 2D documentation. By utilizing the ubiquitous floor plan format, this system lowers the barrier to entry for automation and offers an immediate tool to alleviate the workload of expert reviewers in municipal and private sectors. Compliance checking is often constrained not only by the availability of BIM models, but by the explicit information needed to make those models suitable for automated evaluation. This work suggests a need to reconsider which regulatory checks truly require fully structured BIM data, and which can be reliably performed using geometric information already present in standard design outputs. In this context, CV analysis of 2D floor plans offers an alternative pathway for selected compliance checks that do not depend on rich semantics. As such, we see the proposed approach as a complementary subsystem within ACC environments, enabling partial automation of compliance checking without imposing any additional modeling constraints or information requirements. A systematic analysis is still needed to determine which regulatory checks can be reliably supported by this approach, and to evaluate its potential to reduce the burden placed on designers by additional modeling constraints and information requirements.

Limitations and future work

While the results are promising, certain limitations remain. The current dataset is relatively small (182 plans) and is mostly made up of apartments floorplans. The detection results for specific classes, such as partitions (recall of 32.5%), require improvement. Future research will focus on expanding the dataset to encompass a wider variety of architectural styles and regulatory contexts. This can be achieved by manually scaling and adding annotations to existing datasets or tagging architectural 2D plans which are readily available worldwide. An additional avenue can utilize self-supervised learning methods such as DINO (Caron et al., 2021) to speed up the manual tagging process. Further work is also needed to refine the detection of small or complex objects to include the orientation of sanitary fixtures in our YOLO predictions. As the effectiveness of the algorithmic ACC is tightly coupled with detection accuracy, the effectiveness of the entire process is expected to improve. An alternative direction for dataset expansion is to incorporate more complex regulatory scenarios by generating 2D representations, such as sections or detailed views derived from BIM models. This would enable the evaluation of more spatially complex compliance requirements. Such an approach further supports the concept of a computer vision subsystem operating within a predominantly BIM-based compliance checking workflow, where different representations are leveraged according to the information requirements of each regulatory check.

Additionally, the rule-based logic should be extended to cover a broader range of building codes beyond wet rooms as well as regulations from other countries. To scale this framework beyond manually encoded heuristics, future work will explore the integration of Large Language Models (LLMs) to automatically generate compliance checking algorithms adapted to local building codes. Using techniques such as In Context Learning (ICL) we can base new regulatory requirements on our existing heuristic methods.

Ultimately, this research serves as proof of the concept that CV can effectively bridge the gap between traditional architectural deliverables and modern automation, paving the way for more resilient and inclusive ACC systems. By leveraging LLMs to automatically translate natural language regulations into executable logic, it is possible to eliminate the reliance on human-generated checks and achieve a fully automated, adaptable compliance verification process. Such a process will be especially useful in less developed countries, where BIM adoption is still low. Another potential avenue is in retrofit work, where BIM information of the existing building stock is rarely available.

ALIGNING HETEROGENEOUS VIEWS: STAKEHOLDER TERMINOLOGY AND MULTI-LEVEL MAPPINGS IN THE AEC INDUSTRY

Jakob Martin[1], Cornelius Preidel[1], Simon Vilgertshofer[1], André Borrmann[2]

Abstract

Construction stakeholders refer to the same asset using discipline-specific terms and abstraction levels, producing representations with inconsistent naming conventions and modeling granularity. Alignment across views often fails even with standards such as IFC unless semantic relations and transformations are made explicit. We contribute a typology of cross-view mapping requirements as a preceding decision layer for alignment. It determines the mapping type, intended semantic relation, and required transformation between views, guiding candidate generation and validation. Using representative examples from planning, construction, and operations, we show why cross-view alignment requires more than label matching alone.

Introduction

Semantic interoperability and semantic consistency remain challenges in the Architecture, Engineering, Construction, and Operations (AECO) domain, because project information is produced and consumed through many discipline-specific tools, standards, and organization-specific conventions (Ozturk, 2020; Pauwels et al., 2017). Beyond technical friction, poor data quality causes major economic losses, including rework triggered by data-related decision errors (FMI, 2021). While open standards such as Industry Foundation Classes (IFC) are well established in practice and widely adopted to support information exchange, they still fall short of enabling fully consistent and seamless integration. Persistent challenges arise from inconsistent naming conventions, incompatible property structures, and divergent semantics, particularly when project-specific extensions and local naming conventions are applied (Ozturk, 2020; Beck, 2023). As a result, project information ecosystems and exchange workflows frequently fail to provide consistent, linkable, and computationally interpretable data across stakeholder boundaries.

These recurring mismatches are closely related to ontology matching, which provides established primitives and workflows for relating heterogeneous schemas and knowledge representations, including correspondence types, confidence scoring, and hybrid matching and validation methods (Euzenat and Shvaiko, 2013).

A key reason is that stakeholders use different terminology and conceptualize and delineate assets differently, often referring to partially overlapping portions of the physical world. In this paper, *referent* denotes the underlying physical asset, space, or process, while modeled objects may differ slightly in scope across views (e.g., whether a door frame is considered part of the door) (Beck, 2023). Rather than enumerating all roles, we treat their information artifacts as view-based projections of this referent.

Figure 1 illustrates three recurring AECO views: a *design view* emphasizing geometry, types and instances, and design intent; a *checking view* restructuring information into rules, thresholds, and pass or fail outcomes; and an *operations view* focusing on maintainable assets, maintenance plans, and spare parts.

The central challenge is that these views can be internally consistent, yet difficult to link across contexts.

These view-specific representations differ in terminology, modeling intent, and information logic. Depending on the stakeholder task, the same referent may be represented as a geometric element, as the subject of rules and constraints, or as a maintainable asset with operational responsibilities. As a result, views systematically use different naming and classification conventions, delineate and group elements differently (in terms of granularity and decomposition), and encode information using different modeling constructs such as entities, attributes, relationships, or constraints, each optimized for a specific purpose rather than cross-view integration.

Across lifecycle phases, stakeholders need to reference and query the same assets consistently, for example, to ensure reliable handover, provide compliance evidence, and track the impact of design changes. Explicit mappings are therefore required to connect these heterogeneous representations. In practice, alignment is rarely just a matter of renaming labels or matching synonyms. Typical cases include entity-to-entity mappings, such as linking an IfcDoor element in a design model to the corresponding asset entry in a facility management system, such as a computer-aided facility management (CAFM) record. Another common case is an attribute-to-entity transformation, in which a fire rating expressed as a property is reinterpreted as an explicit requirement or compliance constraint. A further recurring case is many-to-one aggregation, in which several modeled doors are grouped into one operational set, such as a fire compartment boundary or a maintenance batch. These mapping types determine which semantic relations and transformations must be applied before data

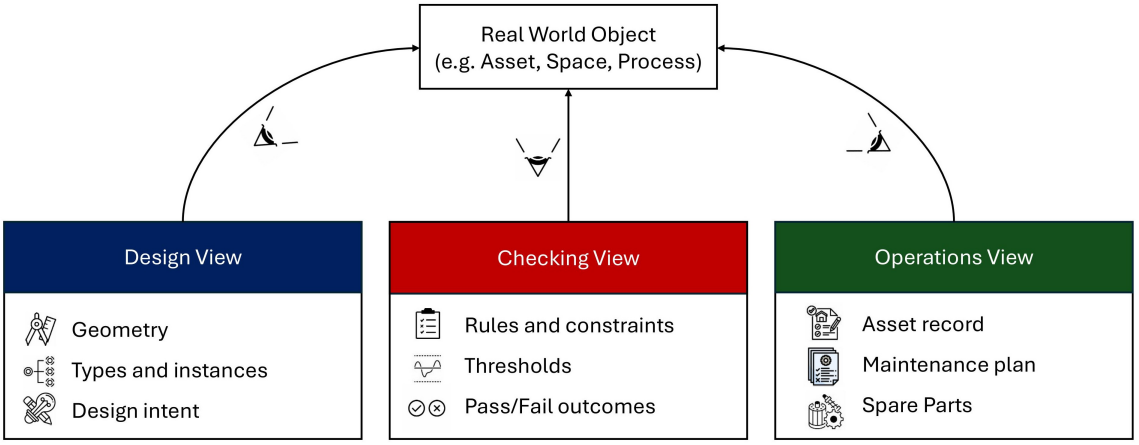

Figure 1: A shared physical referent is represented through different stakeholder views. The design view emphasizes geometry and design intent, the checking view encodes rules, thresholds, and pass/fail outcomes, and the operations view organizes information around maintainable assets. Meaning-preserving integration requires explicit semantic relations and transformations between views.

can be integrated or reasoned over across stakeholder systems.

Ontology matching approaches typically emphasize correspondences between entities or concepts. In AECO integration, link semantics are often context dependent and require interpreting modeling intent and scope differences between views; the core challenge is to determine the intended semantic relation and the required transformation for meaning-preserving integration (Beck, 2023).

This becomes evident when linking design models to downstream uses such as compliance checking and facility management handover. Although much of the required information may already be present, it often has to be restructured or made explicit to become usable in the target view. Even with IFC-based exchange, semantic ambiguity and alternative representation choices can create structural mismatches across federated models and stakeholder systems (Venugopal et al., 2015). More broadly, interoperability research in AECO/FM shows that data loss and communication problems persist across lifecycle exchanges despite the use of established standards (Ozturk, 2020).

This paper contributes a typology of cross-view mapping requirements as a preceding decision and structuring layer for cross-view alignment. It determines the mapping type, the intended semantic relation, and the required transformation between views, guiding candidate generation and validation. The goal is to reduce redundant information creation across disciplines by making explicit where information resides and how it can be referenced and transformed, so that it can be reused and delivered in the form each stakeholder expects. Rather than framing alignment as a uniform similarity-matching task, we derive mapping types that operate at different levels of granularity and semantic interpretation. Using representative examples from planning, construction, and operations, we characterize recurrent mismatch patterns and specify the semantic relations and transformations needed to resolve them, including direct entity correspondence, attribute-to-entity transformation, cluster-based mapping, granularity shift, and value or unit normalization. The contribution is twofold. First, the typology makes explicit which kind of mapping problem is present in a given integration scenario and, by doing so, clarifies the specific semantic relations and transformations that are required for meaning-preserving integration, rather than treating alignment as a uniform matching task. Second, the typology makes these distinctions actionable for AI-supported alignment workflows by specifying what evidence and mapping outputs are needed for candidate generation, validation, and reuse.

State of the Art

Prior work on ontology alignment has established how to define correspondences and transformations between heterogeneous representations (Portisch et al., 2022; Thiéblin et al., 2020). Ontology mapping and alignment research frames interoperability as the establishment of correspondences between entities in different models, enabling information to be interpreted, translated, and queried across sources (Abd Nikooie Pour et al., 2023). Such correspondences are not restricted to equivalence. They may encode subsumption or disjointness and often require transformations, for example, unit conversion, aggregation, or reinterpretation, to preserve semantics (Beck et al., 2021; Beck, 2023). In information exchange across AECO workflows, similar issues arise when stakeholders apply different boundaries and discipline-specific conventions, for example, gross versus net area definitions or properties expressed in different units, which cannot be resolved reliably through label similarity alone.

Matching approaches differ mainly in the information sources they use, for example, labels, structure, data instances, or formal semantics, and in how they combine them (Portisch et al., 2022; Abd Nikooie Pour et al., 2023). Across these approaches, candidate correspondences are typically treated as hypotheses whose usefulness depends on the application context, and many applications require

user scrutiny before results are operationalized (Portisch et al., 2022; Beck et al., 2021).

Prior work on semantic interoperability in AECO indicates that lifecycle integration, meaning reuse, comparison, and translation of project information across design, construction, and operations views often require more than identifying similar terms (Beck et al., 2021). Ontology alignment research distinguishes between discovering candidate links and specifying mappings that preserve meaning under transformation, for example, when aggregation, decomposition, unit conversion, or reinterpretation are required (Thiéblin et al., 2020; Portisch et al., 2022).

In the AECO domain, semantic interoperability has been addressed through standards, ontologies, and linked data approaches, yet recurring gaps remain across lifecycle handovers. IFC provides a shared exchange schema, but IFC-based exchanges still exhibit variability in representation choices and a frequent reliance on property-set extensions, which can introduce ambiguity and structural mismatches across stakeholders and software toolchains (Venugopal et al., 2015). Semantic web research has therefore explored representing BIM data as RDF and OWL to enable explicit linking and cross-dataset querying, including ifcOWL as a representation that allows BIM graphs to be processed with ontology-based methods (Pauwels and Terkaj, 2016; Vilgertshofer et al., 2017). Lightweight ontologies, such as the Building Topology Ontology (BOT), provide shared structural primitives for linking elements, spaces, and zones to complementary sources, such as monitoring and operations data (Rasmussen et al., 2021). Complementary to such lightweight linking ontologies, modular ontology suites such as DiCon cover richer process and workflow semantics for digital construction and integration scenarios (Zheng et al., 2021). Linked data studies further show that interoperability can be achieved through explicit, maintained linking relations between datasets, provided that these relations are made machine-interpretable and that governance mechanisms are in place (Curry et al., 2013; Vilgertshofer et al., 2017).

Recent research operationalizes semantic enrichment and BIM knowledge graphs in concrete workflows, for example, for digital twin data integration and graph-based enrichment of BIM representations (Ramonell et al., 2023; Wang et al., 2024; Bloch et al., 2022). In parallel, machine-readable information requirements and automated checking approaches, such as the Information Delivery Specification (IDS) introduced and maintained by buildingSMART International, support systematic verification of required IFC information in practice (buildingSMART International, 2026; Kremer and Beetz, 2023; Fischer et al., 2024; Akbas et al., 2025). This line of work illustrates how view-specific requirements can be formalized, but it typically assumes that the required information is already structured in the target view and does not address how heterogeneous stakeholder representations should be related when transformations or grouping decisions are needed. However, recent reviews characterize this body of work as still fragmented and largely workflow- and method-driven, with limited consolidation of reusable patterns for relating heterogeneous stakeholder representations (Bloch et al., 2022). This motivates the development of an explicit mapping typology for recurrent cross-view mismatches in AECO.

The proposed typology complements rather than replaces ontology alignment and IDS-based checking. While ontology alignment provides general correspondence types and matching strategies, and IDS specifies target-side information requirements for validation or exchange, our contribution addresses the preceding AECO-specific task of determining what kind of cross-view mapping problem is present and which semantic relation and transformation are required for meaning-preserving integration. The typology therefore serves as a decision and structuring layer before candidate generation, rule execution, or downstream validation takes place. Based on this positioning, the following methodology derives the typology from recurrent cross-view scenarios and abstracts them into a set of mapping types.

Methodology

The State of the Art highlights that alignment problems often differ in the intended semantic relation and in the required transformation, and that these differences are frequently not captured when alignment is treated as a uniform matching task. Building on these observations, we systematize recurrent mismatch patterns into mapping types that make the required relation and transformation explicit.

The typology was derived through comparative analysis of recurrent cross-view integration scenarios involving design, checking, construction, and operations representations. In this paper, three lifecycle examples are discussed in detail, covering design-to-checking, design-to-construction, and design-to-operations transitions. These examples are complemented by additional recurrent cases reflected in the broader type definitions summarized in Table 1. The analyzed artifacts include BIM element representations, checking-oriented rule or constraint representations, construction-oriented grouping views, and operations-oriented asset records. Scenarios were selected deliberately to cover recurring handover and coordination situations, clearly different modeling intents across views, and distinct semantic relations or transformation requirements.

For each case, the source and target view were compared along five dimensions: information units, identifiers, boundaries, grouping, and representation form, meaning whether information is represented as explicit entities or encoded as attributes. A mapping type was assigned when a recurring combination of semantic relation and required transformation could be observed across the analyzed examples. For example, in the design-to-checking case, the door remains the same referent, but the checking view

changes the representation context and reinterprets fire-rating information from an attribute into an explicit constraint object. This combination leads to direct entity correspondence for the door itself and attribute-to-entity transformation for the fire-rating requirement.

Accordingly, the typology is an analytical generalization derived from recurrent patterns in representative cases rather than from large-scale benchmarking, and it does not claim statistical completeness. In this paper, the most representative types are illustrated through concise lifecycle scenarios, while additional types are summarized in Table 1 to indicate the typology's broader applicability.

We refer to the source view as the representation from which information is taken, and to the target view as the representation to which data are mapped to satisfy the stated integration goal. These terms describe mapping direction only and do not assume a fixed lifecycle order.

Mapping Typology for Stakeholder Views

This section introduces a mapping typology that systematizes recurrent cross-view mismatches in AECO by the semantic relation and transformation required for meaning-preserving integration. To support practical use, Table 1 summarizes each mapping type as a recurring integration pattern. For each type, it identifies typical situations in stakeholder views that indicate the need for this mapping, and it specifies what kind of mapping result is required so that meaning is preserved in the target view.

Table 1 shows that resolving cross-view mismatches often requires structural rather than term-level alignment. Depending on the mapping type, integration requires identity linking, constraint lifting, operational grouping, granularity reconciliation, or value and unit normalization. The following scenarios illustrate three representative patterns, while granularity shift and value or unit normalization are summarized in Table 1.

Lifecycle Examples

This section shows how different stakeholder views lead to recurring mismatch patterns. It also shows how these patterns fit the typology categories defined in the Mapping Typology for Stakeholder Views section. Each example describes the source and target view, identifies the mismatch pattern, assigns a mapping type, and explains the semantic relation and transformation needed for actionable mapping across views.

Planning View

The planning view is contrasted with a compliance-based checking view to illustrate how a shared physical referent is conceptualized under different modeling intents. In the design view, the door is represented as a geometric building element, typically as an explicit object with shape, placement, and descriptive properties such as fire rating, acoustic rating, and clear opening width and height. In the compliance view, the focus is not only on the door itself but also on the rule context in which it participates. The door

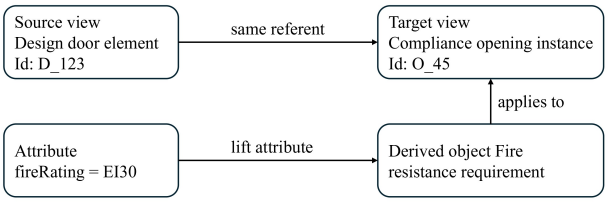

Figure 2: Planning pattern: identity link and attribute lifting.

is considered an opening that must meet egress and fire safety standards. The checking workflow requires explicit constraints that are evaluated against the model. Figure 2 summarizes the mapping output structure required to connect these two representations.

There are two mismatch patterns. First, the door entity in the design view must be linked to the door or opening instance in the checking view. This is a direct entity correspondence, since both target the same referent but use different naming and referencing conventions and delineate the element differently due to modeling conventions. Second, the fire rating stored as a property in the design view must be an explicit constraint in the compliance view. This is an attribute-to-entity transformation. The target view requires a constraint object with explicit semantics, like a required fire resistance class and an explicit evaluation target.

A correct mapping output has two linked statements. The first links the design door entity to the checking door or opening instance using an equivalence relation. The second lifts the fire rating attribute into a compliance constraint object. It then links this constraint to the door instance as its evaluation target. The transformation requires normalizing the fire rating value and linking it with the correct rule context. Label similarity may help rank candidates. However, it is insufficient to infer the intended constraint semantics or the correct target mapping scope (which elements, at what level of granularity) without structural and contextual interpretation.

Construction View

To highlight phase-specific aggregation, the construction case relates a planning-oriented model view to a construction-oriented view centered on work packaging. The construction view organizes information by work packages, assemblies, and temporary states. In the construction view, the main units are often not single model elements. Instead, they are operational units for scheduling, procurement, and site work. Doors may be treated as installation packages, floor-based batches, or trade-specific scopes. These scopes combine multiple components and tasks. Figure 3 summarizes the cluster-based mapping relation needed to link element-level design representations to construction packages.

A common mismatch is a many-to-one operational grouping across views: multiple design elements correspond to a single construction concept, so a grouping transformation

Table 1: Mapping typology for stakeholder views and the semantic relations and transformations required for resolution.

Mapping type	**Definition**	**Typical trigger in stakeholder views**	**Required semantic relation**	**Required transformation**
Direct entity correspondence	A modeled entity in one view refers to the same real-world referent as an entity in another view, but identifiers, boundaries, or context differ. This type applies when the integration goal requires cross-view identity or traceability.	Cross-phase linking where the same object is represented in design and operations, for example, a design element versus an FM asset record for the same referent.	Equivalence, or a same-referent link, between entities.	Identifier linking and normalization, optional projection of relevant attributes, and provenance capture for traceability. Label similarity can support ranking, but it cannot establish identity when identifiers and scopes differ.
Attribute-to-entity transformation	Information encoded as an attribute in the source view must be lifted into an explicit object in the target view because the target view represents it as a requirement or constraint to be evaluated or reasoned over. This type applies when the target contains an explicit constraint object that is not present in the source and must be derived from values and context.	A property is descriptive in one view but normative in another, for example, a performance property in design that must become an explicit constraint in a checking view.	Constraint on, requirement for, or governs relation linking the derived constraint object to the relevant entity.	Attribute lifting into an explicit object, value parsing and normalization, interpretation of units and thresholds, and linkage to the checked entities. Label similarity alone cannot determine the target object type and its semantics.
Cluster-based mapping	A set of elements in one view corresponds to a single concept or unit in another view, where the target concept is defined operationally or functionally. Assign this type when the target concept is defined by membership across multiple source elements and the boundary is not explicitly defined in the source view.	Operational groupings are not explicit in the source view, for example, grouping elements into a maintenance bundle, an operational zone, or a compartment-related set.	Aggregation, part of, or member of a relation linking source elements to the target cluster concept.	Grouping and aggregation based on spatial, functional, or rule-based criteria, with optional creation of a derived target object representing the cluster. Label similarity alone cannot determine membership and boundary conditions.
Granularity-shift mapping	An entity in one view corresponds to multiple entities or a composed structure in another view because stakeholders model at different levels of granularity. Use this type when integration requires decomposition or composition across a part hierarchy, or alignment between type-level and instance-level representations.	Design uses type definitions or assemblies, while construction and operations use instances, components, or maintainable parts, for example, a type definition mapped to multiple installed assets, or an assembly mapped to its components.	Part of, composed of, or an instance of relations connecting coarse and fine-grained representations.	Decomposition or composition, propagation of attributes across levels, consistency checks to preserve totals, constraints, and traceability across levels. Label similarity alone cannot infer the correct hierarchy level.
Value and unit normalization mapping	The same intended property exists in both views, but its value semantics differ due to units, reference conditions, calculation rules, rounding conventions, or code lists. Use this type when the mapping challenge is primarily at the value level rather than the entity level.	Cross-domain exchanges of quantities and performance values, for example, gross versus net area conventions, thermal or acoustic ratings expressed under different standards, or values encoded as codes in one view and numeric values in another.	Same property relation with an explicit transformation function, or equivalence under conversion.	Unit conversion, normalization to reference conditions, code list translation, optional recomputation from available parameters, and validation against allowed ranges or constraints. Label similarity alone cannot guarantee comparable values.

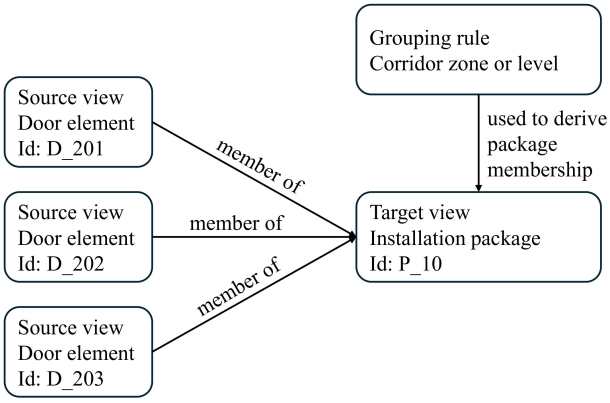

Figure 3: Construction pattern: clustering elements into an installation package.

is required. For instance, a set of doors in a corridor zone may be installed by a single subcontractor during a single scheduled activity. As a result, these doors form a single operational package in the construction view. The design view provides multiple distinct door entities, each with its own properties. In contrast, the construction view groups them as a package entity with references to its members and added attributes, such as planned start date, responsible trade, and installation status.

This mismatch is a cluster-based mapping. Here, the target concept is defined operationally, and its boundary is not clear in the design view. The transformation requires creating a group concept and assigning member relations from each door entity to the package. A correct mapping output includes a construction package object with a list of source doors and a grouping rule. The grouping rule can use spatial zone, level, or schedule logic. The mapping must keep the original door identifiers and introduce a stable identifier for the package. This allows construction reporting and later handover to reference both the group and the elements across phases.

Operations View

The operations case shows how a design representation is reinterpreted in facility management, where a door is managed as a maintainable asset linked to responsibilities and requirements such as maintenance and inspection. In the design view, the door exists as a building element instance with geometric and specification properties. In the operations view, the door becomes an asset record within an equipment register, linked to maintenance plans, spare parts, inspection intervals, warranty information, and potentially sensor or access control system identifiers. Figure 4 summarizes the mapping output structure needed to preserve traceability between the design element, the FM asset record, and operational groupings such as maintenance batches.

Two mismatch patterns often occur. First, the door entity must link to its asset record in the FM system. This is a direct entity correspondence. Both target the same physical door but use different naming and referencing conventions. They may also use different boundaries. For example, an asset record may include both the door leaf and hardware, while the design model separates these components. Second, FM workflows often create groupings that do not exist in the design. Doors may be managed as a maintenance batch, such as all doors of a given type on a floor, or as an operational set, such as a fire compartment boundary. This results in a cluster-based mapping.

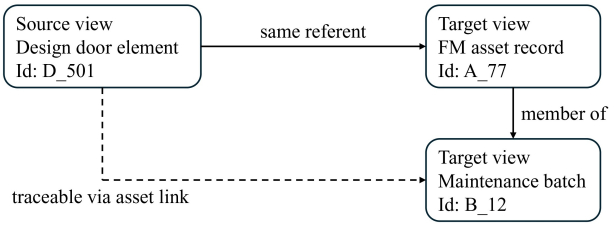

Figure 4: Operations pattern: identity link and operational grouping.

A correct mapping output must keep traceability between views. The output links each design door to its FM asset record and notes which identifiers each side uses. For maintenance batches, the output adds a grouping concept and assigns membership at the asset level. This lets FM tasks be managed at the batch level without losing links to the original elements. The transformation needs identifier reconciliation, optional aggregation rules, and preservation of essential attributes. Key attributes include location, type classification, fire rating, and manufacturer data if available.

Implications for AI-Supported Alignment

Our contribution lies in a mapping typology that provides a preceding decision and structuring layer for AI-assisted alignment workflows connecting different stakeholder views. By determining the mapping type, the intended semantic relation, and the required transformation, it constrains candidate generation and validation.

For direct entity correspondence, the main objective is to resolve identity across differing identifiers, modeling conventions, and element boundaries. For attribute-to-entity transformation, the workflow must detect when a descriptive property needs to be reinterpreted as an explicit requirement or constraint object in the target view. For cluster-based mapping, the workflow must recognize when multiple source elements collectively correspond to an operational concept and must make the grouping boundary and membership relations explicit. Granularity-shift mapping requires reconciling representations across levels of detail, and value and unit normalization mapping requires explicit conversion or normalization logic.

This process, therefore, requires type-specific training and reference data to support both automated candidate generation and subsequent validation. Lexical similarity and terminology resources are useful for candidate retrieval and ranking, but they are rarely sufficient when bound-

ary decisions or semantic transformation is involved. For direct entity correspondence, robust evidence is typically provided by persistent identifiers where available, geometric and spatial consistency, containment relations, and stable type information. For attribute-to-entity transformation, relevant cues include requirement-oriented vocabulary, normative contexts, and value patterns that encode classes, thresholds, or compliance-relevant categories. Cluster-based mapping benefits from shared context and operational metadata, for example, co-location within a zone, shared classification, or explicit grouping rules derived from scheduling logic, inspection regimes, or maintenance strategies.

Human supervision remains essential because mapping correctness is context-dependent and directly affects lifecycle tasks. Validation effort should be prioritized for cases with ambiguous identity evidence, uncertain attribute interpretation, or unclear grouping boundaries. Once validated, these cases can be stored as reference mappings. Over time, curated reference sets enable calibration of type detection, support more reliable candidate ranking, and reduce recurring manual effort in comparable scenarios.

The typology also provides a concrete basis for specifying the minimum mapping outputs that an AI-assisted workflow must produce. Each mapping should record its mapping type, identify the linked source and target information units, and make the intended semantic relation explicit. When transformation is required, the aggregation rule or attribute-lifting logic should be represented in a reproducible form. Provenance metadata and a confidence estimate should be included to support auditability and to enable revision when models, standards, or organizational conventions evolve.

Discussion

Lessons Learned

The lifecycle examples show that semantic heterogeneity across stakeholders is driven not only by terminology, but also by representational differences. Even when referring to the same referent, views vary in what is modeled as an entity versus an attribute, and in how boundaries and groupings are defined. Therefore, interoperability often requires mappings beyond term equivalence, including transformation or aggregation logic.

Direct entity correspondence requires identity resolution across inconsistent identifiers and boundary conventions. Same-referent cases do not necessarily imply strict equivalence, because different views may adopt different boundaries or decomposition logics for the same physical asset. In such cases, the typology helps distinguish direct correspondence from granularity shift, for example when one view represents a door as a single object while another distinguishes frame, leaf, and hardware. To preserve traceability, such mappings should record provenance and, where ambiguity remains, an explicit boundary assumption and review status. Attribute-to-entity transformation requires normative interpretation, turning a descriptive value into an explicit requirement or constraint representation. Cluster-based mapping requires membership and boundary decisions that are often organization-specific and hard to infer reliably.

For practice, the typology suggests classifying the mapping need first, because evidence, validation effort, and maintenance burden differ by type. For standardization, it supports guidance on stable identifiers, operational groupings, and explicit requirement representations.

Limitations

The typology is scoped to recurrent cross-view mismatch patterns illustrated through representative examples from planning, construction, and operations and does not claim exhaustive coverage of AECO interoperability situations. Geometric conversion, coordinate reference transformations, and purely syntactic schema translation are outside scope.

Because mapping needs and boundaries depend on project context, organizational conventions, and metadata quality, some cases remain ambiguous, especially where identifiers are inconsistent or decomposition differs across views. The present paper establishes the typology through analytical comparison of representative cases rather than through a large annotated benchmark. Accordingly, it does not yet report inter-rater agreement, quantitative coverage, or downstream tool-performance evaluation. Its contribution is to provide a structured basis for distinguishing recurrent semantic relations and transformation requirements in AECO view alignment.

An important next validation step is therefore to test whether different analysts consistently assign the same mapping type, semantic relation, and transformation requirement to the same case, particularly in boundary-sensitive situations involving decomposition, grouping, or partial overlap of referents. This is especially relevant because the typology is intended to structure downstream AI-supported candidate generation, validation, and traceability.

Conclusion

AECO stakeholders represent the same real-world assets, spaces, and processes through different terminologies, conventions, and abstraction levels. As a result, structural mismatches persist even with IFC and cannot be resolved reliably through label matching alone.

This paper proposed a mapping typology that characterizes recurrent cross-view mismatch patterns across planning, construction, and operations and makes explicit the semantic relations and transformations required to resolve them. By turning alignment into an explicit decision layer, the typology supports more systematic interoperability practice and provides a foundation for AI-supported candidate generation and validation.

Abstract

This paper proposes a robust Variational Physics-Informed Neural Network (VPINN) framework specifically tailored for the structural analysis of thin Kirchhoff-Love plates. We utilize Approximate Distance Functions (ADFs) for hard boundary constraints and a hybrid spectral variational formulation to overcome challenges associated with fourth-order partial differential equations, such as vanishing gradients and the need for C^1-continuous meshing. Our VPINN framework can learn a parametric design space and enable real-time, mesh-free structural analysis, eliminating the ''modeling-meshing-solving'' cycle. The results confirm that our VPINN accurately captures critical stiffness trends and global deformation modes, satisfying the precision requirements for conceptual design and topology optimization.

Introduction: Background, related literature, and research aim

Structural engineering plays a pivotal role in defining parameters of safety, material efficiency, and decision-making processes in building projects (Ketabi and Heravi, 2022). Among structural components, slabs often serve as the primary horizontal load-bearing elements. The vast majority of slabs in residential and commercial buildings are geometrically characterized as ''thin plates'' (span-to-depth ratio $L/h > 20$), where the structural response is dominated by bending, and transverse shear deformations are negligible (Timoshenko and Woinowsky-Krieger, 1959). Consequently, the Kirchhoff-Love plate theory, which neglects shear deformation, serves as the most appropriate mechanical description for these elements (Marti et al., 2022). While the Mindlin-Reissner theory is essential for thick plates ($L/h < 10$) to account for shear flexibility, its application to thin slabs introduces unnecessary computational variables and complexity (Teixeira de Freitas et al., 2025). The Kirchhoff-Love theory allows for more computationally efficient models accurately reflecting the stiffer behavior of thin slabs (Marti et al., 2022), potentially leading to more resource-efficient material usage during building production.

The Finite Element Method (FEM) is widely adopted to analyze the structural behavior of slabs. However, despite its high fidelity, FEM faces significant limitations in the context of rapid, iterative design; its reliance on mesh generation becomes a bottleneck during design optimization loops with frequent geometry changes (Park and Kang, 2024). Moreover, most commercial FEM software utilizes Mindlin-Reissner formulations during FEM (using C^0-continuous elements) to avoid the numerical difficulties associated with Kirchhoff-Love theory; implementing Kirchhoff-Love in FEM would require the displacement field to be C^1-continuous (smooth slope everywhere), necessitating complex and computationally expensive elements, such as Hermite or Argyris (Zienkiewicz and Taylor, 2000). However, the generalized utilization of Mindlin-Reissner in FEM unavoidably introduces, in the case of thin slabs, the computational inefficiencies mentioned earlier.

Recently, Physics-Informed Neural Networks (PINNs) have emerged as a promising alternative for solving Partial Differential Equations (PDEs) (Raissi et al., 2019). Unlike FEM, PINNs are mesh-free and differentiable, allowing them to learn the solution operator over a continuous parametric space. This can enable a single trained network to predict the structural response across thousands of design variations instantly, effectively replacing the time-consuming ''modeling-meshing-solving'' cycle with real-time inference (Raissi et al., 2019). However, standard PINNs relying on the strong form of the governing equations struggle with the fourth-order derivatives present in the Kirchhoff-Love bi-harmonic equation ($\nabla^4 w = q/D$); the computation of high-order derivatives via automatic differentiation often leads to numerical instability and vanishing gradients, Wang et al. (2021a).

To address this, two variational approaches that reduce the order of differentiation have gained traction: the Deep Energy Method (DEM), based on the Ritz method (minimizing potential energy) (Samaniego et al., 2020), and the Variational Physics-Informed Neural Network (VPINN), based on the Galerkin method (minimizing the residual of the variational form) (Kharazmi et al., 2021). DEM is intuitive, but recent studies suggest that its unconstrained loss formulation can exhibit instability when learning across complex geometric parameter spaces due to spectral biases in the energy landscape (Wang et al., 2021b). In contrast, the Galerkin-based VPINN framework offers a robust mechanism to project residuals onto test functions, providing improved stability for parametric problems (Kumar and Singh, 2025). In particular, Huang and Peng (2024) proposed an improved plate DEM utilizing finite differ-

ence approximations via convolutional kernels and domain decomposition with coordinate transformations for irregular Kirchhoff plates, achieving high pointwise accuracy on L-shaped geometries. However, their method was demonstrated only for single-instance configurations with structured grids, whereas the parametric setting, where a single network must generalize across a continuous family of geometries, remains largely unexplored.

Therefore, for thin slabs, leveraging VPINN can take advantage of the suitability of the Kirchhoff-Love theory while addressing the combination of computational inefficiencies discussed above; however, such a solution has received limited attention in the literature. As such, this paper proposes a robust framework for VPINN specifically tailored for the analysis of thin slabs. By utilizing the variational form of Kirchhoff-Love theory, we reduce the derivative requirements to the second order, ensuring numerical stability while maintaining mechanical consistency. We demonstrate the framework's capability to learn a parametric design space and discuss its potential to enable real-time, mesh-free structural analysis.

Kirchhoff-Love plate theory

The mechanical behavior of the slab is modeled using the Kirchhoff-Love plate theory, which provides the governing mathematical description for thin structural elements where the span-to-thickness ratio is sufficiently large ($L/h \geq 20$) (Timoshenko and Woinowsky-Krieger, 1959). This theory relies on the kinematic assumption that straight lines remain inextensible and normal to the mid-surface before and after deformation. Consequently, transverse shear strains are neglected, and the deformation is fully characterized by the transverse displacement $w(x, y)$ of the mid-surface $\Omega \subset \mathbb{R}^2$. Under the assumption of linear isotropic elasticity and small deformations, the relationship between the bending moments M and the generalized curvatures $\boldsymbol{\kappa}$ is governed by the constitutive equation $\mathrm{M} = \mathrm{D}\boldsymbol{\kappa}$ (Reddy, 2006).

The equilibrium of the plate under a distributed transverse load q is described by the strong form of the governing partial differential equation. By combining the kinematic relations, constitutive laws, and equilibrium conditions, the problem reduces to the classical bi-harmonic equation, i.e., a fourth-order partial differential equation:

$$D\nabla^4 w = D\left(\frac{\partial^4 w}{\partial x^4} + 2\frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4}\right) = q \quad \text{in } \Omega, \quad (1)$$

where ∇^4 denotes the bi-harmonic operator and D is the flexural rigidity of the plate, defined as:

$$D = \frac{Eh^3}{12(1-\nu^2)}, \quad (2)$$

dependent on the Young's modulus E, Poisson's ratio ν, and the slab thickness h.

To form a well-posed problem, Eq. (1) must be complemented by boundary conditions. In this study, we focus on clamped edges, which are representative of slabs rigidly connected to stiff vertical supports (e.g., shear walls or monolithic columns). For clamped edges (Γ_C), the boundary conditions are defined as follows:

$$\Gamma_C : \left.\begin{aligned} w &= 0 \\ \frac{\partial w}{\partial n} &= 0 \end{aligned}\right\}, \quad (3)$$

where n denotes the outward unit normal direction.

To avoid the numerical instability of computing fourth-order derivatives in PINNs (Wang et al., 2021a), we adopt the variational formulation. Multiplying Eq. (1) by a test function $v \in \mathcal{V}$ satisfying homogeneous essential boundary conditions and integrating by parts twice yields:

$$\int_\Omega D\left[\nabla^2 w \nabla^2 v - (1-\nu)\mathcal{K}(w, v)\right] d\Omega = \int_\Omega qv \, d\Omega, \quad (4)$$

where $\mathcal{K}(w, v)$ represents the Gaussian curvature interaction term:

$$\mathcal{K}(w, v) = \frac{\partial^2 w}{\partial x^2}\frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 w}{\partial y^2}\frac{\partial^2 v}{\partial x^2} - 2\frac{\partial^2 w}{\partial x \partial y}\frac{\partial^2 v}{\partial x \partial y}. \quad (5)$$

Although $\int \mathcal{K} d\Omega$ theoretically vanishes for clamped slabs, we retain the full formulation for generality. Minimizing this variational residual requires only second-order derivatives, significantly enhancing numerical stability compared to strong-form collocation methods.

Approximate Distance Functions (ADFs)

Standard PINNs enforce boundary conditions via penalty terms, which introduce competing objectives and often lead to inexact satisfaction for fourth-order problems. To overcome this, we employ Approximate Distance Functions (ADFs) (Sukumar and Srivastava, 2021) for ''hard constraint'' enforcement. In this framework, the neural network output $\hat{w}(\mathrm{x})$ is constructed not as a direct approximation of the displacement, but as a composite ansatz:

$$\hat{w}(\mathrm{x}) = \Phi(\mathrm{x}) \cdot \mathcal{N}(\mathrm{x}; \theta), \quad (6)$$

where $\mathcal{N}(\mathrm{x}; \theta)$ is the raw output of the deep neural network parameterized by weights θ, and $\Phi(\mathrm{x})$ is a geometrically constructed distance function that strictly encodes the boundary requirements.

Theory of R-Functions

The function $\Phi(\mathrm{x})$ is constructed using the theory of R-functions (real-valued logic functions), which allows for the composition of complex domain geometries from simple primitives (e.g., lines, circles) using Boolean operations. For a domain Ω formed by the intersection or union of N primitive shapes, the global distance function $\phi(\mathrm{x})$ is derived using the R-equivalence operation:

$$\phi(\mathrm{x}) = \mathcal{R}_m(\phi_1, \phi_2, \ldots, \phi_N), \quad (7)$$

where ϕ_i are the distance functions of the individual primitives. The R-equivalence operation ensures smoothness

(C^m-continuity) and gradient normalization ($|\nabla\phi| = 1$ near the boundary), preventing gradient pathologies during optimization (Biswas et al., 2004).

Application to clamped slabs

For the specific case of clamped Kirchhoff-Love plates, the boundary conditions on the clamped edge Γ_C require both the deflection and the normal derivative to vanish ($w = 0$ and $\partial w/\partial n = 0$). To satisfy both conditions simultaneously using the ADFs, the geometric ansatz in Eq. (6) is modified to use the square of the distance function:

$$\Phi(\mathrm{x}) = [\phi(\mathrm{x})]^2. \tag{8}$$

Since $\phi(\mathrm{x}) = 0$ on Γ_C, it follows that $\Phi(\mathrm{x}) = 0$. Furthermore, the derivative of the ansatz is $\nabla\Phi = 2\phi\nabla\phi$, which also vanishes on the boundary where $\phi = 0$. Consequently, the trial solution $\hat{w} = \phi^2\mathcal{N}$ automatically satisfies:

$$\hat{w}|_{\Gamma_C} = 0 \quad \text{and} \quad \left.\frac{\partial\hat{w}}{\partial n}\right|_{\Gamma_C} = 0, \tag{9}$$

regardless of the values predicted by $\mathcal{N}$. This eliminates the need for boundary loss terms, reducing optimization to a purely physical energy minimization problem.

VPINN framework for parametric slab analysis

In this section, we present the details of the VPINN framework as sketched in Fig. 2.

Geometric parametrization and input space

The structural component under investigation is a non-convex, L-shaped slab, a geometry frequently encountered in architectural layouts around elevator cores or re-entrant corners (Timoshenko and Woinowsky-Krieger, 1959). To establish a comprehensive parametric design space, the geometry is driven by two independent dimensionless parameters, $\mathcal{P} = \{R_1, R_2\}$, which control the aspect ratios of the horizontal and vertical slab segments, respectively.
The physical dimensions of the slab are derived from these parameters to ensure that the domain remains within a normalized bounding box. As depicted in Fig. 1, the total height (b_1) is normalized to unity (1.0) and the top leg width (a_2) is fixed at 0.5. The remaining dimensions are directly controlled by the parameters, such that the total width is $a_1 = b_1/R_1$ and the right leg height is $b_2 = a_2/R_2$.
The parameters R_1 and R_2 vary continuously within the range $[1.0, 1.6]$, creating a family of geometries ranging from thick, compact L-shapes to slender, extended configurations. A critical geometric feature implemented in this framework is the introduction of a circular fillet normalized radius of $r = 0.05$ at the re-entrant corner (the inner corner of the L-shape). This modification removes the geometric singularity associated with sharp re-entrant corners. As noted by Sukumar and Srivastava (2021), smoothing re-entrant corners is essential when using distance-based ansatz functions, as it ensures the gradient of the distance function remains well-defined and continuous ($\nabla\phi \in C^0$) along the entire boundary.

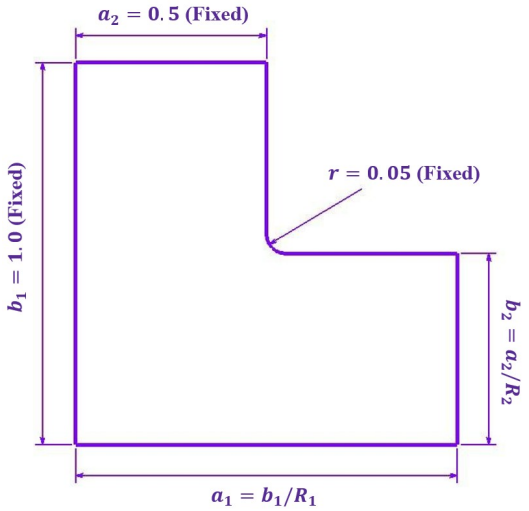

Figure 1: Parametric L-shaped slab geometry

Consequently, the neural network input space is four-dimensional, consisting of the spatial coordinates and the design parameters: $\mathrm{x}_{in} = \{x, y, R_1, R_2\}$.

Neural network architecture in the VPINN

To approximate the solution map $\mathcal{N}(\mathrm{x}_{in}; \theta)$, we employ a fully connected feed-forward neural network, commonly referred to as a Multi-Layer Perceptron (MLP), which serves as the core approximator within the VPINN framework. The architecture is designed to map the four-dimensional input vector $\mathrm{x}_{in} = \{x, y, R_1, R_2\}$ to the scalar latent deflection field w_{model}.
The network depth and width are configured to ensure sufficient expressive capacity for learning the complex solution manifold across the parametric design space. The architecture consists of 6 hidden layers, with each layer containing 512 neurons. This results in a deep over-parameterized model capable of learning the complex parametric solution manifold. To facilitate the training of this deep architecture and prevent the degradation problem (vanishing gradients), residual skip connections are implemented across the hidden layers (He et al., 2016). Mathematically, the output of the l-th layer $\mathrm{z}^{(l)}$ is given by:

$$\mathrm{z}^{(l)} = \sigma(\mathrm{W}^{(l)}\mathrm{z}^{(l-1)} + \mathrm{b}^{(l)}) + \mathrm{z}^{(l-1)}, \tag{10}$$

where W and b are the weights and biases, and σ is the activation function.
A critical feature of this implementation is the use of the Self-Scalable Tanh (Stan) activation function. Unlike standard fixed activation functions (e.g., ReLU or Tanh), the Stan function includes a single global learnable scalar parameter β, shared across all layers of the network, that allows the model to adaptively scale the slope of the activation during training. The function is defined as:

$$\sigma(z) = \tanh(z) \cdot (1 + \beta z). \tag{11}$$

As demonstrated by Gnanasambandam et al. (2023), this specific formulation provides a smooth, non-saturating response. By optimizing a single global scaling factor β, the network can automatically tune the aggregate spectral properties of the approximation without the computational overhead or optimization complexity of layer-wise adaptation. Furthermore, Weight Normalization is applied to all linear layers to decouple the magnitude of the weight vectors from their direction, further stabilizing the optimization process (Salimans and Kingma, 2016).

Ansatz construction for hard boundary constraints

A defining characteristic of the proposed framework is the exact satisfaction of boundary conditions through a geometric ansatz, rather than relying on penalty terms in the loss function. To achieve this, we implement the hard constraint formulation derived in the previous section. The final physical deflection field, $\hat{w}(\mathrm{x})$, is constructed by modulating the raw scalar output of the neural network, $w_{model}(\mathrm{x})$, with the square of the approximate distance function $\phi(\mathrm{x})$:

$$\hat{w}(\mathrm{x}) = w_{model}(\mathrm{x}) \cdot [\phi(\mathrm{x})]^2. \tag{12}$$

Since $\phi = 0$ on Γ_C, both $\hat{w}$ and $\partial\hat{w}/\partial n$ vanish automatically, confining the optimization to kinematically admissible functions and eliminating boundary penalty terms (Berg and Nyström, 2018; Sukumar and Srivastava, 2021).

Construction of test functions

In the VPINN framework, the choice of the test space $\mathcal{V}$ is critical for the accuracy and stability of the numerical integration. While traditional formulations often rely solely on polynomial bases (Kharazmi et al., 2021), we adopt a hybrid spectral approach to capture a broader range of solution frequencies. Specifically, we construct the test space by combining Legendre polynomials, Chebyshev polynomials, and trigonometric functions. This leverages the orthogonality and polynomial approximation power in Legendre and Chebyshev (Canuto et al., 2006) while incorporating the periodic spectral properties of trigonometric series to address the ''spectral bias'' inherent in fully connected neural networks (Rahaman et al., 2019), thereby enhancing the network's ability to resolve complex local features.

The Galerkin formulation requires test functions to satisfy homogeneous essential boundary conditions ($v = 0$, $\nabla v \cdot \mathrm{n} = 0$ on Γ_C) (Hughes, 2012). We enforce this via the same geometric masking used for the trial ansatz (Sukumar and Srivastava, 2021). Let $B_k(\mathrm{x})$ denote the k-th order raw basis function (selected from the combined pool of Legendre, Chebyshev, or trigonometric functions) evaluated at coordinate x. The admissible test function $v_k(\mathrm{x})$ is constructed as:

$$v_k(\mathrm{x}) = B_k(\mathrm{x}) \cdot [\phi(\mathrm{x})]^2, \tag{13}$$

where $\phi(\mathrm{x})$ is the same approximate distance functions (ADFs) used for the trial ansatz. By modulating the hybrid basis with the squared distance field, we guarantee that every test function in the discrete space $\mathcal{V}_h$ vanishes along with its normal derivative at the boundary. This allows for a consistent mesh-free implementation where the variational form residuals are computed solely via domain integration, avoiding the numerical complexity of boundary integrals.

Variational loss formulation

The VPINN minimizes the residual of the integral variational form rather than pointwise strong-form residuals. Since all boundary integrals vanish due to the hard constraints on both $\hat{w}$ and v_k, the variational residual for the k-th test function reduces to:

$$\begin{aligned}\mathcal{R}_k(\theta) = \int_\Omega D\Big[& (\hat{w}_{xx} v_{k,xx} + \hat{w}_{yy} v_{k,yy}) \\ & + \nu(\hat{w}_{xx} v_{k,yy} + \hat{w}_{yy} v_{k,xx}) \\ & + 2(1-\nu)\hat{w}_{xy} v_{k,xy} \Big] d\Omega \\ & - \int_\Omega q v_k d\Omega.\end{aligned} \tag{14}$$

To numerically evaluate these integrals, we employ Monte Carlo integration over the sampled interior points. The total loss function $\mathcal{L}(\theta)$ is constructed by aggregating the squared residuals over the finite set of N_v test functions:

$$\mathcal{L}(\theta) = \sum_{k=1}^{N_v} |\mathcal{R}_k(\theta)|^2 . \tag{15}$$

By minimizing this scalar loss, the optimizer forces our VPINN to satisfy the principle of virtual work over the entire parametric domain. This formulation is purely physics-based and unsupervised, requiring no labeled data or reference solutions (Kharazmi et al., 2021).

Results and discussion

To evaluate the predictive capability of the proposed parametric VPINN framework, we conduct a comparative analysis against high-fidelity FEM reference solutions generated using the legacy FEniCS finite element library with the Ciarlet-Raviart mixed formulation, which decomposes the biharmonic equation into two coupled second-order equations. The FEM discretization employs quadratic Lagrange elements (P_2) on unstructured triangular meshes with approximately 236,440 vertices per configuration, with mesh convergence verified to within 0.5% variation in maximum deflection. For the training phase, the spatial and parametric domains were discretized using 80,000 collocation points generated via uniform quasirandom sampling, ensuring efficient coverage of the irregular L-shaped geometry. The network parameters were optimized using the L-BFGS algorithm in a single optimization step containing approximately 300,000 internal line-search iterations, following the PhysicsNeMo single-step pattern. The optimization process exhibited robust convergence, reducing the variational residual loss from an initial magnitude

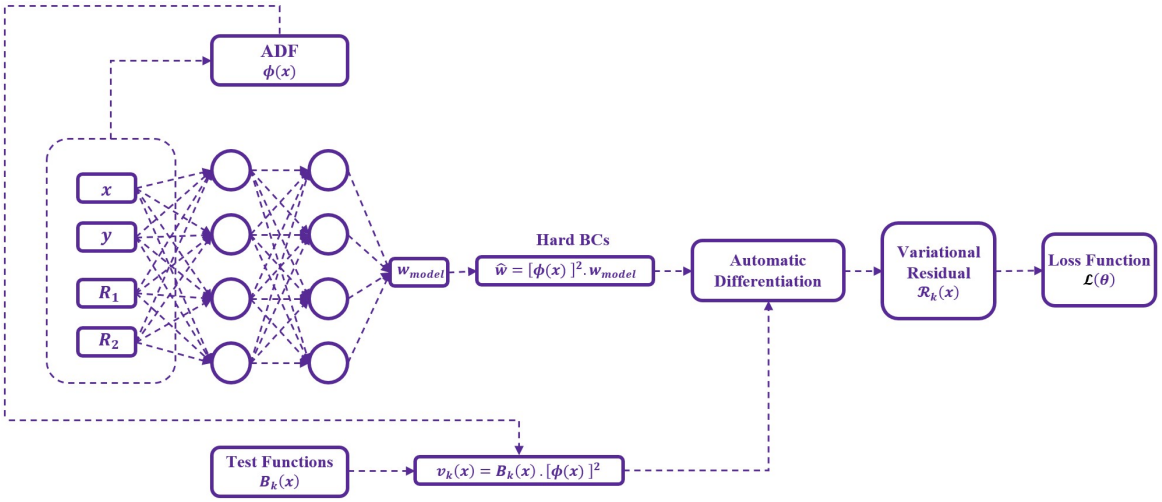

Figure 2: Schematic diagram of the proposed VPINN

of $O(10^1)$ to a final stable residual of $O(10^{-6})$, confirming that the network successfully located a distinct energy minimum.

For the numerical experiments, the physical problem is fully non-dimensionalized. The flexural rigidity is normalized to $D = 1$, the uniform transverse load is set to $q = -1$, and the Poisson's ratio is fixed at $\nu = 0.3$. Furthermore, the spatial domain size is non-dimensionalized such that the entire geometry is strictly bounded within the unit square defined by coordinates $(0, 0)$ and $(1, 1)$. The total offline training cost was approximately 4 hours on a single NVIDIA A100 (80GB) GPU, with a peak memory consumption of approximately 79 GB. In contrast, each FEM reference solution required approximately 63 seconds at mesh resolution 400 (≈236,440 vertices). The amortized computational advantage of the trained VPINN becomes favorable beyond approximately $N_{\text{break}} \approx \lceil T_{\text{train}}/T_{\text{FEM}} \rceil \approx 230$ design evaluations, a threshold readily exceeded in optimization workflows requiring hundreds to thousands of iterations. The neural network was trained once over the parametric domain, and subsequently evaluated to predict the deflection fields for varying geometric configurations without any retraining. This inference process demonstrates true real-time capability, requiring approximately 0.015 seconds per design evaluation on an NVIDIA A100 (80GB) GPU.

Generalization across geometric parameters

We present inference results for two representative geometric cases that test the network's ability to generalize across both symmetric and asymmetric configurations:

1. **Case I:** $R_1 = 1.0, R_2 = 1.0$. This case represents the baseline geometry, characterized by a fully symmetric configuration with equal leg dimensions.

2. **Case II:** $R_1 = 1.0, R_2 = 1.6$. This case represents a boundary of the parametric design space, corresponding to a highly asymmetric configuration with a compressed right leg ($b_2 = 0.3125$). It validates that the VPINN has captured the independent sensitivity of the deflection field to each geometric parameter, rather than simply learning symmetric scaling.

Figure 3 illustrates the comparison between the predicted deflection field $\hat{w}_{\text{VPINN}}$ and the reference solution $\hat{w}_{\text{FEM}}$ for these configurations. A comprehensive quantitative evaluation across all 16 grid points in the parametric space (Fig. 4) is presented in the following subsection.

Error analysis and validation

The absolute error distributions (right column of Fig. 3) reveal the exact satisfaction of boundary conditions. The error vanishes completely at the clamped edges (Γ_C), empirically confirming the theoretical validity of the ansatz construction $\hat{w} = w_\theta \cdot \phi^2$. The VPINN correctly identifies the shift in the maximum deflection point in the asymmetric Case II, demonstrating that the network has effectively learned the parametric dependence of the solution map.

To comprehensively evaluate the framework's generalization across the design space, we conduct a systematic grid evaluation over 16 configurations spanning $R_1, R_2 \in \{1.0, 1.2, 1.4, 1.6\}$. Figure 4 presents the global relative (L_2) error and maximum deflection relative ($\Delta w_{\max}$) error as heatmaps over the parametric grid. The model achieves a mean L_2 error of 7.87% (min: 5.75%, max: 11.55%) and a mean $\Delta w_{\max}$ of 5.90% (min: 0.68%, max: 11.49%) across all 16 cases. Error analysis reveals a systematic increase for larger R_1 values, corresponding to narrower bottom-leg geometries where the aspect ratio is most extreme. The outlier at $(R_1 = 1.6, R_2 = 1.2)$ represents the most elongated configuration, where the fixed-order test function basis provides reduced effective resolution. Notably, the maximum deflection error, the quantity most relevant for serviceability assessment, remains below 10% for 14 of 16 cases, confirming the model's suitability for rapid design screening. This error magnitude is consistent with serviceability tolerances in Eurocode 2 (EN 1992-1-1, $w_{\max} \leq L/250$) and the 10% threshold for successful PINN solutions established by the PINNacle bench-

mark (Hao et al., 2024).

Critically, the error distribution analysis challenges common assumptions regarding L-shaped domains. While the re-entrant corner typically dominates numerical error due to reduced regularity, our parametric filleting successfully regularizes this region. Consequently, maximum deviations shift to the outer clamped corners, where the strict enforcement of zero-slope constraints imposes high-frequency gradients.

This behavior highlights the specific interaction between the test space and the boundary constraints:

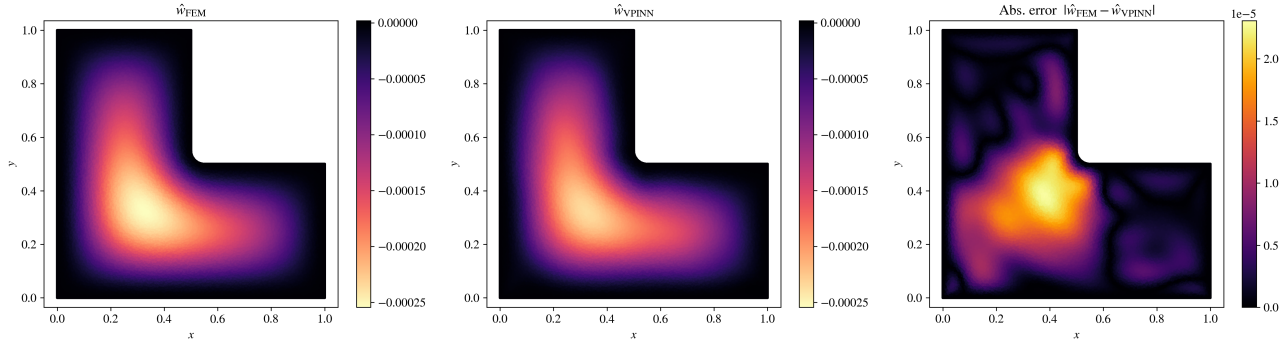
1. **Hybrid Spectral Resolution:** The use of a mixed test space combining Legendre polynomials and Chebyshev polynomials (Canuto et al., 2006) with trigonometric functions (Rahaman et al., 2019) was crucial for stabilizing the variational loss. While this hybrid basis effectively captures the global oscillatory modes of the plate, the high-frequency gradients required to strictly enforce the zero-slope condition ($\nabla w \cdot \mathrm{n} = 0$) at the sharp outer corners remain computationally demanding to resolve with high precision. The systematic error increase observed for larger R_1 values in Fig. 4 confirms that the fixed-order basis provides non-uniform resolution across geometries with extreme aspect ratios.

2. **Trade-off against Coordinate Mapping:** In classical spectral methods, achieving high-precision convergence on irregular domains with corner singularities typically requires coordinate mapping or domain decomposition to regularize the geometry (Boyd, 2001). However, applying such mappings in a parametric learning framework is computationally prohibitive. A continuous parametric mapping would require the computation of parameter-dependent Jacobians at every collocation point, significantly increasing the training cost and architectural complexity. Consequently, our Cartesian approach represents a deliberate trade-off: accepting a bounded approximation error (mean L_2 of 7.87% across 16 configurations) to enable a unified, mapping-free parametric model that enables real-time inference.

3. **Design-Centric Accuracy:** In the context of inverse design and topology optimization, the primary requirement is the accurate prediction of stiffness trends and relative performance between different geometries, rather than the recovery of the exact solution to floating-point precision. As evidenced by the systematic evaluation across 16 configurations (Fig. 4), our VPINN consistently captures the correct global deformation mode and parametric sensitivity, with a mean maximum deflection error of 5.90%. This confirms that the model has learned the parametric physics required to drive an optimization loop across the entire design space.

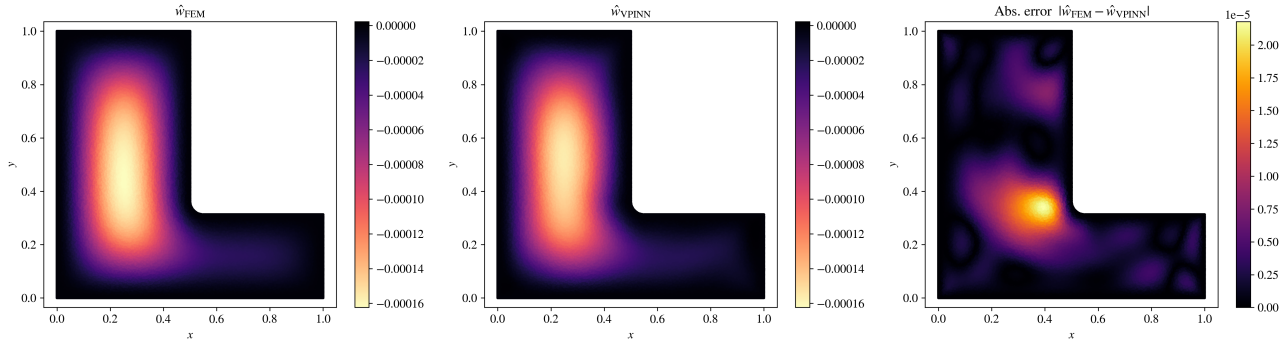
Conclusions

This study has developed and validated a robust parametric VPINN framework specifically tailored for the structural analysis of thin Kirchhoff-Love plates. By integrating ADFs for hard boundary constraints with a hybrid spectral variational formulation, the proposed method successfully overcomes the traditional challenges associated with fourth-order partial differential equations, such as vanishing gradients and the need for C^1-continuous meshing.



The scientific and practical implications of this work are summarized as follows:

1. **Robustness of the Variational Formulation:** The utilization of a hybrid test space (combining Legendre polynomials, Chebyshev polynomials, and trigonometric functions) proved essential for numerical stability. The framework achieved robust convergence, reducing the variational energy residual from $O(10^1)$ to $O(10^{-6})$. This confirms that limiting the derivative requirements to the second order via the variational form is a superior strategy for bending-dominated problems compared to strong-form collocation.



2. **Exact Boundary Adherence:** The implementation of the geometric ansatz $\hat{w} = w_\theta \cdot \phi^2$ guaranteed the exact satisfaction of clamped boundary conditions, as empirically confirmed by vanishing error at all clamped edges across the 16 evaluated configurations. This eliminates the need for hyperparameter tuning of boundary penalty terms, a common bottleneck in standard PINN architectures, and ensures kinematic admissibility regardless of the network's training state.

3. **Parametric Efficiency vs. Precision Trade-off:** Systematic evaluation across 16 configurations spanning the $R_1 \times R_2$ design space demonstrated a mean global L_2 error of 7.87% and a mean maximum deflection error of 5.90%, with 14 of 16 cases remaining below 10%. While higher than refined FEM, this represents a strategic trade-off. By avoiding computationally expensive coordinate mappings, our VPINN framework delivers a unified, mapping-free parametric model that accurately captures critical stiffness trends and global deformation modes, satisfying the precision requirements for conceptual design and topology optimization.

4. **Real-Time Design Capability:** Once trained (approximately 4 hours on a single NVIDIA A100 GPU), the VPINN enables inference of mechanical fields in approximately 0.015 seconds per design, amortizing the training investment after approximately 230 evaluations compared to FEM. This eliminates the classical ''modeling-meshing-solving'' cycle and paves the way for integrating physics-based surrogate models into real-time design workflows, allowing struc-

tural engineers to explore thousands of design iterations with immediate structural feedback.

Future work will extend this framework along three directions: (i) expanding the parametric space to include slab thickness, load distributions, and mixed boundary conditions; (ii) benchmarking against data-driven surrogate approaches to quantify the advantages of physics-based training; and (iii) incorporating reinforced concrete nonlinearities, including cracking and steel reinforcement, to bridge the gap between conceptual design and detailed verification.

POTENTIAL OF LARGE LANGUAGE MODELS FOR CONSTRUCTION QUOTATION WORKFLOWS

Anja Brelih, Žiga Krvina, and Robert Klinc
University of Ljubljana, Faculty of Civil and Geodetic Engineering

Abstract

Large language models (LLMs) can automate text-intensive tasks in construction. However, preparing investigation quotations remains manual and time-consuming, with outputs varying between engineers due to non-deterministic steps like item selection and text drafting. This study proposes an LLM-assisted human-in-the-loop (HITL) workflow and evaluates several models (GPT 4.1, GPT 5, Claude Sonnet 4.5, and a fine-tuned open-source model, QwQ 32B) on 596 inquiry-quotation pairs. GPT 5 achieved the highest item-selection F1 score, while Claude 4.5 delivered comparable accuracy with the fastest processing time. This approach improves quotation efficiency and consistency, demonstrating practical benefits for construction workflows.

Introduction

Artificial intelligence (AI) is increasingly adopted in project management to support decision-making, automate repetitive tasks, and improve overall project performance (Taboada et al., 2023; Brelih et al., 2025). Recent advances in large language models (LLMs) have enabled systems that can understand and generate technical text, creating new opportunities for automating construction workflows.

Construction projects are characterised by unique products, processes, and project-specific contexts, which limit the applicability of rigid, fully predefined automation approaches (Turk, 2006). Quotation preparation is a critical but time-consuming activity for engineering companies. Preparing a quotation typically involves analysing client inquiries, selecting appropriate investigation or service items, estimating quantities, and composing a structured technical and commercial response. While parts of this workflow can be automated using conventional software, key steps remain non-deterministic and rely heavily on expert judgement. These include (1) selecting relevant investigation or service items and (2) formulating a coherent quotation text adapted to the specific inquiry.

This paper examines whether LLMs can effectively support and partially automate quotation preparation. Generic LLMs do not have access to internal company knowledge such as service catalogues, pricing structures, and domain-specific standards. To address this limitation, an open-source LLM was fine-tuned with domain-specific data and evaluated against selected commercial LLM solutions. For the use case, data from a company operating in the field of geotechnical investigations was used.

The contributions of this paper are threefold: (i) the design of an LLM-supported quotation workflow for (geotechnical) engineering practice, (ii) quantitative evaluation of multiple LLMs using accuracy- and time-based performance metrics, and (iii) assessment of the practical impact of LLM integration on quotation preparation efficiency and consistency.

The remainder of the paper is structured as follows. Section 2 presents related work, section 3 describes the quotation workflow and LLM integration concept, section 4 outlines the methodology, section 5 reports the results, section 6 discusses implications, and section 7 provides conclusions.

Related work

This section reviews relevant research on the application of AI in construction workflows, the use of LLMs for technical and domain-specific tasks, and existing AI-based approaches for cost estimation and quotation processes.

AI in construction workflows

Within construction informatics, research focuses on methods for creating, processing, and exchanging construction-specific information in both human- and machine-readable forms. AI has therefore been increasingly explored as a decision-support technology in construction management, particularly for scheduling, resource allocation, risk forecasting, and monitoring (Taboada et al., 2023).

Recent studies indicate that AI-powered systems can assist project teams by synthesising heterogeneous data sources, generating alternative scenarios, and providing early warnings of potential deviations (Mikhridinova et al., 2024). However, many existing approaches rely on predefined workflows and limited interaction capabilities, which restrict their adaptability in highly dynamic project environments.

LLMs for technical and domain-specific tasks

Large language models have demonstrated strong capabilities in understanding natural language and generating coherent technical text (Devlin et al., 2019;

Lewis et al., 2020). Their integration into AI agents enables advanced reasoning, task planning, and interaction with external tools through application programming interfaces (Ruan et al., 2023; Liu et al., 2024).

Recent surveys highlight the growing role of LLM-based agents as intelligent collaborators that can process diverse information, coordinate tasks, and support complex decision-making (Xi et al., 2025). Nevertheless, their effectiveness is constrained by the quality of training data, limited domain adaptation, and the stochastic nature of model outputs (Brelih et al, 2025). Consequently, human-in-the-loop (HITL) designs are widely recommended, particularly in safety-critical domains such as construction.

AI support for cost estimation and quotation processes

AI techniques have been explored for various cost-related tasks, including cost estimation, resource optimisation, and project staffing (Taboada et al., 2023; Mikhridinova et al., 2024). These studies demonstrate the potential of LLM-based systems to assist engineers in analysing project data and generating recommendations.

More recently, Gatto et al. (2025) propose an LLM-based methodology to automate the classification and extraction of cost-related descriptions in building projects, mapping textual specifications to a hierarchical taxonomy and populating a structured database to support downstream estimation tasks. Their work highlights how LLMs can reduce manual effort in interpreting and organising cost-relevant information, while also exposing the need for careful prompt design and validation in real-world workflows.

However, existing research primarily addresses cost prediction or high-level decision support rather than the end-to-end preparation of quotations. Little attention has been given to automating the selection of investigation or service items and the generation of quotation texts tailored to specific client inquiries.

Research gap

While prior research demonstrates the potential of AI and LLM-based agents to support construction workflows, there is a lack of empirical studies. This paper addresses this gap by evaluating multiple LLMs and proposing an LLM-supported quotation workflow tailored to domain-specific requirements for construction practice.

Quotation preparation workflow and LLM integration

In the company analysed, quotation preparation is a multi-step process initiated by a client inquiry received via email, which includes a brief project description, location, and requested services. An engineer reviews the inquiry, identifies the relevant type of geotechnical investigation, and manually selects appropriate service items from the internal service catalogue. Based on the selected items, quantities are estimated and prices are retrieved from internal pricing lists.

The engineer then prepares a quotation document that combines structured information (selected items, quantities, prices) with unstructured text describing the scope of work, assumptions, and conditions. The final quotation is reviewed and sent to the client. This workflow is largely manual and depends on individual experience, which can result in variability in both content and structure.

Although parts of the workflow follow predefined rules, several steps require expert judgement. Selecting of investigation or service items based on the inquiry content, estimating of quantities for individual items, and formulating of a coherent quotation text tailored to the specific project are non-deterministic steps and similar inquiries may result in different valid solutions depending on interpretation and experience.

LLM-supported workflow

To address these limitations, an LLM-supported workflow with human-in-the-loop (HITL) was designed. Upon receipt of a client inquiry, the inquiry text is provided to the LLM along with contextual information about available services, pricing structures, and domain-specific guidelines.

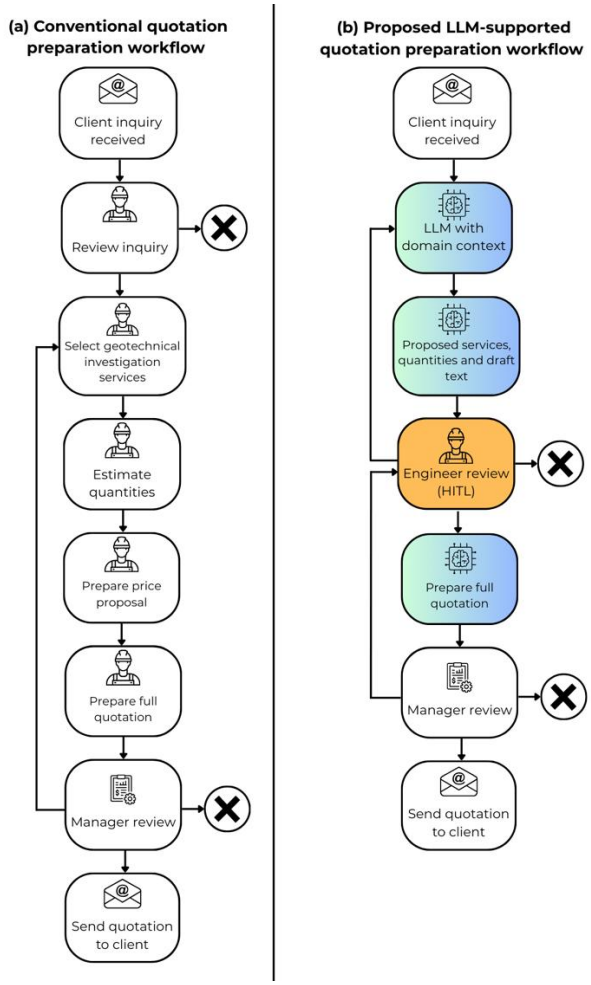

Figure 1: (a) Conventional quotation preparation workflow and (b) Proposed LLM-supported quotation preparation workflow.

The LLM generates a proposed set of service items, suggested quantities, and a draft quotation text. The engineer reviews the proposed output, makes corrections where necessary, and approves the final quotation. This HITL approach ensures that responsibility remains with the engineer while reducing the time required for routine tasks.

Quotation preparation combines structured data (service items, quantities, prices) with semi-structured and unstructured textual information (project descriptions, assumptions, and conditions). These characteristics make the process well suited for LLM, as LLMs are particularly effective at processing natural language and generating coherent technical text.

The repetitive nature of quotation preparation and the availability of historical quotations enable the creation of domain-specific training and evaluation datasets, supporting model adaptation and performance assessment.

The proposed workflow, shown in Figure 1, shifts the engineer's role from manual creation (a) to supervisory validation and refinement (b).

In this context, the HITL design is not just a safeguard but a critical architectural choice for deploying AI systems in construction workflows. The LLM serves as a cognitive assistant, while engineers retain full authority over validation, correction, and approval. This ensures that accountability and compliance remain firmly anchored in human expertise, which is essential in a highly regulated and safety-sensitive industry. HITL enables explainability, auditability, and trust, which are key requirements when AI-generated outputs may affect technical or financial decisions. Recent studies emphasized that in many industrial domains, fully autonomous AI agents may not be justified, and AI is more effective when deployed as a supervised contributor, particularly in contexts demanding trust, reliability, and regulatory compliance (He et al., 2024; Kotsiopoulos et al., 2024).

Methodology

We evaluated both commercial and open-source LLMs for supporting quotation preparation. The commercial models included GPT 4.1 and GPT 5 (OpenAI), and Claude Sonnet 4.5 (Anthropic). As an open-source baseline, we used QwQ 32B in (i) its base form and (ii) a fine-tuned version adapted to the company domain using anonymized examples from past project inquiries.

To assess the impact of supplementary project information, GPT 4.1 and GPT 5 were evaluated in two input configurations: (a) inquiry text only and (b) inquiry text plus attachments (when provided with the client inquiry). All models were prompted using a unified prompt template requiring a structured output (JSON) to ensure comparability across model families. This schema was designed to reflect real quotation workflows, and included fields such as project metadata, client inquiry content, and the desired response structure (e.g., service item list, estimated quantities, response text). Prompts were iteratively refined across models to ensure consistency. Domain knowledge was embedded into the prompts through a combination of static context injection (e.g., glossaries, service catalog excerpts, company-specific terminology) and heuristic templates derived from past quotation examples. Due to contractual and confidentiality constraints, external tool integration (e.g., retrieval-augmented generation) was not used, and no real-time application programming interface (API) calls were permitted.

Listing 1: Example prompt structure (abbreviated)

SYSTEM PROMPT:

Task: *Based on the client inquiry, generate a structured JSON listing of required geotechnical services, quantities, and a brief rationale.*

Context: *The company is based in Melbourne, Australia.*

Instructions:

1. *Review the client inquiry.*
2. *Select required work items from a predefined list.*
3. *Estimate quantities and justify selections in one sentence each.*
4. *Output a JSON array including item name, quantity, and justification.*

CLIENT INQUIRY *(excerpt):*

"…4 boreholes to 10 m or refusal. Provide retaining wall parameters and bearing capacity. Northern wall = gravity, Southern = MSE…"

EXPECTED OUTPUT FORMAT (JSON):

```
[
{"work_item": "Soil Drilling (<10m)", "quantity": 4},
{"work_item": "CBR Testing", "quantity": 3},
{"work_item": "Geotechnical Report", "quantity": 1}
]
```

The evaluated models were selected to represent both state-of-the-art commercial systems and high-capacity open-source alternatives. GPT 4.1 and GPT 5 (OpenAI) were included due to their status as leading commercial LLMs at the time of our research, with broad adoption and strong performance across technical NLP tasks. Claude Sonnet 4.5 (Anthropic) was selected based on reports of fast inference and strong reasoning in applied scenarios. QwQ 32B was chosen as a high-capacity open-source model suitable for domain fine-tuning. Its fine-tuned variant (QwQ 32B FT) was trained on domain-specific data to explore the feasibility of internal model adaptation without commercial licensing. Simpler baselines (e.g., BERT variants, rule-based systems) were not included, as the application scenario required generative capabilities and flexible outputs.

We compiled a dataset of 596 quotation inquiries collected over several years from a geotechnical

engineering firm. These inquiries vary in format, language quality, and complexity, reflecting realistic working conditions. From this dataset, we extracted a representative evaluation set of 120 inquiries, which were manually annotated with expected service items and quantities for comparison.

Fine-tuning of the open-source model

The open-source model was adapted using a two-stage, parameter-efficient fine-tuning approach:

1. Domain adaptation (DA). The model was adapted on domain texts describing geotechnical investigation service items (including professional item descriptions) to incorporate company terminology and service scope knowledge.
2. Supervised fine-tuning on input-output (inquiry-quotation) pairs (I/O). The base model, augmented with the DA adaptation, was further fine-tuned using supervised learning on curated inquiry-quotation examples. Each training example consisted of (i) an instruction plus the anonymised inquiry text as input and (ii) a strict JSON output containing the selected service items and their quantities as the learning target. This stage was designed to improve both domain-appropriate item selection and adherence to a consistent, machine-readable output structure.

The resulting fine-tuned model is referred to as QwQ 32B-FT in the remainder of the paper.

Dataset

The dataset consists of 596 real inquiry-quotation pairs collected from a geotechnical engineering company. Each pair contains (i) the anonymised client inquiry (email text and associated attachments, where applicable) and (ii) the corresponding engineer approved quotation, from which the reference service items and quantities were extracted.

The dataset was divided into 476 training pairs (80 %) and 120 test pairs (20 %). The training set was used exclusively for fine-tuning QwQ 32B-FT. The 120 pair test set was used for evaluation of all models.

Due to the signed NDA and client confidentiality, original data cannot be disclosed. However, a manually constructed mock example is provided below to illustrate the structure of a typical case:

Listing 2: Example inquiry-quotation pair

Inquiry (excerpt):

We are preparing a residential development in Werribee. Please include standard fieldwork, Atterberg limits, PSD tests, and recommendations for slab-on-ground foundations.

Output (excerpt):

[{"work_item": "Soil Drilling (<3m)", "quantity": 2},
{"work_item": "Atterberg Limits", "quantity": 2},
{"work_item": "PSD Testing", "quantity": 2},
{"work_item": "Geotechnical Report", "quantity": 1}]

Evaluation metrics

Performance was quantified using both quality and operational metrics. Service item selection is treated as a multi-label selection problem, evaluated using precision, recall, and F1 score. In addition, we measured quantity accuracy and processing time.

Quantity accuracy is the ratio of correctly determined quantities to all quantities proposed by the model for the selected items.

Processing time is the end-to-end time required to generate a complete structured output for the inquiry set. The paper reports the total time for 120 inquiries and average time per inquiry.

Results

This section reports model performance on the 120 inquiry test pairs using item selection metrics (precision, recall, F1), quantity accuracy, and processing time. Table 1 summarises the quantitative comparison across GPT 4.1, GPT 5, Claude Sonnet 4.5, QwQ 32B base, and QwQ 32B-FT. Figure 2 visualises the trade-off between effectiveness (F1) and speed (processing time).

GPT 5 with attachments achieved the highest F1 score (50%), driven by the highest recall (65 %), while Claude Sonnet 4.5 achieved a similar F1 score (48 %) with the fastest processing time (6.84 s/inquiry). The open-source baseline QwQ 32B performed substantially worse than commercial models on all quality metrics. QwQ 32B-FT improved precision (from 11 % to 21 %) and F1 score (from 8 % to 18 %) but remained far below the commercial LLMs. Quantity accuracy is low for all evaluated models (≤ 15 %), indicating that quantity determination remains a major bottleneck even when item selection improves.

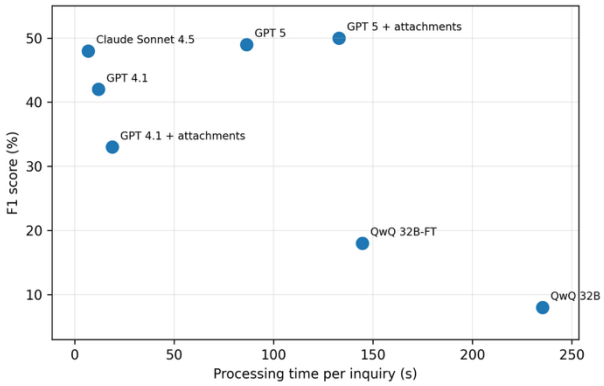

Figure 2: Scatter plot of F1 score relative to processing time.

Figure 2 shows that Claude Sonnet 4.5 offers the best balance between speed and quality (high F1 score at low latency), while GPT 5 achieves a slightly higher F1 score but with significantly longer runtime, especially when attachments are included. Figure 2 also shows that the fine-tuned version of the open-source model (QwQ 32B-FT) improved significantly in processing time as well as in F1 score, compared to the base model QwQ 32B.

Model	Precision (%)	Recall (%)	F1 score (%)	Quantity accuracy (%)	Total processing time (h)	Processing time per inquiry (s)
GPT 4.1	41	52	42	10	0,4	12,0
GPT 4.1 + attachments	38	38	33	8	0,63	18,9
GPT 5	43	63	49	13	2,88	86,4
GPT 5 + attachments	43	**65**	**50**	**15**	4,43	132,9
Claude Sonnet 4.5	**45**	55	48	11	**0,228**	**6,84**
QwQ 32B	11	7	8	1	7,84	235,2
QwQ 32B-FT	21	17	18	5	4,82	144,6

Table 1: Model performance on 120 inquiries.

Figure 3 shows that quantity accuracy remains consistently low across all evaluated models, with the best-performing configuration (GPT 5 with attachments) achieving only 15 %. Even models that perform well in service item selection and text generation do not reliably determine numerical quantities. This confirms that quantity estimation is the main bottleneck for higher levels of automation in quotation preparation and supports the use of hybrid workflows, where LLMs propose candidate items and draft text, while quantities are computed or verified using deterministic or rule-based tools.

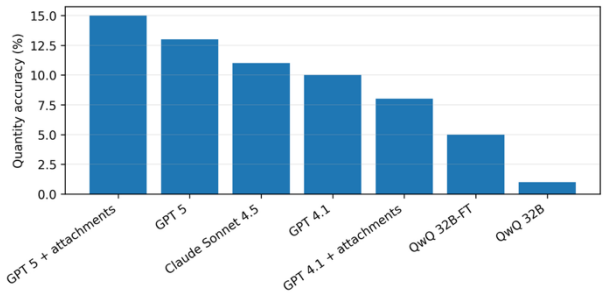

Figure 3: Quantity accuracy across evaluated model configurations.

Although all the accuracies were low, there is a notable increase in accuracy for the fine-tuned open-source model QwQ 32B-FT (4%) compared to the base model QwQ 32B (1%).

Discussion

The results indicate that commercial LLMs can meaningfully support quotation preparation by improving the accuracy of selecting geotechnical investigation service items, but they do not yet provide reliable quantity estimation without additional safeguards. Across models, the highest F1 score for item selection is approximately 50 %, meaning that even the best-performing configuration on average still misses or misidentifies a substantial portion of required items. This level of performance supports the proposed human-in-the-loop workflow: the models can accelerate drafting and reduce manual effort, but responsibility and final validation must remain with engineers.

A key practical finding is the quality-latency trade-off. GPT 5 with attachments achieves the best overall selection performance (highest F1 score and recall), but at a markedly higher processing time than other models. In contrast, Claude Sonnet 4.5 achieves an F1 score close to the best-performing GPT 5 configuration while being the fastest model in this study. For deployment in a real quotation preparation workflow, where the primary goal is to quickly provide a strong draft for engineer review, Claude Sonnet 4.5 appears to offer the most favourable operational profile.

The effect of attachments is not uniform. For GPT 5, attachments provide small improvements in recall and F1 score, suggesting that additional project context can help when the model can reliably integrate it. For GPT 4.1, however, adding attachments decreases performance sharply. This suggests that naively appending additional documents may introduce noise, cause relevant content to be diluted, or trigger truncation effects in long contexts.

The persistently low quantity accuracy across all models (≤15 %) is the most important limitation for practical adoption. This aligns with broader observations in construction-focused LLM research: generative models can produce fluent text and plausible suggestions, but numerical correctness and strict domain constraints remain challenging, especially without structured inputs and verification mechanisms. For quotation preparation, this motivates a hybrid architecture. LLMs can propose candidate items and draft explanatory text, while quantities should be computed or checked by deterministic tools (e.g. rule-based calculators) and engineer before finalisation.

The open-source model results clarify the current limits of local deployment. Although QwQ 32B-FT improved over the base QwQ 32B model, it did not reach competitive performance against commercial models. Moreover,

processing time remained high, undermining the operational benefits of automation. This does not preclude open-source adoption, but it indicates that achieving comparable performance likely requires larger models, higher-quality domain datasets, stronger retrieval augmentation, or more extensive fine-tuning, each requiring non-trivial engineering and infrastructure effort.

Finally, several limitations affect generalisability. The dataset originates from a single (geotechnical) company and a specific service catalogue, so model behaviour may differ in other contexts. The evaluation focuses on structured outputs (items and quantities), and the quality of the generated quotation text was not scored with a dedicated metric, although it is operationally important. Although the use case focuses on inquiries for geotechnical investigations, the results, and especially the workflow, are applicable across the entire construction domain.

While this study focuses on generative LLMs for their flexibility and alignment with comapny expectations, we acknowledge the absence of classical baselines such as BERT classifiers or rule-based matching systems. These approaches have been successfully applied to other construction-related tasks but were not included here due to the specific need for coherent text generation and adaptive item selection. Additionally, time and resource constraints limited the scope of model benchmarking. Future work could extend the evaluation to include retrieval-augmented generation or hybrid architectures that incorporate rule-based precision.

A qualitative review of model outputs suggests that accuracy was higher for inquiries with clear structure or phrasing patterns similar to previously encountered examples. In contrast, performance declined for inquiries that were vague, combined multiple project scopes, or included fragmented or informal language. Quantity errors mainly resulted from incomplete or ambiguous inputs. Many inquiries lacked explicit numerical requirements or used inconsistent units. These findings highlight the importance of structured input and human oversight when deploying LLMs in quotation workflows.

Limitations and Future work

This study is limited by its focus on a single company and service domain, which may affect generalisability to other construction contexts. Although models were evaluated using structured outputs, the quality of generated text was not assessed, despite its relevance in operational settings. Classical baselines and retrieval-augmented generation pipelines were excluded due to project scope and the requirement for flexible, generative outputs. Additionally, quantity estimation accuracy remains low across all models, highlighting the need for structured inputs and complementary rule-based tools. Future work could address these gaps by evaluating across multiple organisations, benchmarking against hybrid approaches, and assessing text quality and compliance in practical deployment.

Conclusions

This paper addresses the acceleration of quotation preparation using LLMs, where expert judgement is required for selecting appropriate service items and drafting quotation text. We designed an LLM-supported quotation preparation workflow and empirically evaluated several LLMs on a real dataset of inquiry-quotation pairs for geotechnical investigations, comparing commercial models (GPT 4.1, GPT 5, Claude Sonnet 4.5) with an open-source baseline (QwQ 32B) and its fine-tuned version (QwQ 32B-FT).

The results show that commercial LLMs significantly outperform open-source models in item selection, with GPT 5 (+ attachments) achieving the highest F1 score and Claude Sonnet 4.5 offering the best balance between F1 score and processing time. However, quantity accuracy is consistently low across all models, indicating that reliable quantity determination remains the main barrier to higher levels of automation.

Overall, the findings support the adoption of LLMs as drafting and decision-support tools within a human-in-the-loop process, while highlighting the need for hybrid architectures that combine LLM generation with deterministic quantity computation and validation. These findings underscore the value of HITL approaches not only as operational safeguards, but as foundational design choices that align AI support tools with the needs of high-stakes engineering domains. Future work should extend evaluation to multiple organisations, quantify text quality and compliance, and integrate rule-based or tool-assisted quantity estimation to reduce risk and improve end-to-end quotation reliability.

MULTIDIMENSIONAL WEIGHTED RANKING RECOMMENDATION SYSTEM FOR CIRCULAR MATERIAL MATCHMAKING

Noah Gerber[1], Ibrahim Al-Hazwani[2], and Pei-Yu Wu [3]
[1]ETH Zurich, Zurich, Switzerland
[2]University of Zurich, Zurich, Switzerland
[3]Delft University of Technology, Delft, The Netherlands

Abstract

Circular construction relies on digital marketplaces to overcome supply chain fragmentation, yet manual search for reclaimed components remains a critical bottleneck. This research develops a context-aware recommendation system for reusable material matchmaking. Utilizing a multidimensional weighted ranking algorithm with hard and soft constraints, the system adaptively aligns material attributes with project requirements. Validated through expert elicitation and a design simulation user study, results demonstrate high material findability and low cognitive load. However, insufficient algorithmic transparency can induce user friction. This work establishes a foundation for role-centric matchmaking, with future research focusing on similarity score cutoffs, enhanced interpretability, and API-driven cross-platform interoperability.

Introduction

Digital material marketplaces are evolving into mediatised platforms that foster a circular construction sector by enabling the sustainable reuse of building materials. Nevertheless, many existing reuse platforms operate within isolated local communities, preventing economies of scale and restricting the volume of available secondary products compared to primary materials. Consequently, the low quantity and high diversity of reclaimed batches often preclude their procurement in new construction projects. Recent literature identifies several critical barriers to platform effectiveness: (1) structural and economic obstacles such as high upfront costs; (2) operational constraints caused by the lack of spatial and temporal synchronization between deconstruction and construction phases; (3) informational gaps stemming from a lack of automated data entry and standardized performance documentation (Wilson et al., 2025; Quertamp et al., 2025); and (4) low user adoption. Notably, 70% of marketplaces prioritize auxiliary services (e.g., building inventory, logistics) over core digital infrastructure (Menny et al., 2024), resulting in underutilized databases that fail to reach the critical mass necessary to bridge the gap between supply and demand.

To address these challenges, research suggests transitioning from project-centered to role-centric matchmaking through asynchronous loops that mitigate strict synchronization requirements (Menny et al., 2024). Technological interventions such as blockchain, the InterPlanetary File System (IPFS) (Protocol Labs, 2026), and Digital Product Passports (Honic et al., 2024) are being explored to ensure traceability (Wilson et al., 2025). Furthermore, the integration of standardized circularity indicators and interoperable APIs aligned with Circular Economy standards (ISO/TC 323, 2018) facilitates cross-platform communication. Finally, participatory action research and regulatory alignment with Extended Producer Responsibility laws ensure that digital tools meet real-world operational needs and compliance requirements (Podkalicka and Fredriksson, 2023; Quertamp et al., 2025).

While these frameworks provide the necessary infrastructure for data exchange, their utility depends on early-stage intervention within the design process to maximize reuse potential before in-situ reclamation. Building upon this requirement, this study develops a Context-Aware Recommendation System (CARS) designed to facilitate the matchmaking of both in-situ components and off-site reclaimed materials. By employing a multi-phased participatory design approach with actors from Swiss marketplaces, this research seeks to: (1) identify critical decision-making factors to encode heterogeneous inputs into a unified schema; (2) integrate temporal and geospatial preferences into a context-aware engine to enhance logistical viability; and (3) provide explainable recommendations to foster user trust. To achieve this, the system encodes semantic and quantitative material records into a multidimensional vector database, facilitating similarity matching based on the mathematical proximity between dynamic user requirements and material attributes. By incorporating image data and explainability features, the system addresses the ”black box” friction common in traditional vector retrieval.

The paper demonstrates the feasibility of integrating a CARS into a user-friendly interface that delivers personalized matchmaking based on dynamic constraints. By enabling users to interactively adjust priority levels across multilingual inventories, the system generates ranked outcomes with matching scores that reveal the underlying weighted logic. This guides users to iteratively refine search parameters and explore alternative material choices when exact matches are insufficient. Preliminary findings validate that high operational speed and intuitive weighted search logic effectively bridge the gap between technical retrieval and architectural design rationale. However, the results also highlight a critical need for enhanced semantic

transparency and similarity thresholds to ensure reliability as databases scale. This research contributes a methodological framework for optimizing the quality and diversity of early-stage matchmaking in circular construction.

Related work

Relevance of context-aware recommender systems
CARS address the structural fragmentation and logistical constraints of material reuse by synchronizing spatial and temporal data. Unlike static systems, CARS incorporate dynamic attributes, such as disassembly windows and geographic proximity, to adapt results to immediate project needs (Adomavicius et al., 2011; Afzal et al., 2024). This approach mitigates the data sparsity and cold-start problems inherent in unique, transient secondary material databases by leveraging contextual constraints to estimate preferences when historical interaction data is absent (Kulkarni and Rodd, 2020). Consequently, the system models evolving professional requirements throughout the project lifecycle rather than relying on fixed interest models (Huang et al., 2024).

Distinctive nature of secondary matchmaking
Secondary material matchmaking differs from standard e-commerce due to high item heterogeneity and the absence of reciprocal supplier constraints. The process shifts from exact stock keeping unit matching to similarity matching of non-standardized components using quantitative, qualitative, and vector-based image data (Adomavicius et al., 2011). Furthermore, professional selection requires a multi-criteria evaluation framework rather than a single consumer rating (Afzal et al., 2024). Practitioners must concurrently weigh technical specifications, aesthetics, and environmental impact. This necessitates a ranking system capable of balancing diverse factors against specific professional workflows rather than simple popularity metrics.

Explainability in professional decision-support
Explainability transforms the recommendation engine from an opaque ”black box” into a transparent support framework, establishing the epistemic trust necessary for high-stakes construction decisions (Tintarev and Masthoff, 2015). By allowing users to explicitly define attribute weighting, such as prioritizing structural load over aesthetics, the system provides requirement-specific justifications for its suggestions (Lai et al., 2024). This transparency is vital for validating unique, reclaimed components. Explicitly describing how a material aligns with complex project constraints ensures that recommendations are both actionable and interpretable within professional discovery processes.

Methodological framework

This research employs a multi-phased participatory design approach to develop a context-aware matchmaking platform. Initial scoping involved consultations with experts from Swiss secondary material companies to elicit operational workflows and define technical metadata requirements. An iterative development phase followed, where stakeholders evaluated prototype design considerations and prioritized functionalities. Finally, the platform underwent empirical evaluation through a structured user study with four native German-speaking participants. This linguistic selection ensured valid interaction with the localized interface and database.

User requirements

Technical and metadata requirements
Effective matchmaking necessitates the integration of high-fidelity material attributes across three categories: fundamental dimensions and classification; performance metrics (e.g., thermal or acoustic properties and mounting specifications); and a standardized physical condition scale. Expert elicitation indicates that practitioners prioritize chronological age over manufacturer identifiers when assessing reclaimed value. Furthermore, high-quality visual documentation is critical for the remote assessment of unique components. To ensure interoperability, the search schema aligns with DIN SPEC 91484 (DIN German Institute for Standardization, 2024) and Digital Product Passport frameworks (Honic et al., 2024), facilitating a unified infrastructure for cross-platform exchange.

Role-specific functional requirements
Matchmaking architectures must accommodate the divergent workflows of specialized professional groups. Architects and designers prioritize reliability and contextual inspiration, typically matching available inventories against pre-defined design constraints. Conversely, business owners and contractors emphasize carbon savings and regulatory compliance over initial procurement costs. To ensure functional integrity, these stakeholders require integrated services such as quality assurance, professional testing, and specialized cleaning. The system addresses these needs through a dual-announcement model comprising both supply listings and search requests. This bifacial architecture facilitates a proactive procurement process tailored to the logistical demands of circular economy actors.

Operational and logistical requirements
Systemic viability depends on managing the physical constraints of the construction sector. Geospatial filters are integrated to mitigate transport costs, which frequently dictate the economic feasibility of secondary materials. To address the primary cost drivers in the reuse cycle, the system supports material demand prediction to optimize storage management. Additionally, operational data regarding deconstruction viability (e.g., ease of disassembly, fragility, and weight) is essential for sourcing materials in situ.

Psychological and soft factors
Material provenance, historical context, and environmental significance are decisive factors in the selection of reclaimed components. To manage the complexity of

non-standardized items, the system utilizes intuitive interface features designed to minimize cognitive load and user anxiety. Successful matchmaking requires a synthesis of a component's history, physical health, and spatiotemporal availability. Aligning these narrative qualities with rigorous technical constraints ensures a reliable material exchange.

Design goals

Based on the research framework and expert elicitation, five core design goals are established to transition digital marketplaces toward multidimensional decision support.

1. Multidimensional similarity matching
The system implements similarity matching to shift from rigid queries to the flexible discovery of heterogeneous components. Representing qualitative and quantitative dimensions within a vector database enables the engine to suggest functional alternatives aligned with latent project objectives rather than restricted search terms.

2. Spatiotemporal and logistic optimization
Geospatial proximity and temporal availability are integrated as dynamic factors managed through user-defined priority levels. This addresses the critical synchronization required between in-situ deconstruction windows and reconstruction schedules, ensuring logistical feasibility.

3. Role-centric recommendation logic
The engine adapts weighting parameters to the distinct priorities of stakeholders. While individual users may focus on cost, professional architects often emphasize carbon savings and technical reliability. Tailoring the ranking logic to these requirements ensures professional relevance.

4. Trust through explainability and user experience design
Transparent recommendations detail the reasoning behind matches, such as shared mounting specifications or condition ratings. This transparency, combined with streamlined interaction patterns, bridges the trust gap regarding the performance of reclaimed materials in a risk-averse sector.

5. Data interoperability and aggregation
The platform functions as a meta-aggregator to address market fragmentation. By aligning with international standards and aggregating data across multiple engines, the system provides a comprehensive regional overview, ensuring recommendations are derived from high-quality, interoperable datasets.

System overview

Material data schema

The data integration and structural representation, denoted as M, synthesizes metadata of each material item into an integrated schema.

$$M = \{\text{id}, I, Q, P, S, L, T\}$$

$$\begin{cases} I = (T, D) & \text{Title and description} \\ Q \in \{\text{new, good, poor}\} & \text{Quality interval} \\ P \in \mathbb{R}_{\geq 0} & \text{Unit price} \\ S = (w, h, d) \in (\mathbb{R}^+)^3 & \text{Volumetric Dimensions} \\ L = (\phi, \lambda) & \text{Geospatial coordinates} \\ T = (t_{start}, t_{end}) & \text{Temporal period} \end{cases} \quad (1)$$

The material schema is formalized as a multi-layered tuple. The identification layer $\{\text{id}, I\}$ integrates a unique identifier with a descriptive metadata. Economic and qualitative dimensions are represented by unit price P and material integrity Q, with the latter categorized into three discrete intervals to facilitate standardized circular recovery assessment. Finally, the system encodes physical, geospatial, and temporal constraints via S, L, and T, which define volumetric attributes (w, h, d), coordinates (ϕ, λ), and the operational validity period (t_{start}, t_{end}).

Platform architecture

The platform is engineered for data ingestion and semantic retrieval using a serverless framework. The system is partitioned into two distinct operational pipelines leveraging edge computing to minimize latency and ensure linear scalability, as illustrated in Figure 1.

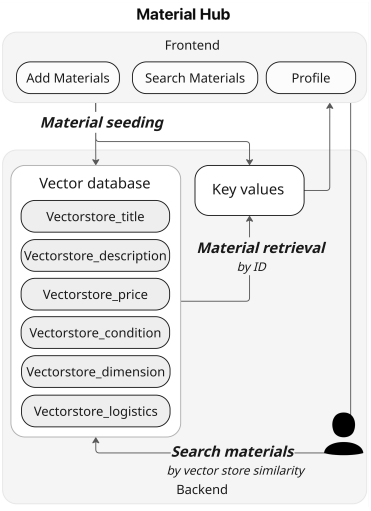

Figure 1: System archtiecture and workflow.

Material seeding pipeline

The seeding pipeline initiates with edge-based input processing via Cloudflare Workers. These functions execute data normalization and validation of attributes, including Swiss eBKP classification codes (Swiss Society of Engineers and Architects, 2020), pricing, and dimensions. Following refinement, the Gemini Embedding model (Lee et al., 2025) transforms textual descriptions and technical

parameters into high-dimensional vectors. These representations are indexed within Vectorize, a distributed vector database maintaining the latent space of all material profiles.

Material retrieval pipeline

The retrieval pipeline facilitates semantic search by translating natural language queries into vector representations. The architecture executes similarity analysis using a k-nearest neighbor (k-NN) algorithm to calculate the cosine similarity between the query vector and stored indices. By identifying elements based on spatial proximity in the latent space, the system overcomes the limitations of traditional keyword matching for non-standardized material descriptions.

Material recommendation system widget

Integrating specifications into the digital *Material Hub* (Figure 2) triggers a ranked list of recommendations based on calculated matching scores. System widgets allow for the iterative adjustment of preference weights, enabling real-time exploration of alternative candidates.

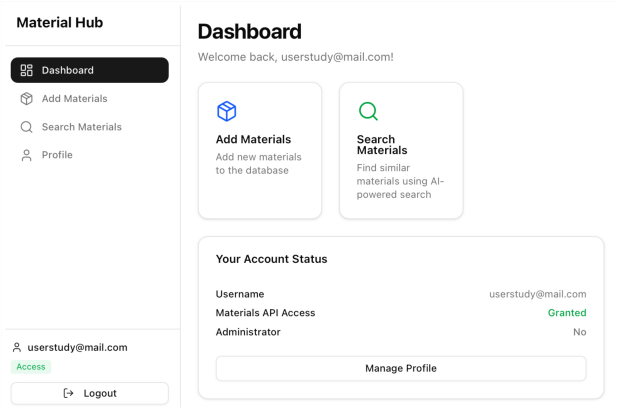

Figure 2: Material Hub dashboard prototype highlighting the integrated modules for material registration, multidimensional search, and user profile management.

Material data ingestion

The system supports dual-mode data ingestion: automated batch processing via inventory files (e.g., pre-renovation or pre-demolition audits) or manual entry, as shown in Figure 3. The automated pipeline utilizes Large Language Models (LLMs), specifically Llama 3.1 8B Instruct (Meta AI, 2024), to parse unstructured data and extract material properties. In cases of data scarcity, the system maintains integrity by imputing missing values based on category averages. Imported materials are automatically mapped to Swiss eBKP-H classification codes (Swiss Society of Engineers and Architects, 2020) to standardize heterogeneous documentation into a structured database.

Preference adjustments

To optimize discovery within multidimensional decision spaces, the system utilizes a weighted vector retrieval

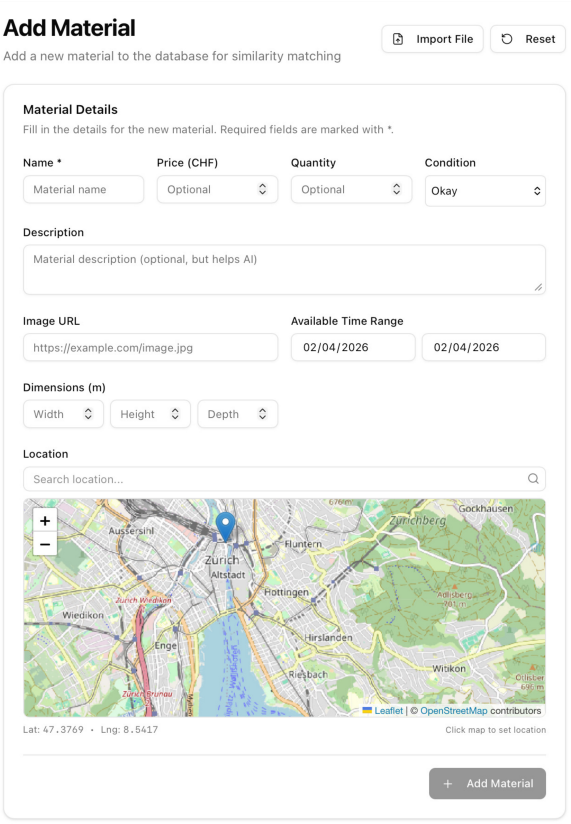

Figure 3: User interface for material data ingestion by batch processing or manual entry.

mechanism. Users calibrate the recommendation engine by assigning discrete priority levels to specific attributes, which are translated into quantitative weights. This process employs a dual-constraint logic: hard constraints serve as binary filters to exclude non-compliant materials, while default soft constraints facilitate fuzzy matching to preserve high-potential alternatives.

Geospatial logistics and proximity

The system integrates an interactive mapping interface powered by OpenStreetMap to manage geographical constraints. Users define a central project coordinate and a search radius, restricted to a maximum of 100 km. This parameter is empirically derived from expert interviews, reflecting the logistical threshold where transportation costs and environmental impacts typically become counterproductive for reclaimed materials.

Global weight distribution and ranked results

To enhance interpretability, the system visualizes the contribution of individual attributes to the final similarity scores. As illustrated in Figure 5, the global weighted attributes of the aggregated k-matched items are displayed in a stacked bar chart.

The top k items are ranked using a late-fusion integration logic that synthesizes unstructured semantic data with structured constraints, presented in modular cards in Figure 6. To provide granular transparency, each entry dis-

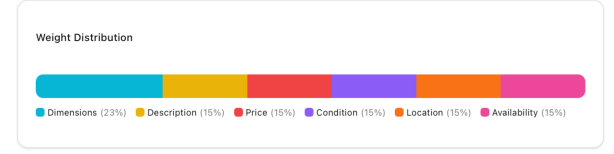

Figure 5: Global weight of attribute-level contribution to the similarity scores of k-matched items.

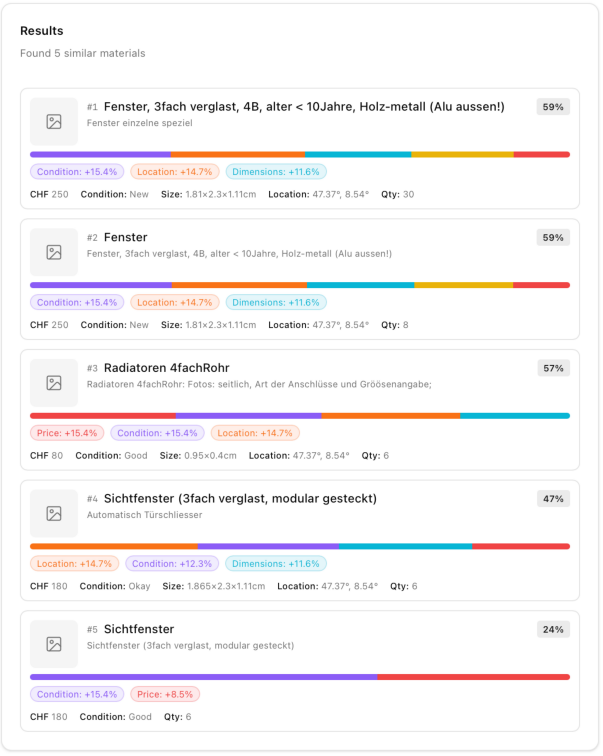

Figure 6: Ranked material candidates with localized attribute decomposition for the search query "windows."

plays a "local weight" representing the aggregate alignment of its specific attributes. We define $s_{\text{sem}}(m_i)$ as the cosine similarity between embeddings, and $s_j(m_i) \in [0,1]$ as normalized scores for J structured preference criteria (e.g., distance, quantity, and condition). The final ranking score $S_{\text{final}}(m_i)$ is produced via linear aggregation: Items are sorted in descending order of $S_{\text{final}}(m_i)$. This framework ensures the ranking remains interpretable, allowing users to discern the relative importance of latent semantic relevance versus explicit attribute requirements.

$$S_{\text{final}}(m_i) = w_{\text{sem}}\, s_{\text{sem}}(m_i) + \sum_{j=1}^{J} w_j\, s_j(m_i),$$

$$w_{\text{sem}} + \sum_{j=1}^{J} w_j = 1, \quad w_{\text{sem}}, w_j \geq 0.$$

System evaluation

This section presents a multi-faceted evaluation of the platform, assessing technical efficiency via quantitative metrics, retrieval accuracy through a hybrid ranking analysis, and practical utility via controlled user studies.

Performance assessment

Performance was evaluated based on latency (end-to-end processing duration) and scalability (performance stability relative to repository growth). Latency measurements across the retrieval pipeline, comprising embedding generation, vector similarity search, deterministic filtering, and final scoring, indicate that response times remain within thresholds for real-time interaction. Vector similarity search is the most intensive stage. However, the implementation of approximate nearest neighbor indexing significantly reduces retrieval time compared to linear scans. Embedding generation and final ranking operations contribute marginal overhead, as the latter processes a pruned candidate subset.

Incremental dataset scaling experiments confirm that the approximate nearest neighbor indexing structure maintains sub-linear growth, avoiding exhaustive comparisons. This scalability and throughput is augmented by a serverless architecture that enables concurrent operations through automatic worker instantiation. These findings suggest the architecture can support expanding marketplaces without significant performance degradation.

Retrieval quality and error analysis

Preliminary quality assessments verified the alignment of retrieved materials with semantic intent and structured constraints. A comparative analysis between purely semantic and hybrid strategies reveals that while semantic-only retrieval excels at discovering conceptually related materials with divergent terminology, it frequently identifies candidates that fail physical or logistical requirements (e.g., geographic proximity). The hybrid pipeline resolves this by integrating deterministic filtering, successfully pruning unsuitable results while preserving the discovery advantages of vector search.

Error analysis identified three primary failure modes: (1) data sparsity, where incomplete descriptions prevent high-fidelity semantic representations; (2) category overlap,

where distinct materials (e.g., panels vs. beams) share similar descriptive language; and (3) linguistic ambiguity, where vague queries produce broad, low-precision result sets. These findings underscore that structured metadata is essential for resolving the inherent ambiguities of natural language in technical domains.

User study

The user study evaluated the platform's functional performance across four dimensions: usability, retrieval efficacy, design alignment, and qualitative feedback. Participants conducted a design simulation for a temporary pavilion in Zurich, navigating a database to source technical components (e.g., glazing units, HVAC systems) under specific lifespan and safety constraints. This iterative process, as shown in Figure 7, facilitated a multidimensional analysis of system usability, the efficacy of the recommendation engine in discovery, and the alignment of results with architectural design rationales.

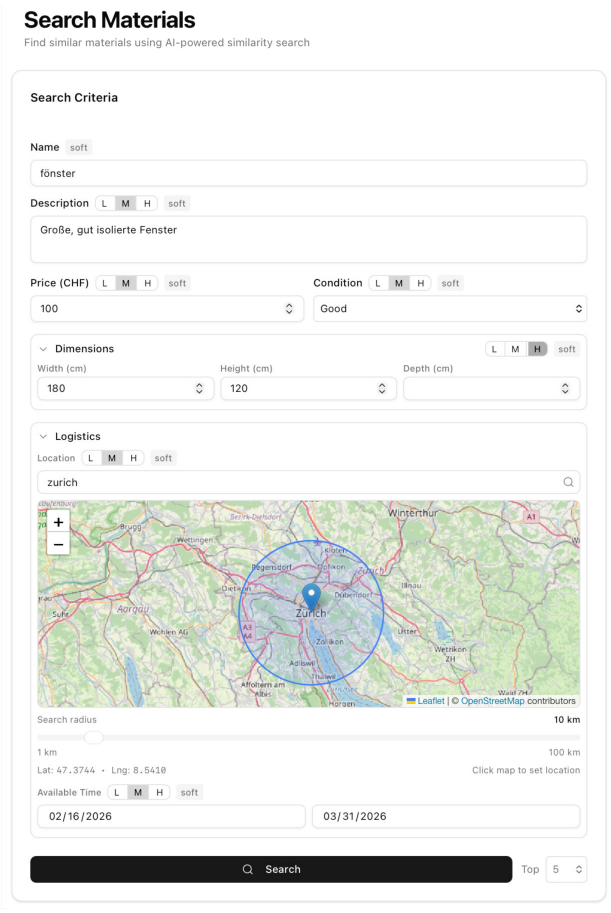

Figure 7: User interface for multidimensional vector search with constraint-based material retrieval logic.

System usability and user experience

Usability was assessed via metrics adapted from the System Usability Scale (Lewis, 2018). Participants reported low system complexity and high consistency, evidenced by high learnability scores (Median = 4.5) and low cognitive load. Technical confidence remained high (Median = 4.0), though variability (SD = 1.50) indicates that individual technical self-efficacy influences the user experience. Workflow fluidity analysis showed strong functional integration between vector search and filtering (Mean = 3.75, SD = 0.50). While 75% of participants perceived the system as highly consistent, divergent scores in intended frequency of use suggest that perceived utility is sensitive to individual professional context.

Information retrieval and discovery efficacy

The efficacy of the vector store and recommendation engine was validated by a mean search success score of 8.0 (SD = 1.15) on a 10-point scale, with no reported search failures. Participants identified "description", "name", and "size" as the most critical metadata for procurement decision-making. However, a "black-box" effect was observed regarding the ranking logic. Participants noted that weighted search results lacked sufficient descriptive interpretation, highlighting a requirement for greater algorithmic transparency and interpretability in the retrieval output.

Design rationale and requirement alignment

The simulation demonstrated the platform's ability to bridge technical retrieval with architectural application. Material selection was driven by semantic matches (type, color) and structured constraints (price, location, and age). Participants successfully identified components aligned with project requirements, demonstrating a correlation between search precision and the ability to justify circularity. However, search friction occurred when qualitative reasoning was required, suggesting that effective reuse advocacy depends on both engine precision and the user's prior technical knowledge.

Qualitative feedback and iterative improvement

Participants cited high operational speed and the weighting algorithm as primary drivers of efficacy. Interactive filters provided "positive friction", allowing users to refine discovery based on geographical requirements. Conversely, significant bottlenecks included high initial information density and the absence of "empty state" feedback. The vector engine's tendency to return loosely related items for unmatched queries, such as displaying glazing units for sanitary ware, caused user frustration.

Discussions

Theoretical positioning and contributions

A primary challenge in circular construction platforms is the semantic gap caused by non-standardized, short-text descriptions, which often triggers cold-start failures in traditional algorithms (Van Capelleveen et al., 2021). While existing systems rely on rigid feature crosses and static metadata (Tserng et al., 2025), they struggle with the linguistic ambiguity of "in-the-wild" data. Our research ad-

dresses this by implementing a late-fusion linear aggregation logic. By utilizing semantic embeddings to navigate jargon-heavy descriptions, the system identifies conceptually relevant materials that keyword-based searches exclude. This adaptive approach enables soft trade-offs where high semantic relevance compensates for minor attribute mismatches, ensuring findability despite the data sparsity identified in our error analysis.

Our evaluation confirms that algorithmic "black-box" behavior remains a significant source of user friction (Blackburn et al., 2026). Participants noted that while the ranking was successful, the rationale behind specific scores remained opaque. This validates the necessity of our proposed "glass-box" framework. By exposing ranking logic via local attribute decomposition, the system allows professional users to verify how semantic intent is balanced against physical requirements. This transparency is critical for reducing the cognitive load and decision-making friction observed during the user study, where a lack of descriptive interpretation was highlighted as a primary bottleneck.

The architecture is positioned to facilitate high-value component flows between demolition and construction, addressing the need for platforms to move beyond disciplinary silos (Blackburn et al., 2026). By adopting an API-ready framework, this work supports the platform-enabled coordination necessary to close resource loops. The multidimensional weighted ranking provides the governance logic required to manage ecosystem-wide interdependencies, shifting the focus from low-grade recycling to high-value resource retention and supporting circular construction through role-centric matchmaking.

Limitations and future work

The system evaluation revealed several technical and user experience limitations that define our future research pathway. The error analysis highlighted a critical need for a similarity score cutoff. Currently, the vector engine lacks a hard threshold, occasionally retrieving unrelated items (e.g., displaying glazing units for sanitary ware queries) when direct matches are absent. Implementing a calibrated cutoff will enable "no results found" notifications, preventing the user frustration observed during redundant filter refinement. While the weighting algorithm is technically sound, the user study identified a gap in semantic transparency. Future iterations will replace the current toggles with dynamic weight tuning and introduce semantic proximity labels. These features, alongside integrated imagery and empty-state feedback, will transform the ranking logic into a more interpretable tool, mitigating the information density issues reported by participants. To enhance data robustness, the architecture will be restructured as an API service layer to ingest structured material data from existing public marketplaces. Furthermore, the limited sample size necessitates future evaluations with larger, diverse participant groups to benchmark the hybrid system against other context-aware recommender systems and validate the findings across broader supply-and-demand scenarios.

Conclusions

This study validates that a multidimensional vector ranking system, augmented by dual-constraint logic, effectively supports the sourcing of reusable materials for architectural design. The preliminary findings indicate that while high operational speeds and weighted results facilitate discovery, the lack of transparency in algorithmic ranking and the ambiguity of weight-based toggles can obscure the system's underlying logic. Participants highlighted a "black box" friction where the rationale for specific material suggestions remained unclear, confirming that explainability is as critical as retrieval accuracy for professional adoption. To address these challenges, the research establishes that implementing similarity thresholds, clearer semantic labeling, and the progressive disclosure of filters is necessary to mitigate user frustration and build trust in the recommendation output. Future development will focus on API-driven scalability and the integration of broader marketplace datasets to solidify the platform's role as a meta-aggregator. By bridging the gap between technical material retrieval and architectural design rationale, this work provides a methodological foundation for optimizing circular material flows within the construction sector.

TURNING CONSTRUCTION CHECKLISTS INTO MACHINE-READABLE INSPECTION SCHEMA

Till Weist, Leon Pfenning, and Prof. Sven Rogalski
Darmstadt University of Applied Sciences, Darmstadt, GER

Abstract

Construction verification currently relies on unstructured checklists, hindering integration with autonomous agents. To scalably convert these legacy instructions into machine-readable data, we propose a Hybrid Inspection Pipeline. This system uses LLMs and "Balanced Retrieval-Augmented Generation" to map text into an "Inspection Triad" aligned with IFC and AEC3PO ontologies. Achieving 92.5% semantic precision, the pipeline eliminates hallucinations using a deterministic fidelity loop. Ultimately, this framework provides the executable logic necessary for autonomous inspection agents, establishing a foundation for future construction research.

Introduction

The construction industry is characterized by a digital paradox, whereby buildings are designed in sophisticated three-dimensional (3D) environments yet are verified on-site using tools that have remained unchanged for decades (Nkosi, 2025). Contemporary digitization endeavors prioritize the capture of geometry (BIM) while the Quality Assurance (QA) process, responsible for verifying Built as Planned attributes, has exhibited a comparatively lagging adoption of digital methodologies (Toyin, 2025). Presently, the Quality Assurance (QA) sector utilizes a manual inspection process, wherein inspectors employ pen-and-paper checklists or static digital checklists to verify compliance (Sawhney & Knight, 2024). These analog methods are not only susceptible to human error but also face challenges in scaling up to meet the demands of a growing labor shortage and increasingly complex project requirements (Baiburin, 2017). As Naderi et al. (2025) point out, this reliance on human-centered instructions creates a significant gap, thereby preventing the integration of inspection tasks with software agents or autonomous robotic systems.

In order to address this discrepancy, the industry has developed standardized semantic frameworks, with the most notable examples being the Industry Foundation Classes (IFC) and the AEC3PO Ontology. While IFC provides the standardized geometry and spatial data of the building, AEC3PO extends this by providing the structural scaffold for regulatory management. It functions as a metadata container, organizing compliance requirements and linking them to legal documents, thereby creating a structured target for digital inspection (Dridi et al., 2024). However, a critical interoperability gap persists: While these target standards are well-defined, the source data—thousands of legacy inspection instructions—remains locked in unstructured text (Guo et al., 2021). Consequently, a scalable mechanism to migrate these analog checklists into a standardized digital format has yet to be developed. As a result, manual translation remains a labor-intensive and inconsistent bottleneck. As posited by Besta et al. (2025), this paper proposes a Hybrid Inspection Pipeline as a solution to the identified semantic interoperability gap. We propose a reinterpretation of the conversion of checklists from a generative interpretation task to a rigorous mapping problem. A workflow has been developed that aligns inspection texts with the IFC and AEC3PO ontologies using a Grammar-Constrained Extraction Pipeline. The utilization of Large Language Models (LLMs) in conjunction with stringent schema constraints enables the automation of the mapping of free text to standardized classes, exhibiting a high degree of reliability. This approach involves the conversion of unstructured field instructions into computable, object-oriented data.

Related Work

Early efforts in construction information extraction relied heavily on rule-based natural language processing (NLP) and syntactic pattern matching (Zhang & El-Gohary, 2016). While these methods have proven effective for highly structured regulatory documents, they have demonstrated fragility when applied to the heterogeneous natural language found in field checklists. In order to address this issue of rigidity, research has shifted towards the utilization of Deep Learning (DL) models. Approaches that utilize Long Short-Term Memory (LSTM) networks (Wang & El-Gohary, 2022) and Transformer-based architectures like BERT (Moon et al., 2022) have been shown to significantly improve entity recognition and classification tasks.

However, a critical limitation persists in these discriminative models: they excel at identifying entities (e.g., tagging a "wall"), but struggle to construct the complex, hierarchical object relationships required by strict ontologies like AEC3PO. As indicated in a recent systematic review (Sousa & Martins, 2024), while Deep Learning (DL) models have demonstrated high accuracy in document classification, their capacity to extract

detailed, actionable logic remains constrained without substantial task-specific training data.

Recently, (Chen et al., 2024) sought to address this discrepancy by integrating Large Language Models (LLMs) with Deep Learning for compliance verification. While their hybrid approach demonstrated enhanced reasoning capabilities, it primarily relied on few-shot prompting without strict output enforcement. This distinction is of critical importance: Even when optimized, probabilistic prompting cannot guarantee the syntactic validity required for downstream software agents. As emphasized by Fuchs et al. (2025) in their review of automated compliance systems, the dearth of "computable" regulatory data persists as a predominant impediment. Current State-of-the-Art (SOTA) methods frequently yield "likely" matches rather than the guaranteed valid schema instances necessary for safe robotic execution. Consequently, a gap remains for a method that treats text extraction not as probabilistic prediction, but as a constrained mapping problem.

The transition toward machine-readable regulatory frameworks has been driven by the "Linked Building Data" (LBD) movement. In the early stages of this research, the focus was on translating static building codes into computable logic. This was primarily achieved by using the ifcOWL ontology to validate Industry Foundation Classes (IFC) data (Pauwels et al., 2017; Beach et al., 2025). These approaches have been demonstrated to effectively automate the process of "Design Compliance" verification, which queries whether a digital model aligns with the stipulated code requirements (e.g., "Is the hallway > 1.2m wide?").

Recently, the AEC3PO ontology (Architecture, Engineering, and Construction Compliance Checking and Permitting Ontology) has emerged as a comprehensive standard for harmonizing the structural metadata of regulatory knowledge (Dridi et al., 2024). In contrast to rigid code-checking schemas, AEC3PO provides a flexible, top-level schema for defining compliance checks, offering classes for CheckStatements, verification methods, and evidence requirements. Nevertheless, a fundamental gap persists in the application of these ontologies. While AEC3PO provides a standardized "container" for regulatory information, its function is primarily descriptive rather than prescriptive. It delineates the relationship between a legal clause and a data requirement; however, it lacks a standardized library of executable properties necessary for automated grounding. Consequently, extant research remains predominantly oriented toward Design Verification (checking the BIM model against the Code), rather than Execution Verification (checking the physical construction against the Instruction). Recent works, such as the Ontology for Construction Quality Assurance (OCQA), have modeled inspection planning (Seiß et al., 2025). However, these works do not address the semantic interpretation of the inspection content itself. The instructions themselves, such as "Verify that all bolts are torqued to 50Nm," are expressed in unstructured natural language. Presently, there is an absence of an automated mechanism to bridge this semantic gap, which involves the mapping of raw text to specific Object-Property-Value triplets that can populate the AEC3PO container.

Methodology I: The Schema

In order to address the semantic discrepancy between unstructured inspection instructions and machine-readable frameworks, the Inspection Triad has been proposed as a solution. This framework functions as the intermediate formal representation, thereby isolating the components of a compliance check that are indispensable to the process.

Multi-Target Instructions

A fundamental barrier to digitization is the compact style of legacy checklists. From a pragmatic standpoint, human-authored items are frequently activity-centered, consolidating multiple checks around a singular verb to reduce reading time. Consider the following example from our dataset:

"Check for proper installation of Mirror, Paper Holder, Towel Rack, Shower Curtain Rod."

While efficient for a human, this structure poses a "many-to-one" problem for autonomous systems. The single instruction encompasses four distinct inspection targets. It is imperative to recognize that the control flow of an agent or digital twin is inherently bound to specific spatial coordinates. Consequently, the execution of "bundled" tasks is contingent upon their disaggregation. Our analysis of 200 industry inspection tasks (Mahoney, 2008) confirms the prevalence of this issue. We found that 61% of tasks were compound instructions, bundling multiple requirements into a single sentence. Consequently, we define Atomicity as a prerequisite for processing: a valid inspection task must contain exactly one activity mapped to exactly one target object.

Syntactic Pattern

Despite the structural messiness of Activity-Centered tasks, our analysis reveals a consistent underlying linguistic structure across the dataset. When decomposed, valid inspection instructions invariably follow a specific syntactic pattern:

$$\text{Instruction} \approx [\text{Verb}] + [\text{Object}] + ([\text{Modifiers}]/[\text{Conditions}])$$

Every executable instruction contains an action (Verb) and a reference to an entity (Object). The specificity of the instruction relies on the Modifiers (quantities, temporal cues, or reference standards). However, our analysis highlights gaps in how these slots are filled. 7.5% of tasks lacked a clear object reference (e.g., using generic terms like "units"), and 4% relied on ambiguous modifiers (e.g., "proper," "adequate") rather than measurable criteria. These gaps highlight that inspection instructions are rarely self-contained algorithms; rather, they serve as shorthand prompts for experienced professionals. This profound lack of explicit logic confirms that raw field data is unstructured.

Inspection Triad

We address the structural complexity and inherent ambiguity of legacy checklists by mapping raw linguistic patterns onto the Inspection Triad (T), a formal data structure designed for autonomous execution.

$$T=(\tau,\alpha,\kappa)$$

This structure formalizes the raw text into three necessary and sufficient components:

The Target (τ) ← [Object]: This component anchors the instruction to a single, specific building element. If the source text contains multiple objects the task must be split so that each result in a distinct Triad. Further there is a resolution constraint: if an inspection target is not identified and is ambiguous, the Triad cannot be completed. Logically, an inspection cannot be executed without a confirmed physical anchor.

The Action (α) ← [Verb]: It maps the instructional verb to a specific inspection procedure.

The Criterion (κ) ← [Modifiers]: It captures the quantitative limits or conditions. Where a criterion is not explicitly defined, the schema defaults to a binary Pass/Fail requirement anchored to the verification method of the Action (α).

While the triad represents the irreducible atomic unit of verification, the framework supports higher-order logic. Complex regulatory requirements, such as conditional "IF-THEN" sequences, are facilitated by nesting multiple triads within logical operational wrappers. This ensures that even intricate compliance logic maintains data integrity at the component level.

Ontological Integration

The Triad serves as the bridge between raw site data and standardized digital frameworks. In this architecture, the AEC3PO ontology provides the structural scaffold (the semantic "containers"), while the Industry Foundation Classes (IFC) provide the physical grounding.

The Target (τ) is operationalized as a semantic pointer to the Digital Twin. By utilizing the IFC standard to identify specific entities (e.g., IfcWall, IfcDoor), the system ensures that every instruction is spatially addressable within the Building Information Model (BIM). This "pointer-based" approach ensures the inspection data remains lightweight, referencing existing geometry rather than duplicating it.

Simultaneously, the Action (α) and Criterion (κ) are instantiated through the Domain-Specific Extension (DSE), which provides the prescriptive definitions required for automated execution.

Domain-Specific Extension (DSE)

While the AEC3PO Ontology provides the necessary semantic containers (the "Scaffold"), our initial gap analysis revealed it lacks the prescriptive definitions required for automated execution. Standard classes like aec3po:CheckStatement describe that a check exists, but not how to measure specific properties like "Flatness" or "Torque."

To bridge this semantic gap, we developed the DSE as a controlled vocabulary of 50 distinct inspection properties, formally extending the high-level AEC3PO classes into executable leaf nodes (e.g., aec3poext:VerticalityCheck).

The development of the DSE followed a rigorous Ontology Learning methodology. We compiled a corpus of 1,500 industry inspection tasks (Mahoney, 2008). To identify the salient inspection criteria, we applied Term Frequency-Inverse Document Frequency (TF-IDF) extraction. This statistical method allowed us to filter out generic stop words and isolate the domain-specific nouns and modifiers with the highest information density (e.g., "width," "spacing," "cracks"). These candidate terms were then formalized into rigid definitions through expert review, ensuring the DSE is not a theoretical construct, but a data-driven representation of actual field requirements.

Methodology II: The Pipeline

While the Inspection Triad defines the target semantic structure, the challenge remains to reliably populate this structure from unstructured legacy documents. As established in the literature review, Generative Large Language Models (LLMs) often struggle with strict schema adherence and factual consistency when operating in unconstrained environments (Ji, et al., 2023). To mitigate these stochastic risks, we propose the Hybrid Inspection Pipeline.

This architecture shifts the extraction task from a purely generative paradigm to a "Propose and Verify" workflow. As illustrated in Figure 1, the system is composed of three distinct functional layers: (A) Semantic Ingestion and Atomization, (B) The Extraction Engine, and (C) Data Formatting and Storage. The result of this process is a serialized list of inspection requirements, each containing a unique name and technical description.

Layer A: Semantic Ingestion and Atomization

The input layer serves as the normalization pre-processor. Legacy inspection data typically exists in "frozen" formats (PDFs, scanned images) where semantic hierarchy is conveyed through visual layout rather than machine-readable tags. Layer A utilizes Optical Character Recognition (OCR) to digitize these documents. A critical preprocessing step is Atomization. As identified in our analysis of the dataset, legacy instructions are compound, bundling multiple targets into a single sentence. To satisfy the "One-Target-One-Action" requirement of the Inspection Triad, we employ a Grammatical Parser combined with lightweight LLM-based validation.

This component identifies the grammatical ROOT (Action), direct object (Target), and adjectival modifiers (Criterion) using linguistic dependency rules. By applying deterministic heuristic rules, the system ensures that every extracted object is bound to a specific action. This logic allows for the decomposition of compound instructions where a single action governs multiple physical targets. If the parser identifies a verb without a corresponding object, the instruction is immediately flagged as "Incomplete" to prevent downstream processing errors.

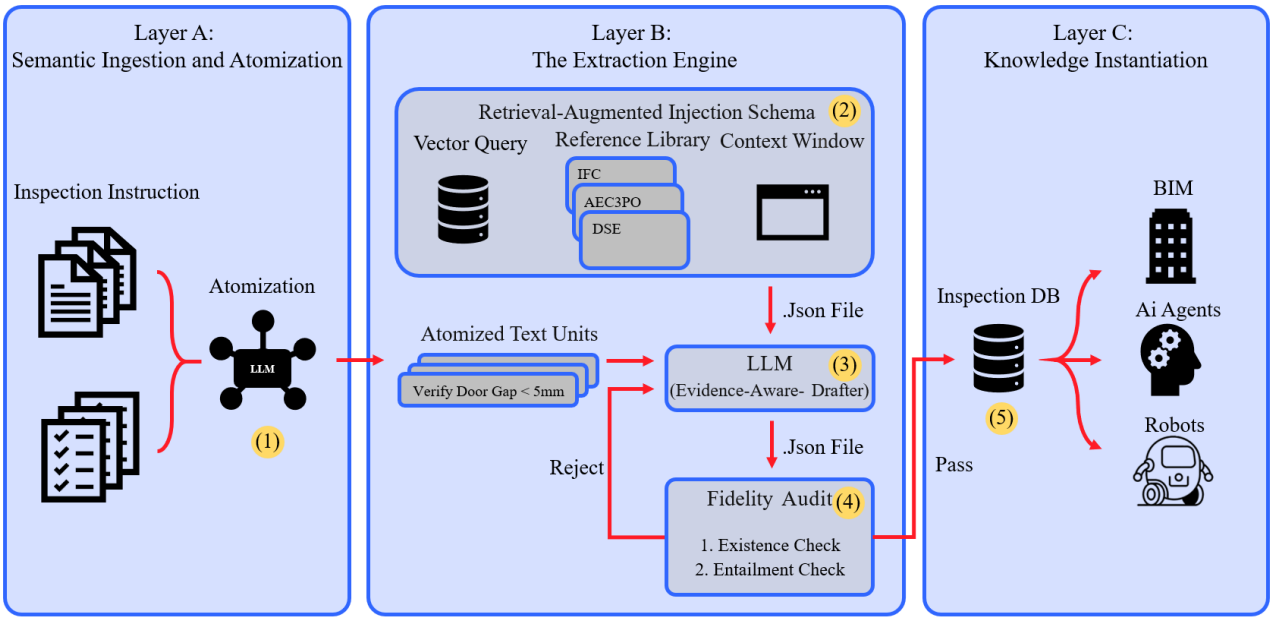

Figure 1: Architecture of the Proposed Framework

This linguistic skeleton, along with the original text, is then passed to the LLM for a final verification and refinement pass. If an incomplete action is detected, the LLM is also tasked with resolving the missing context. As shown in the data flow of Figure 1, this ensures the module decomposes compound sentences into discrete, atomic text units (1). For example, the input “Verify gap for door and window” is split into two independent units: “Verify gap for door” and “Verify gap for window.” This ensures that downstream extraction (Layer B) operates on unambiguous, single-subject inputs.

Layer B: The Extraction Engine

Layer B represents the core algorithmic contribution of this framework, acting as the semantic bridge between atomized natural language and formal ontologies. To resolve the interoperability gap, this layer implements a Retrieval-Augmented Schema Injection (RASI) strategy combined with a deterministic Fidelity Loop. The primary barrier to utilizing extensive ontologies like IFC and AEC3PO within a Large Language Model (LLM) is the risk of "Attention Dilution" and hallucination. To mitigate these risks, the system maintains a Dual-Source Reference Library consisting of two distinct vector indices: physical object definitions (IFC) and prescriptive inspection logic (DSE). During runtime, the engine performs a Balanced Retrieval (2) to counteract "Object Drowning"—a phenomenon where high-frequency physical terms (e.g., "Wall" or "Slab") statistically overshadow abstract inspection rules in the vector space, leading to incomplete data extraction. By enforcing a fixed-ratio retrieval quota (e.g., k/2 from each index), the system independently queries both the Target and Logic indices to pull an equal number of IFC classes and DSE properties. These results are interleaved and dynamically injected into the LLM’s context window, transforming the extraction from an open-ended generative task into a constrained classification task that forces the model to select from a verified ontology subset rather than fabricating non-standard properties.

Semantic ambiguity in the source text, specifically the use of vague modifiers like "properly" or "adequate," is addressed through Semantic Best-Fit Mapping. By providing the LLM with a filtered subset of technical definitions from the DSE, the workflow acts as a semantic anchor; the model performs a contextual interpolation to map subjective human language to the most semantically relevant engineering property provided in the retrieved context. In instances where no explicit metric exists, the system defaults to the most frequent domain-specific interpretation within the DSE. Even with these schema constraints, generative models may hallucinate quantitative values. To eliminate this risk, Layer B enforces a two-stage Fidelity Audit. In the first stage, the LLM is tasked with Evidence-Aware Drafting (3), requiring it to return a Citation Tuple (Value,Substring) containing the exact verbatim evidence from the source text. In the second stage, a deterministic verification module performs an Existence Check to ensure the substring exists in the original document, and a Logic Entailment Check to verify the extracted value is supported by that quote. If the audit fails, a Rejection Feedback Loop (4) triggers a re-evaluation or flags the item as "Unprocessable," ensuring that only grounded, verifiable logic is serialized into the final digital repository.

Layer C: Knowledge Instantiation

Validated Triads from Layer B are serialized into a Digital Inspection Repository (5), which functions as an active API Gateway. Instead of static files, this system aggregates atomic checks into location-based sets (e.g., "Sector A Requirements"), creating a queryable endpoint accessible to downstream consumers such as BIM Applications, autonomous robots, or AI compliance engines.

Implementation

To validate the Hybrid Inspection Pipeline, a functional prototype was developed using a modular Python 3.9 architecture. A primary design driver was component decoupling; the extraction logic is intentionally isolated from the underlying model providers to ensure the architecture remains agnostic. While the current prototype utilizes specific Google and open-source tools, the framework is designed to swap backend LLMs or vector stores as the technology landscape evolves.

System Architecture & Tech Stack

The core Extraction Engine was implemented using the google-genai SDK, specifically utilizing the Gemini 2.5 Flash model. This model was selected for its optimization for high-throughput, low-latency tasks. To ensure scientific reproducibility and deterministic extraction, the model was configured with a Temperature of 0.0.

The system utilizes a Structured Prompting strategy where the LLM is provided with a strict JSON schema. If the Fidelity Loop identifies a discrepancy, the system initiates a targeted follow-up query, providing the model with specific error feedback to refine the extraction in a "human-in-the-loop" style automated correction.

Linguistic Atomization

For the initial decomposition of compound instructions, the prototype utilizes the spaCy NLP library with the en_core_web_lg (large) model. This accuracy model was chosen to ensure precise identification of complex instructions. The implementation specifically leverages spaCy's Dependency Parser to programmatically identify:

The ROOT (the primary action verb or Action α).

The dobj (direct object or Target τ).

The amod/compound modifiers (forming the basis for Criterion κ).

This "Linguistic Skeleton" is then verified by a fast LLM pass to ensure atomicity before any ontological grounding occurs, preventing downstream processing of multi-subject tasks.

The Semantic Knowledge Base (RAG)

The source ontologies were embedded using the SentenceTransformers framework with the all-MiniLM-L6-v2 model, producing 384-dimensional vectors.

We compiled two distinct vector stores—the Target Index (IFC4) and the Logic Index (DSE). Unlike standard keyword indices, these stores contain also metadata: the IFC Index includes Entity Definitions, while the DSE entries include Data Types (e.g., Boolean, Float) and Standardized Verification Methods.

These indices are persisted locally as .json vector arrays. This ensures full data sovereignty and vendor independence.

The Balanced Retrieval Strategy

Early testing revealed a phenomenon we term the "Drowning Effect". Standard vector retrieval tends to favor concrete nouns over abstract concepts. A query like "Check the flatness of the slab" would return 20 results related to "Slab" (Object) and zero results related to "Flatness" (Rule), causing the LLM to hallucinate the property check.

To counteract this, we engineered a Balanced Retrieval Strategy. The retriever does not simply fetch the top-k results. Instead, it enforces a quota: It independently queries the Target Index and the Logic Index, retrieving the top-k/2 matches from each. These distinct result sets are then merged into the unified context window. By decoupling the retrieval of targets and properties, the framework maintains semantic parity within the prompt. This prevents the stochastic exclusion of abstract rules and guarantees that the model's context window reflects the dual-component nature of the Inspection Triad.

Schema Validation & Error Handling

To bridge the gap between probabilistic AI and the deterministic requirements of engineering data, we integrated Pydantic v2.0. We defined the InspectionTriad as a strict Python class, forcing the LLM to act as a structured data parser. The pipeline automatically validates every generated response against this class. If a ValidationError is triggered (e.g., malformed JSON or missing mandatory fields), the system initiates an automated retry loop (up to 3 attempts). This creates a "Type-Safe" boundary that prevents malformed data from propagating to the digital repository.

The Fidelity Loop

The Fidelity Loop was implemented as a deterministic Python module to eliminate silent hallucinations. It acts as a non-probabilistic auditor by performing two sequential string-matching checks on the LLM output:

Stage 1: Existence Check. The module verifies that the evidence_quote provided by the LLM exists verbatim in the source document. Any character mismatch triggers an immediate rejection.

Stage 2: Entailment Check. The module ensures that extracted quantitative values (e.g., "50Nm") or property types (e.g., "Torque") are present within the cited evidence_quote. This prevents the model from fabricating values unsupported by the evidence.

This "Trust but Verify" logic transforms the system from a generative writer into a deterministic extraction verifier. It provides the rigorous safety layer necessary for high-stakes construction compliance.

Evaluation

To validate the efficacy of the proposed Hybrid Inspection Pipeline, we conducted a systematic evaluation focused on two key performance indicators: Semantic Precision (the ability to correctly map text to the Inspection Triad) and Operational Safety (the ability to detect and reject hallucinations).

Experimental Setup

Due to the absence of a standardized, publicly available benchmark for construction inspection extraction, a novel evaluation dataset was curated for this study. The dataset comprises 200 distinct inspection instructions synthesized from a combination of real-world inspection checklists and technical field reports (cf. Mahoney, 2008; gsa.gov, 2025; carlislesyntec.com, 2021).

To ensure the evaluation was representative of real-world site conditions and to mitigate selection bias, the instructions were purposively stratified into three complexity levels. This distribution guarantees that the dataset reflects the linguistic heterogeneity of the industry rather than a simplified subset of easily parsed data.

Geometric Checks: Explicit quantitative constraints (e.g., "Verify window width is < 1200mm").

Semantic Classifications: Checks relying on specific object enumerations and subclass distinctions (e.g., "Ensure T-Beam is free of defects" vs. "Ensure Beam is...").

Ambiguous/Qualitative: Instructions lacking clear metrics or relying on subjective professional judgment (e.g., "Check for proper installation").

For each input, a human domain expert manually annotated the "Expected Inspection Triad," defining the Target IFC Class and the specific prescriptive property from the Domain-Specific Extension (DSE).

To ensure a fair comparative analysis, all experimental runs utilized the Gemini 2.5 Flash model. The temperature was set to 0.0 across all tests to ensure deterministic outputs and minimize stochastic variance, thereby isolating the impact of the retrieval architecture on the results.

While traditional Rule-Based NLP (Natural Language Processing) was initially considered, it was ultimately excluded from the final benchmarking. Legacy NLP systems are fundamentally limited by the "brittleness" of manually curated rules; they are prone to overfitting to specific vocabulary and fail to account for the high linguistic variance of site reports. Consequently, an NLP baseline would represent a "straw man" comparison rather than a contemporary performance standard. Instead, the study benchmarks the Hybrid Pipeline against two state-of-the-art LLM strategies:

Zero-Shot (Blind): The model attempts to map instructions to IFC and DSE schemas based purely on internal training data, without external library access.

Zero-Shot (Full Context): The entire IFC and DSE libraries are injected into the prompt (approx. 8,500 tokens), testing performance under maximum "Context Overload."

Hybrid Pipeline (Balanced RAG): The proposed method utilizes the Balanced Semantic Retriever to inject only the 5 most relevant IFC classes and 5 most relevant DSE properties into the prompt.

Performance Metrics

System performance was evaluated across two primary dimensions: Extraction Quality and Operational Safety. Information Retrieval performance for the Triad (Target, Action, Criterion) was quantified using the following metrics:

Precision (P): The ratio of correctly identified Triad components to the total components extracted.

Recall (R): The ratio of successfully mapped instructions to the total instructions in the dataset.

F1-Score: The harmonic mean of Precision and Recall, providing a balanced measure of system robustness:

For the safety analysis, we introduced the Hallucination Catch Rate, defined as the percentage of fabricated values (hallucinations) successfully identified and blocked by the Fidelity Loop before data entry.

Results: Semantic Precision

Quantitative results indicate that the Hybrid Pipeline significantly outperforms baseline methods in both technical accuracy and computational efficiency.

Table 1: Performance Comparison Across 200 Inspection Instructions

Method	Precision	Recall	F1-Score
Zero-Shot (Blind)	34.5%	38%	0.36
Zero-Shot (Full Context)	76%	82%	0.79
Hybrid (Balanced RAG)	92.5%	91%	0.91

The "Full Context" approach suffered from "Attention Dilution," where the model's reasoning capabilities were degraded by irrelevant ontological data, often leading to the selection of phonetically similar but semantically incorrect IFC classes. Conversely, the Hybrid Pipeline's retriever isolated the most relevant candidates, maintaining high precision. Furthermore, the Hybrid Pipeline achieved a 13x reduction in token usage compared to the Full Context method, demonstrating superior scalability for enterprise-level BIM integration.

Results: The Fidelity Loop

A primary barrier to AI adoption in AEC is the risk of "hallucinated" data. The Zero-Shot baselines exhibited a combined hallucination rate of 11.4%, where the LLM generated plausible but non-existent quantitative values (e.g., inventing a "5mm" tolerance) based on general patterns.

The Fidelity Loop achieved a 99.5% Hallucination Catch Rate. By enforcing a strict "Verbatim Evidence" requirement, the system effectively blocked fabricated data. Residual failures typically involved "partial hallucinations," where the model correctly identified a numeric value but slightly altered the unit or context (e.g., misinterpreting "5 meters" as "5mm" during the mapping phase).

Error Analysis

A qualitative review of the 7.5% error margin in the Hybrid Pipeline identified "Retriever Ambiguity" as the primary failure mode. For example, the instruction "Check the seal on the pipe" was correctly mapped to the Action SealantVerification, but the retriever proposed the Target IfcSurfaceFeature instead of IfcPipeSegment due to the close proximity of these terms in the high-dimensional vector space. Future iterations will explore the integration of cross-encoders to further refine the retrieval ranking and reduce semantic noise.

Discussion

The evaluation confirms that a constrained LLM pipeline can function as a reliable semantic bridge. However, moving this framework from a controlled prototype to a production-scale construction environment requires addressing several key operational limitations.

Automated Scalability of the Knowledge Base

The current system's reliance on a manually curated Domain-Specific Extension (DSE) remains a primary scalability bottleneck. To move beyond manual labor, future research should explore a "Loop-Back Ontology Learning" mechanism. In this framework, instructions that fail the Fidelity Audit due to missing DSE definitions are not discarded. Instead, they are sent to a "Candidate Pool" where an LLM clusters frequent failures to suggest new ontological leaf-nodes. This allows the system to evolve dynamically, expanding its technical vocabulary through a semi-automated, human-in-the-loop process.

Orchestration of Complex Regulatory Logic

While the Inspection Triad ensures high precision for atomic tasks, it currently lacks the native syntax to represent complex conditional dependencies (e.g., multi-step "if-then" requirements). To support the rich logical expressions found in safety regulations, the framework must transition from "Atoms" to "Molecules." By introducing a "Logical Orchestration Layer," multiple atomic Triads can be nested using standard Boolean operators (AND, OR, IF). This adaptation would allow the pipeline to maintain its current extraction reliability while supporting the sophisticated reasoning required for advanced compliance checking.

Transition to Active 4D BIM Integration

Currently, the pipeline functions as a one-way extraction tool rather than an active participant in the project lifecycle. To bridge the gap between static logic and physical execution, an "End-to-End Handshake" with live project data is necessary. Future work will investigate a direct integration with the project schedule (4D BIM), where the completion of a construction task (e.g., "Slab Pour") automatically triggers the extraction of relevant Triads. By querying the BIM database for specific GlobalIDs in real-time, the system can provide executable tasking for autonomous agents or mobile robots based on the actual progress of the site.

Resolution of Temporal and Qualitative Edge Cases

The system encountered specific failures when handling temporal constraints (e.g., "Verify 28 days after pour") and vague qualitative modifiers (e.g., "Adequate"). Future iterations will require a dedicated temporal logic parser to differentiate between execution timing and performance duration. Additionally, for subjective instructions, the pipeline could be adapted to output a "Confidence Score," flagging ambiguous text for human clarification rather than forcing a binary mapping. This ensures the machine-readable output remains a "Trust-but-Verify" source of truth for downstream automated systems

Conclusion

This research demonstrates that the transition from unstructured legacy checklists to machine-readable inspection schemas is achievable through a constrained, hybrid pipeline. By shifting the extraction task from open-ended generation to ontological mapping via the Inspection Triad, we provide a method for populating the AEC3PO and IFC frameworks with executable logic.

The significance of this work lies in its ability to transform static regulatory metadata into "computable" field instructions. While existing BIM-to-Field workflows prioritize geometry, the proposed framework establishes the semantic foundation necessary for autonomous agents to perform site inspections with deterministic reliability. Future development in automated ontology learning and 4D BIM integration will be essential to scale this system across the diverse and evolving landscape of global construction standards.

Abstract

Vision–language models provide an alternative to supervised computer vision, enabling open-set object recognition without retraining or large datasets. Recent advances like GroundingDINO enable open-vocabulary object detection using natural-language prompts, but their sensitivity to prompt formulation in the AEC domain remains underexplored. This study assesses GroundingDINO's reliability in detecting construction objects through analysis of prompt variations, including lexical variation and prompt multiplicity. A custom dataset of 48 objects was tested under eight prompts. Results show lexical variation affects detection performance, with "regular base term" achieving a 56.1% F1 score. Multiple prompting lowers performance by ~2%, highlighting AEC's effectiveness and limits.

Introduction

Computer vision has been increasingly adopted in the Architecture, Engineering, and Construction (AEC) domain to support operational and managerial tasks such as progress monitoring, safety inspections, and quality control. However, deployment faces challenges due to scene changes, object diversity, occlusions, and project-specific visuals. Conventional supervised object detection needs large, labelled datasets and a fixed set of objects, limiting scalability and adaptability across projects and phases. (Duan et al., 2022). Vision–language models (VLMs) provide the foundation for open-vocabulary object detection (OVOD), enabling detection driven by natural-language prompts rather than predefined class sets, and have shown promise in overcoming closed-set limitations in AEC applications (Adil et al., 2025).

Vision–language models (VLMs) support open-vocabulary object detection (OVOD), which uses natural-language prompts instead of fixed labels. This offers an alternative to closed-set detection in AEC (Adil et al., 2025). OVOD models such as *GroundingDINO* (Liu et al., 2023) accept textual queries and provide spatially grounded detections, allowing flexible scene querying without retraining or extensive annotation. However, the quality and relevance of the detections generated by VLMs depend heavily on the prompt's quality and formulation (Minderer et al., 2024; Nebbia and Kovashka, 2024). Prior work shows prompt design greatly influences vision-language model performance and outcomes, underscoring their sensitivity to wording and structure (Gu et al., 2023). Since prompts are key to customizing VLM behavior, their design is crucial to aligning outputs with specific AEC needs.

In safety- and management-critical workflows, sensitivity to prompt formulation may lead to missed detections or false positives, undermining trust in automated systems. While recent studies have demonstrated the feasibility of VLM-based methods for construction-related tasks, the role of textual prompt formulation has not yet been systematically examined in AEC contexts, where scene complexity and operational requirements pose additional challenges. Moreover, prompt-related reliability issues, such as inconsistent detections or hallucinated objects, have not been explicitly analyzed in complex construction scenes. To address this gap, this paper presents a structured evaluation of prompt robustness for open-vocabulary object detection in construction settings. Focusing on *GroundingDINO*, the study investigates two key factors: (1) lexical variation, examining how different linguistic representations of the same construction object affect detection performance, and (2) prompt multiplicity, assessing the impact of single versus multiple prompts on accuracy and false positives. Using a custom dataset of construction-related objects spanning indoor and outdoor scenes, the study aims to benchmark the practical effectiveness and limitations of prompt-driven OVOD for AEC operational and managerial applications.

Related Works

Recent literature on OVOD methods has drawn mainly on pre-trained vision-language models, such as CLIP (Radford et al., 2021), which enable a detector to be queried with natural-language inputs, thereby overcoming the limitations of closed-vocabulary paradigms. In this context, numerous works have adopted hand-crafted textual prompts, in which the class name is inserted into simple linguistic templates (e.g., "a photo of a {class}"), sometimes combining multiple templates and averaging their embeddings to reduce dependence on a single formulation (Minderer *et al.*, 2024). These approaches have demonstrated the effectiveness of textual prompting for querying OVOD models, but they implicitly assume a stable correspondence between the canonical class name and the visual concept. A subsequent line of research challenged this assumption by examining lexical variation in prompts, including the use of synonyms and

semantically related terms. Recent studies show that replacing the base term with synonyms or near-synonyms can significantly degrade performance, highlighting the limited semantic robustness of OVOD models relative to equivalent linguistic variations (Nebbia and Kovashka, 2024). To mitigate this sensitivity, class-embedding enrichment strategies have been proposed by aggregating multiple prompts that include both the base term and its synonyms, suggesting that prompt design is a structural component of the detection process (Gu *et al.*, 2022). At the same time, other works have extended the use of prompts beyond isolated class names, introducing descriptive and attributive nominal phrases, as in the Open-Vocabulary Attribute Detection task, where textual representations consist of name-adjective combinations or more articulated descriptions (Bravo *et al.*, 2023). Even when such formulations are not explicitly defined as "definitions", they implicitly encode information about the function, material, and context of the object, delineating a continuum from the bare class name to increasingly rich and semantically specific prompts. However, most existing studies focus on the impact of these strategies on average accuracy, without systematically analyzing how the prompt's linguistic complexity affects model stability or the risk of generating false predictions. This is the context for *GroundingDINO*, an advanced OVOD model that accepts free-form natural language sentences and returns spatially anchored bounding boxes aligned with textual queries (Liu *et al.*, 2023). *GroundingDINO* is queried using single object names, short sentences with attributes, or multiple prompts separated by punctuation. However, the literature analyzing its performance tends to keep the textual prompt fixed or generic, focusing primarily on variations in the scene or visual content, as in studies that evaluate the model's robustness to visual perturbations while keeping The present work analyses *Groundingdino*'s prompt formulation, especially in construction, building on existing experimental methods and focusing on lexical variation and multiplicity (Mütze et al., 2025).

Methodology

The methodology systematically generates prompts to evaluate the OVOD model's performance across different texts, as shown in Figure 1. After creating a custom AEC dataset, prompt formulations were organized along two dimensions. The first-dimension concerns prompt complexity, distinguishing between easy and complex prompts. Easy prompts are characterized by minimal linguistic manipulation of the target object and involve simple lexical variations, such as a base term or a synonym. In contrast, complex prompts introduce additional levels of linguistic transformation as descriptive definitions, thereby increasing interpretive complexity while still referring to the same visual target. This dimension was designed to assess the model's sensitivity to wording and semantic expressiveness through controlled lexical variations for each object class. The second-dimension addresses prompt multiplicity, differentiating between single- and multiple-prompt configurations. Single Prompt settings rely on a single lexical call for a single object present in the analyzed image, enabling the evaluation of the model's response to isolated linguistic variations. Based on the prompt type identified in the first stage, a Multiple Prompt configuration was subsequently defined, allowing comparison of OVOD performance when detecting AEC-related objects under single- and multi-prompt conditions.

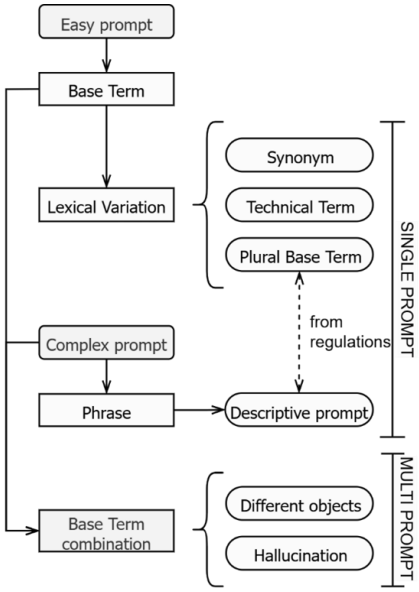

Figure 1: Overview of the prompt formulation strategy

Dataset development

A tailored image dataset was created to facilitate model assessment across various object categories and varying levels of visual complexity. Specifically, 48 construction-related objects were included and mainly organized into indoor and outdoor scenario groups. For each object, three images were selected to represent a range of realistic conditions, resulting in a custom dataset of 144 images. These depict variations in visual appearance: a normal view, where the object is the primary subject; a small-scale view, where the object appears reduced relative to the surrounding context (Lin *et al.*, 2014); and a cluttered view, in which other elements in the scene partially occlude the object (Malaikrisanachalee et al., 2025). A structured naming convention was adopted to organize the dataset. To each object a Base Term was assigned, intended as the canonical object name used for Ground Truth labelling, while a suffix indicated the visual condition (Normal, Small, Cluttered). The Base Terms were formulated using natural, everyday language, following the labelling strategy introduced by Taherian et al. (2025).

Lexical variations definition

In the single-prompt setting, lexical variation was employed to systematically evaluate the model's sensitivity to different textual references for the same visual. Each prompt includes a single linguistic

Table 1: Example of Lexical prompt strategies used in the single-prompt evaluation

Prompt Strategy	Indoor	Outdoor
Base Term [Baseline]	Split System	Construction Barrier
Synonym Term	Air Conditioner	Barricade
Technical Term	Ducted Air-Conditioner	Impact Barrier
Plural Term	Ducted Air-Conditioners	Impact Barriers
Definition Term	Encased assembly or assemblies designed primarily to provide ducted delivery of conditioned air to an enclosed space, room or zone	Energy-absorbing device installed in front of a rigid object to reduce the severity of impact of a vehicle

expression linked to one target object in the image, which helps isolate the impact of wording changes from the image's context or composition. For each object class, multiple lexical variants were created, such as a base term, synonyms, technical terms, plural forms, and descriptive definitions. Concrete examples of the prompt construction for each lexical category are reported in Table 1, which illustrates how prompts were instantiated for representative indoor and outdoor object classes. All variants were evaluated independently under identical but different visual conditions, allowing a controlled comparison of how lexical choices influence detection performance while maintaining a one-to-one correspondence between the prompt and the object.

Base Term

The Base Term labels adopted in this study are based on the labelling strategy introduced by Taherian et al. for evaluating *GroundingDINO* as an OVOD model on construction job sites under complex visual scenarios. In that work, object class labels were intentionally formulated using clear, unambiguous natural-language expressions, with each image assigned to a single target object. This approach ensured a one-to-one correspondence between the text prompt and the visual instance. Following the same principle, Base Term in this study is defined as the most direct and commonly used words for each object class, reflecting standard naming practices used by professionals in the AEC field. These terms act as the linguistic baseline for prompt formulation and show the least linguistically altered way of naming objects, against which the effects of lexical differences are later assessed. However, the work by Taherian et al. did not explicitly analyze the effects of lexical variation on model performance. Building on this gap, the present work further examines the influence of inflectional variants by evaluating whether the use of singular or plural forms of a term affects object recognition accuracy (Minderer *et al.*, 2024).

Synonym Term

Lexical variation using Synonyms Terms was analyzed to verify the model's ability to recognize the same object when indicated using semantically equivalent terms (Nebbia and Kovashka, 2024).For each object class, synonyms were assigned through a cross-dataset analysis of naming conventions in related datasets, including *COCO* (Lin *et al.*, 2014), *Objects365* (Shao *et al.*, 2019), *Open Images* (Open Images V7), and *SODA* (Duan *et al.*, 2022). For missing class, *WordNet* served as a complementary lexical reference (Miller et al., n.d.), and for remaining domain-specific classes not supported by either dataset taxonomies or *WordNet*, additional terminology was derived from online annotation repositories such as *Roboflow* to reflect common usage. This cross-sectional analysis of multiple datasets and resources not only underscored domain gaps, as several object classes in the developed dataset were not well represented in existing datasets, but also allowed for mitigating biases associated with individual taxonomies and evaluating the model's robustness to synonym-based lexical substitutions.

Technical Term and Plural Term

Lexical variation using "related technical terms" was examined, with a focus on terminology in construction sector regulations. The Technical Terms in tests came from international standards in construction and plant sectors, including the *International Organisation for Standardisation* (ISO), the *International Electrotechnical Commission* (IEC), and the *European Norms* (EN/CEN). This choice is motivated by the need to evaluate the model's behavior in the presence of specialized terminology consistent with the application domain's regulatory practice. The main regulations analyzed are listed in Table 2.

In addition, these Technical Terms were also inflected according to standard English grammatical rules to generate Plural Forms, enabling the assessment of the model's response to number variation within specialized terminology.

Descriptive Term

Finally, tests based on descriptive prompts (Descriptive Technical Term) have been established, as many open-vocabulary object detection benchmarks use textual representations based on descriptive sentences rather than individual tokens (Bianchi *et al.*, 2023). Technical regulations often provide descriptive textual definitions of objects, which have been utilized to construct descriptive technical terms. These definitions are regarded as formal and unambiguous linguistic representations of objects.

Prompt Multiplicity

In contrast to single-prompt inference, the multiple-prompt approach enables the model to detect and localize several object categories within a single image. This is achieved by constructing a prompt configuration

composed of multiple textual queries, each corresponding to a target object class. The input prompt is formatted as a sequence of object descriptors separated by delimiters, for example:

Prompt = {"object 1.", "object 2.", ..., "object n."}.

Within this setup, the prompt configuration is further extended to evaluate model hallucination. This is done by augmenting the multi-object prompt with an additional query that corresponds to an object does not present in the image. The absent object is selected from the dataset object categories based on its visual similarity to the AEC-related object(s) depicted in the scene, enabling systematic evaluation of the model's susceptibility to visually induced false detections under multi-prompt conditions. An example of prompt format is as following with further demonstration provided in Figure 5.f:

Prompt = {"object 1", "object 2", ..., "object n", "absent object"}.

Table 2: Regulations analyzed for defining the Single prompt-Technical Term

Standard	Domain

Experiment Setup

Based on the proposed framework, prompt elements were systematically defined and combined to create experimental test cases, enabling a controlled analysis of how different forms of lexical and compositional variation influence the OVOD model's object recognition performance.

OVOD Model

In this research, *GroundingDINO* is used as the OVOD model. *GroundingDINO* is designed to operate in scenarios where the categories to be detected are not fixed in advance but are defined dynamically through textual prompts. In this paradigm, text is the primary means for semantic conditioning of inference, making prompt formulation a key factor in the model's behavior, as discussed in works on grounded detection and phrase grounding (Li *et al.*, 2021; Liu *et al.*, 2023). The model is built upon the Transformer-based DINO detector, a member of the DETR family, and extends it by incorporating grounded language–image pre-training for open-set object detection (Carion *et al.*, 2020; Li *et al.*, 2021). In this approach, categories are not treated as separate labels but as context-aware linguistic representations generated by a Transformer-based text encoder, enabling connections between visual regions and textual descriptions, including lexical variants and free phrases (Devlin *et al.*, 2018; Li *et al.*, 2021). From an architectural perspective, *GroundingDINO* combines a multi-scale visual backbone with a pre-trained language encoder and employs a deep multimodal fusion strategy in which the textual prompt affects multiple stages of the detection process, from visual feature enhancement to query initialisation and final prediction refinement. (Liu *et al.*, 2023). Consequently, variations in prompt formulation can affect text–region alignment and prediction consistency, making the model sensitive to linguistic choices at inference time. For inference in this study, GroundingDINO was implemented using the Hugging Face Transformers via zero-shot-object-detection pipeline (Hugging Face, 2025). Given the input prompts, the model returns bounding boxes, associated labels, and confidence scores for detected regions. Each confidence score is computed by selecting the maximum logit across all candidate labels and applying a sigmoid function to obtain a normalized value between 0 and 1, reflecting the alignment between a region and its most relevant textual label. A single confidence threshold is then applied to filter the final detection outputs. In this study, a threshold of 0.25 was used to retain predictions for further evaluation (Raoofi *et al.*, 2024). Future work will investigate the impact of varying this threshold on detection performance and its interaction with prompt formulation.

Evaluation Metrics

To evaluate the performance, detection outputs were filtered using a confidence threshold of 0.25 prior to ground-truth (GT) association and metric computation. *GroundingDINO* operates on free-form input prompts and the evaluation involves the verification of region–prompt alignment. A predicted bounding box was considered a correct detection if its Intersection-over-Union (IoU) with a GT instance exceeded the threshold, and the assigned class label correctly corresponded to the ground-truth class label. IoU quantifies spatial overlap and is defined as the ratio of the intersection area $|A \cap B|$ to the union area $|A \cup B|$ between the predicted (A) and GT (B) bounding boxes.

IoU is highly sensitive to minor localization errors, where even small pixel-level shifts can reduce the overlap,

despite successful detection. Since the dataset in this study exhibits scale variation and includes particularly small objects per class, the IoU threshold was set to 0.25 ensuring that the detection of small-scale indoor components is not unfairly penalized while maintaining the focus on reliable object presence verification (Eggert *et al.*, 2017). Precision, Recall, and F1-score were computed for each object class and experimental scenario according to Eq. (1). A detection was counted as a true positive when the IoU threshold was met. GT instances without matched predictions were labelled as false negatives, while incorrectly associated predictions were treated as false positives.

$$P = \frac{TP}{TP+FP}, R = \frac{TP}{TP+FN}, F1 = \frac{2\times P\times R}{P+R} \quad (1)$$

Results and Discussion

This section shows *GroundingDINO*'s evaluation results in construction scenarios. The analysis focuses on two main questions: (i) how prompt formulation impacts the reliability of OVOD; (ii) whether using multiple prompts enhances performance.

An initial overview of the results compares the Single-Prompt and Multiple-Prompt configurations for indoor and otdoor scenes, as shown in Figure 2. The Multiple Prompt setup does not significantly outperform the Single Prompt baseline: recall drops slightly from 0.752 to 0.716, while precision (0.448 vs. 0.446) and F1 score (0.561 vs. 0.550) are nearly the same or slightly lower with the multiple-prompt configuration. These results suggest that, in the present experimental setting, increasing the number of prompts does not yield a clear overall improvement in OVOD performance and may introduce additional ambiguity.

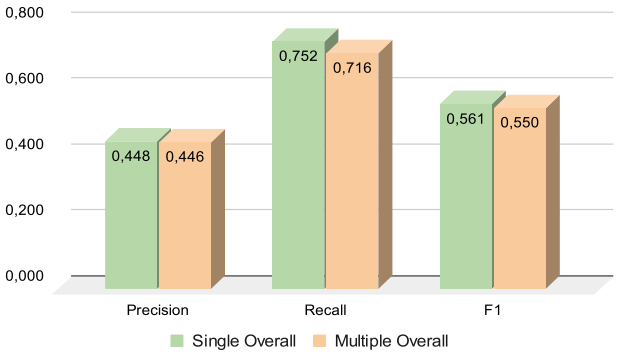

Figure 2: Overall performance comparison between Single Prompt and Multiple Prompt.

A more detailed analysis categorized by scene type indicates that the effect of prompt formulation is significantly influenced by contextual factors. In indoor environments (Figure 3), the utilization of multiple prompts results in a moderate enhancement of the F1 score, rising from 0.547 in the Single Prompt condition to 0.577 in the Multiple Prompt arrangement. This enhancement is chiefly attributable to an increase in recall (from 0.706 to 0.750), with a slight improvement observed in precision (from 0.447 to 0.469). These results suggest that, in structured indoor construction scenes with constrained geometry and reduced background clutter, prompt multiplicity can help the model retrieve a broader set of relevant objects without substantially increasing false positives.

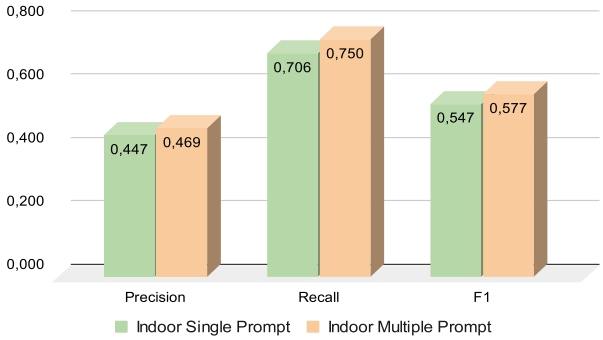

Figure 3: Performance comparison by scene type: Indoor

In contrast, outdoor construction scenes exhibit markedly different behavior (Figure 4). In this case, the Multiple Prompt configuration leads to a simultaneous reduction in recall (from 0.800 to 0.680) and precision (from 0.449 to 0.422), resulting in a more noticeable drop in F1 score from 0.575 to 0.520.

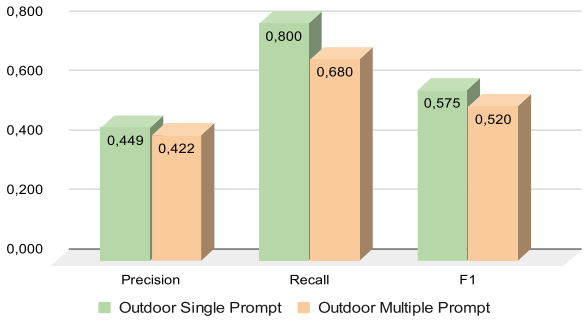

Figure 4: Performance comparison by scene type: Outdoor.

In visually complex, less structured outdoor environments, prompt multiplicity does not yield clear improvements in detecting and discriminating target objects and may be associated with less stable detection outcomes. The presence of heterogeneous materials and temporary structures can raise semantic interference between prompts, leading to both missed detections and false positives. Overall, managing multiple prompts seems more difficult in these environments. To further investigate prompt sensitivity, the following analysis focuses on lexical variation under single-prompt conditions, allowing the effect of wording to be examined independently from prompt multiplicity.

Lexical variation

Table 3 summarizes how lexical variation impacts detection performance. Because this analysis aims to assess the model's sensitivity to lexical differences rather than scene-specific features, the results are aggregated across both indoor and outdoor environments. The Base Term prompt serves as the baseline and achieves the highest overall F1 score (0.561), suggesting that normal and commonly used language for object class names

yields the most reliable alignment between textual prompts and visual representations in this experimental setting. The Synonym Term strategy yields a very similar performance (F1 = 0.555), with nearly identical precision and a slight reduction in recall. This result suggests that *GroundingDINO* exhibits a limited performance variation across closely related lexical forms, although even minor variations in wording can affect recall. A pronounced performance degradation is observed when transitioning to Technical Term prompts. In this case, both precision (0.395) and recall (0.622) decrease, resulting in a lower F1 score (0.483). This behaviour indicates that specialised and domain-specific terminology, while semantically precise from a technical or regulatory standpoint, is less effectively grounded by the model. This reflects a mismatch between the linguistic distributions encountered during large-scale pre-training and the formal vocabulary commonly used in construction standards and technical documentation. The use of Plural Term further degrades performance (F1 = 0.454), with the reduction driven primarily by a drop in precision. This finding suggests that the model is sensitive to inflectional variation and that plurality introduces ambiguity in the mapping between textual prompts and visual instances, even when the underlying semantic concept remains unchanged. This ambiguity increases false detections, thereby reducing detection reliability. The lowest performance is obtained with Definition Term prompts, which exhibit a substantial decline across all metrics (F1 = 0.314). In this configuration, the combination of descriptive modifiers and increased linguistic complexity prevents the model from identifying a stable visual reference for the target object, resulting in both poor recall and a high false-positive rate. Overall, these results suggest a trade-off between lexical variation and detection robustness. While *GroundingDINO* appears to tolerate limited lexical variation, performance tends to decrease as prompts differ from concise normal language object names and incorporate greater technical, inflectional, or descriptive complexity. This emphasizes that in the context of OVOD for construction applications, semantically accurate prompt formulations from a human perspective do not necessarily translate into improved model performance and may instead hinder reliable grounding.

Table 3: Precision, recall, and F1 scores for single-prompt lexical variation strategies.

Prompt Strategy	Precision	Recall	F1
Base Term	0.448	0.752	0.561
Synonym Term	0.451	0.720	0.555
Technical Term	0.395	0.622	0.483
Plural Term	0.347	0.657	0.454
Definition Term	0.230	0.496	0.314

Multiple prompting and Hallucination.

In this section, the analysis focuses on the effects of multiple promoting and hallucination, particularly when prompts include object categories that are not present in the scene. Table 4 reports both absolute performance metrics and relative percentage variations with respect to the single-prompt baseline, enabling a clearer comparison of the impact of hallucination and multi-object prompting configurations on detection performance.

Table 4: Precision (P), recall (R), and F1 scores for SP, MP, and Hall. configurations (Δ% relative to single prompt).

	P	ΔP (%)	R	ΔR (%)	F1	Δ F1 (%)
SP	0.448	–	0.752	–	0.561	–
MP	0.446	−0.4%	0.716	−4.8%	0.550	−2.0%
Hall.	0.447	−0.2%	0.737	−2.0%	0.557	−0.7%

Findings show that Precision remains nearly unchanged across configurations. Moving from single-prompt to multiple-prompt, precision decreases by approximately 0.4%, while the hallucination setting shows only a minor decrease of 0.2%. Recall exhibits a more noticeable change, with a 4.8% decrease for multiple-prompt and 2.0% decrease for hallucination relative to the single-prompt baseline, resulting in modest decreases in F1 score (−2.0% and −0.7%, respectively). These results suggest that hallucination primarily affects the model's ability to reliably retrieve all relevant objects, while having a limited impact on precision.

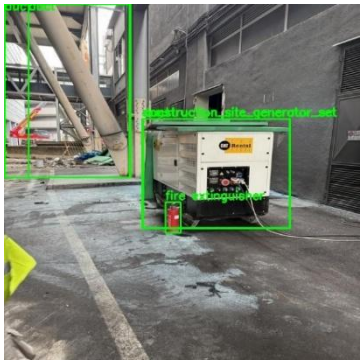
Given the qualitative examples in Figure 5, the results show that the impact of increased prompt multiplicity is class dependent. For instance, the *sprinkler* (Figure 5-a/5-b) category is not detected under single prompting and remains unaffected by multiple prompting. In contrast, some categories exhibit stable behavior across prompting strategies, such as *ladder* (Figure 5-c/5-d), which is correctly detected under both single- and multiple-prompt configurations. Other categories, however, show marked performance variations when multiple prompts are introduced, reflecting increased semantic ambiguity and class-level confusion. This effect is evident for *red & white tape* (Figure 5-d), where multiple prompting leads to an increase in false detections. Moreover, the results indicate that introducing prompts for object categories absent from the scene can induce false detections without affecting the detection of present targets. An example of this behavior occurs when the "absent duct" (Figure 5-f) category is incorrectly assigned to another object in the image while the present object still is correctly detected (Figure 5-e compared to Figure 5-f). Overall, the comparison between configurations indicates that hallucination impacts OVOD performance by adding false detections. This reveals a trade-off between target detection (recall) and detection accuracy (precision), which should be carefully balanced based on the specificity and requirements of the construction scenario under analysis.

Limitations and Future Works

This work is intended as a focused, exploratory study of prompt sensitivity in OVOD for construction scenarios. The experimental design studies different prompt configurations across visual conditions for various object

a) "Sprinkler" - Single Prompt
Failure: Target Missed detection & FPs

c) "Ladder" – Single Prompt
Success: Correct detection without FPs



e) "CS generator"- Single Prompt
Succuss: Correct detection without FPs

b) "Sprinkler", "Vent cover", and "lighting" – Multiple Prompt
Failure: Target missed detection for "sprinkler" but correct detections for other classes.

d) "Ladder" and "Red&white tape"- Multiple Prompt
Success: Correct detection for targets but increased FPs

f) "CS generator set", "Fire extinguisher", and "Duct" – Multiple Prompt
Hallucination: FP for absent object (Duct) but correct detections for present Targets

Figure 5: Qualitative detection examples showing representative successes and failure modes under different prompting strategies

categories, yielding numerous evaluation instances. Although this has enabled structured analysis of prompt behavior, some aspects of the evaluation have been limited, given the scope and space constraints. First, while the dataset captures both indoor and outdoor construction environments with diverse object categories and varying visual conditions to reflect real-world scenarios, the number of images per object category remains limited. Second, the evaluation is conducted using a single threshold for IoU. The IoU threshold was intentionally selected to better account for small and partially occluded objects common in construction scenes. However, it limits comparability with standard object detection benchmarks. Future work will address these limitations by expanding the dataset to include a larger and more balanced set of images across object categories. Additionally, subsequent studies will evaluate performance across multiple thresholds to enable more comprehensive and standardized comparisons. Building on the current findings, future research will also further investigate and refine prompting strategies to improve robustness across diverse construction environments.

Conclusions

This study presented an exploratory investigation of prompt robustness in OVOD for construction scenarios, focusing on lexical variation and prompt multiplicity using *GroundingDINO*. The results of this study indicate patterns rather than providing conclusive evidence and show that prompt formulation plays a relevant role in detection performance, influencing both recall–precision trade-offs and the occurrence of hallucinated predictions. In particular, simple base-term prompts provide the most stable and reliable results, while increasing linguistic complexity tends to reduce detection performance. The analysis also shows that multiple-prompt configurations do not consistently improve performance and may introduce context-dependent effects. While some benefits are observed in structured indoor environments, more complex outdoor scenes are associated with reduced stability and increased false detections. Furthermore, the introduction of hallucinated object categories highlights a limitation of OVOD systems, as the model tends to produce false detections rather than null responses, affecting detection completeness and reliability. These findings suggest a gap between human semantic expectations and the model's grounding behavior, which may affect deployment in safety-critical construction applications. Overall, the study emphasizes the importance of careful prompt design in OVOD-based AEC workflows. Future work will extend the evaluation across multiple IoU thresholds and investigate more robust prompting strategies to improve reliability and reduce hallucination effects in real-world construction scenarios.

Abstract

Information Extraction (IE) from Architecture, Engineering, and Construction (AEC) drawings remains hindered by manual inefficiency, while Layout Detection—a vital "middleware" organizing graphical and textual hierarchies—is underexplored. General document layout models, optimized for text-centric content, lack validation on engineering drawings. This study constructs a custom AEC-specific layouts dataset and benchmarks five deep learning architectures. RF-DETR achieves state-of-the-art performance with an mAP_{50} of 0.949, while the Vision-Language Model Qwen3-VL attains a leading F1-score of 0.911. Conversely, models pre-trained on general document datasets suffer from "domain interference", causing performance degradation. This establishes a robust technical foundation for automated IE in AEC.

Introduction

In the Architecture, Engineering, and Construction (AEC) industry, drawings are still a common medium for information exchange. Efficient Information Extraction (IE) is essential for downstream tasks such as building refurbishment, Quality Assurance (QA), and digital twin development. In contemporary practice, however, IE from drawings remains heavily reliant on manual effort, which is labor-intensive and error-prone. Automating drawing interpretation is thus an urgent industrial priority.

Information within an engineering drawing can be systematically categorized into three hierarchical layers: the *Metadata Layer* (titleblocks), the *Layout Layer* (spatial arrangement), and the *Main Drawing Content Layer* (graphical entities) (shown in Figure 1). Serving as the vital "middleware" between these two, the *Layout Layer* defines the logical relationships and hierarchical structure between disparate elements, such as drawing areas, notes, and titleblocks.

Previous efforts have primarily focused on isolated layers of this hierarchy, such as automated metadata extraction from titleblocks (Lombardi et al., 2025) or localized symbol detection (Khan et al., 2024; Jamieson et al., 2025). While advancing specific tasks, these studies often overlook the overall engineering drawing layout. This research gap is critical because the layout provides the semantic framework necessary for holistic understanding; for instance, the meaning of a symbol often depends on its functional orientation within the layout context. Without this structural link, isolated IE loses the global logic required for complex engineering reasoning.

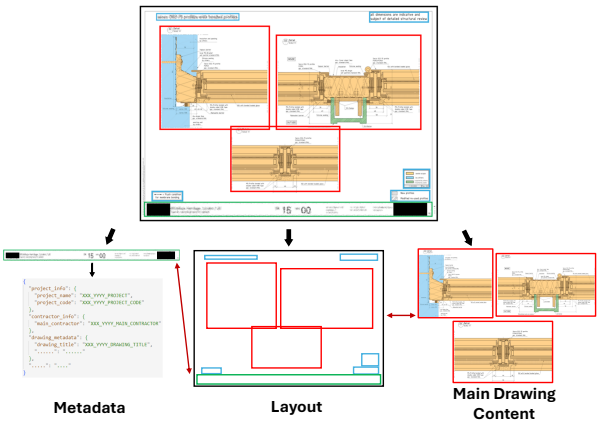

Figure 1: Hierarchical layers of information in AEC drawings

While Document AI has produced powerful Document Layout Analysis (DLA) models like LayoutLM (Xu et al., 2020, 2021; Huang et al., 2022) and DocLayout-YOLO (Zhao et al., 2024b), these are primarily optimized for general text-centric documents such as invoices or academic papers. Due to the unique characteristics of engineering drawings—such as extreme aspect ratios, high-resolution requirements, and sparse graphical density—the performance of general-purpose Document AI models in this domain has not been systematically benchmarked or validated.

To fill this research gap, we collaborated with industry experts to construct the *Facade Engineering Layout Dataset*, comprising 551 high-quality annotated drawings. Based on this dataset, we conducted a comprehensive benchmark of state-of-the-art models, including Faster R-CNN (Ren et al., 2017), YOLOv12 (Tian et al., 2025), RF-DETR (Robinson et al., 2026), Qwen3-VL (Bai et al., 2025) and DocLayout-YOLO, evaluating their efficacy in engineering drawing layout detection. Additionally, an ablation study on DocLayout-YOLO investigates whether general DLA architectural designs and pre-trained weights can be effectively transferred to the AEC domain.

The primary contributions of this research are as follows.

1. We identify the importance of Layout Detection in the AEC domain as a prerequisite for holistic drawing un-

derstanding.
2. We provide an extensive benchmark of multiple deep learning architectures, analyzing their strengths and limitations when dealing with large-scale, high-complexity engineering documents.
3. We reveal a significant "domain interference" effect through the ablation study, demonstrating that specialized architectural designs and pre-trained weights from general document domains can act as negative priors for AEC drawings.

Our findings establish a robust technical pathway for performing detailed IE and QA on engineering drawings in AEC projects.

Related Work

Information Extraction in Engineering Drawings

Engineering drawings encapsulate high-density geometric and semantic data, necessitating their transformation into structured formats for industrial digitalization. Current research predominantly bifurcates into two domains: Metadata Extraction from titleblocks and Main Drawing Content Analysis.

Metadata Extraction from Titleblocks

Early heuristic and OCR-based methods (Kashevnik et al., 2023) often lack robustness against non-standard layouts or scanning artifacts. Recent advancements have shifted toward Transformer-based end-to-end detection. Microsoft's Donut (Kim et al., 2022) bypassed traditional OCR errors by employing a joint visual encoder and language decoder. Furthermore, Lombardi et al. (2025) integrated Faster R-CNN with GPT-4o to parse titleblocks in AEC drawings into structured key-value pairs. They achieved 86% key retrieval and 95% value-matching accuracy, demonstrating Multimodal Large Language Model's potential for semi-structured AEC documents.

Main Drawing Content Analysis

In contrast to titleblocks, information within the main drawing area is dispersed and topologically complex. Zhang et al. (2023) addressed this by modeling mechanical drawings as graph structures, utilizing GraphSAGE to classify geometric contours and annotations. Khan et al. (2026) proposed a two-stage hybrid framework using YOLOv11-OBB to identify text regions (e.g., GD&T, materials, surface roughness), followed by a finetuned Donut model for structured JSON extraction. To extract main drawing content from high-resolution AEC drawings, current studies frequently employ tiling strategies—partitioning massive images into smaller patches to ensure compatibility with Vision Transformers or CNN-based detectors (Jamieson, 2024; Carrara et al., 2025).

Ontology-based floor plan analysis (DAnO)

The work of Schönfelder and König (2025) proposed the *Drawing Analysis Ontology* (DAnO) as an ontology-driven framework for automatic floor plan analysis, focusing primarily on architectural plans. It provides a domain model to represent drawing elements and their semantic relationships, and it is used to support reasoning tasks such as aggregation and consistency checking on floor-plan content. In typical DAnO use cases, each drawing sheet contains a single main plan view, and the ontology targets the interpretation of this view rather than the explicit modelling of multiple layouts within a sheet.

Layout Detection: The Missing Link

Existing AEC "layout" research is primarily restricted to architectural floor plans, focusing on semantic segmentation of object elements (e.g. walls, doors) within individual views (Heras et al., 2014). These approaches fail to address the holistic sheet-level layout of generic AEC drawings, where heterogeneous views—such as plans, sections, and elevations—coexist. To bridge this gap, we propose multi-view layout recognition as a strategic "middleware" stage that facilitates holistic data extraction through the following benefits:

Semantic Contextualization: Layout detection identifies the spatial distribution of drawing areas, which is critical as identical symbols carry distinct semantic meanings depending on their viewport (e.g., plan vs. section). Without this context, isolated symbol detection loses essential semantic associations.

Optimizing High-Resolution Processing: Unlike "blind" tiling techniques that cause semantic fragmentation by severing continuous engineering entities, prioritizing layout detection identifies information-dense "Regions of Interest" (RoI). This facilitates semantic-aware tiling, ensuring high-resolution crops maintain logical boundaries and necessary global context for downstream extraction tasks.

General Document Layout Analysis

While layout analysis remains under-explored in the AEC sector, general Document Layout Analysis (DLA) has transitioned from early heuristic rules (Namboodiri and Jain, 2007) to sophisticated deep learning paradigms. This shift was catalyzed by large-scale benchmarks such as PubLayNet (Zhong et al., 2019) and the structurally diverse DocLayNet (Pfitzmann et al., 2022); the latter has become the primary benchmark in the field due to its accurate and detailed manual labels. Currently, the field is dominated by multimodal Transformers, notably the LayoutLM series (Xu et al., 2020, 2021; Huang et al., 2022), which integrates visual and positional features for SOTA performance. To meet industrial throughput requirements, models like DocLayout-YOLO (Zhao et al., 2024b) have emerged, utilizing a G2L_CRM architecture to achieve competitive accuracy with significantly faster inference speeds. Recent research has further matured toward advanced structural understanding, including reading path reconstruction (Wang et al., 2021) and graph-based document structure analysis (Chen et al., 2025).

The Research Gap: Unique Challenges of AEC Drawings

Despite the maturation of general DLA, research specifically tailored to AEC drawings remains sparse. Models optimized for general documents cannot be directly migrated due to data scarcity and significant domain disparity. Unlike text-centric documents, AEC drawings feature massive formats, a dominance of non-textual symbols, and complex topological interdependencies that require specialized handling.

To address these challenges, this study constructs a high-quality *Facade Engineering Layout Dataset* and provides a comprehensive benchmark of SOTA models on this specialized domain. Moreover, an ablation study of DocLayout-YOLO is conducted to systematically evaluate how its specialized G2L_CRM architecture and large-scale document pre-training weights influence performance when transferred to the unique graphical landscape of AEC engineering drawings.

Methodology

In this section, we outline our methodology for benchmarking engineering drawing layout detection. We first introduce the curation of the *Facade Engineering Layout Dataset* (FELD). This is followed by our selection of candidate models and the standardized experimental framework used for evaluation.

Dataset and Ontology Overview

To support the benchmarking experiments, this study curated the FELD dataset. This dataset consists of 551 facade drawing images derived from 10 real-world construction projects, comprising nine common drawing layout elements. A comprehensive overview of the dataset is provided in Table 1 below.

Table 1: FELD Dataset Overview

Category Name	Image Counts	Annotation Counts
Titleblock	551	604
Titleblock; Revision Table	425	425
Legend	54	91
Notes	145	288
Layout; Elevation	56	60
Layout; Section; Horizontal	239	321
Layout; Section; Vertical	307	376
Layout; Section; GA	23	37
Layout; Plan; GA	21	26
All Categories	**551**	**2228**

GA: General arrangement

Prior to annotation, we first collaborated with facade domain experts to define an AEC Drawing Information Representation Ontology (ADIRO); the ontology is illustrated in Figure 2 below. This ontology is intended to delineate the spatial structure and semantic connotations of the drawings through a hierarchical logical framework. ADIRO is tailored to the needs of IE from engineering drawings, rather than directly adopting existing building ontologies or classification schemes. Existing models and ontologies (e.g., IFC, ifcOWL, Uniclass, Brick, BOT) are designed primarily for BIM authoring, lifecycle asset management, or building automation, and therefore optimize for comprehensive domain coverage and interoperability. As a result, they tend to be large, multi-purpose and conceptually heavy, with many distinctions and constraints that are irrelevant at the level of 2D drawing analysis and information extraction. For drawing IE, we instead require a schema that is tightly aligned with visual patterns in drawings, annotation workflows, and graph-based reasoning, in addition to local spatial relations. A custom ontology allows one to minimise complexity, expose only the concepts and relations that matter for IE, downstream queries, and QA checks, and iterate rapidly as new tasks emerge. Interoperability is preservable by attaching external identifiers (such as IFC types or Uniclass codes) as attributes when required, while the core representation remains simple and learnable. We included nine of the most representative and common layout categories in ADIRO (see Table 1) and established annotation guidelines.

ADIRO is closely related to DAnO (Schönfelder and König, 2025), which defines concepts such as DrawingElement, DisplayElement, and DescriptionElement, and their relationships, enabling semantic graph-based reasoning over text–symbol–geometry relations in architectural plans. In contrast, ADIRO is designed for engineering drawings where multiple layouts commonly coexist on a single sheet. To capture this, ADIRO introduces Layout as a parent concept to DrawingElement: a layout can contain drawing elements as well as other sheet content such as tables, schedules, and textual regions, thereby explicitly modelling the hierarchical structure of multi-layout sheets. While ADIRO and DAnO partially overlap at the level of basic drawing concepts, their scope and structuring differ; we therefore consider ADIRO complementary to DAnO and plan to explore explicit linking or reuse of DAnO modules in future extensions of ADIRO, once we move beyond the layout-focused core required for the present work.

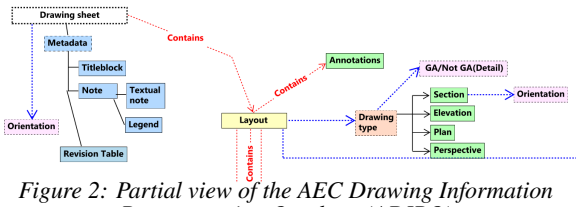

Figure 2: Partial view of the AEC Drawing Information Representation Ontology (ADIRO)

During the annotation phase, domain experts performed labeling which was cross-checked. Standard rasterization was performed to ensure consistency across vector and raster drawings, with all drawings at 300 DPI. Due to the varying dimensions of the originals, the dataset image dimensions range from 3509×2480 to 14042×9934 pixels.

Evaluated Model Architectures

To comprehensively evaluate layout detection in AEC drawings, we selected five architectures representing distinct technical paradigms:

Faster-RCNN & YOLOv12

Faster R-CNN is employed as a robust two-stage baseline to evaluate traditional anchor-based frameworks on large-scale layouts. Conversely, YOLOv12 (m) represents the state-of-the-art in one-stage detectors, selected to assess the balance between real-time inference efficiency and detection accuracy via its Area Attention mechanism.

RF-DETR

RF-DETR is selected as the latest iteration of Transformer-based detection models and currently stands as a SOTA solution in the field. By reframing detection as a set prediction problem, it provides a purely end-to-end pipeline without reliance on Non-Maximum Suppression (NMS). We utilize RF-DETR to evaluate the efficacy of DETR's global attention mechanisms in modeling the intricate topological relationships between disparate drawing zones.

Qwen3-VL

To explore the potential of state-of-the-art multimodal models in specialized domains, we introduce Qwen3-VL. This high-performance vision-language model natively supports long-text streams up to 256K tokens and utilizes an enhanced Interleaved-MROPE (Multimodal Rotary Positional Embedding) to improve spatial modeling for large-scale documents.

By benchmarking Qwen3-VL-8B-Instruct, we evaluate whether the semantic knowledge from large-scale multimodal pre-training can be effectively transferred to the specialized domain of architectural symbolic layouts.

DocLayout-YOLO

Specifically engineered for general DLA, DocLayout-YOLO is included to evaluate its domain-specific architectural optimizations and whether pre-training on general document layout datasets can be effectively transferred to AEC drawings. Based on the YOLOv10m backbone, its core innovation—Global-to-Local Contextual Modeling (G2L_CRM) — enables the model to simultaneously perceive the overall logical structure of a page and fine-grained semantic details. By comparing this model with general-purpose detectors and conducting additional ablation studies, we aim to quantify the extent to which its architectural enhancements and large-scale document pre-training contribute to performance gains when applied to AEC-specific documents.

Experimental Setup

Hardware and Environmental Configuration

All experiments were implemented using the PyTorch framework on the Ubuntu operating system. To ensure computational efficiency, Qwen3-VL-8B-Instruct was trained on an NC24ads-A100-v4 instance with MS-Swift framework (Zhao et al., 2024a), while Faster R-CNN, YOLOv12, RF-DETR, and DocLayout-YOLO were trained on an NC4as-T4-v3 instance.

Model Specifications and Initialization

To ensure a fair and comprehensive comparison, we selected specific variants of each architecture and initialized them with specialized pre-trained weights. Faster R-CNN was implemented using the ResNet-50 backbone with Feature Response Normalization (FRN). For the YOLOv12 and RF-DETR architectures, we utilized their respective medium (m) variants to balance computational cost and detection capacity. These three models were initialized with weights pre-trained on the COCO dataset. In contrast, Qwen3-VL was deployed using the 8B-Instruct version, which had undergone extensive large-scale pre-training. For DocLayout-YOLO, we utilized a version specifically pre-trained on large-scale document layout datasets, namely DocLayNet and DocSynth, to leverage its domain-specific knowledge in general DLA.

Data Partitioning and Preprocessing

Given the imbalanced distribution of labels in engineering drawings, we employed Multi-label Stratification (Sechidis et al., 2011) to partition the dataset into training, validation, and test sets with a ratio of 70:15:15. In the preprocessing stage, no data augmentation was applied. Images were resized while preserving their original aspect ratios to match the default input specifications of each model: 1344×800 pixels for RF-DETR, Faster R-CNN and Qwen3-VL, 640×640 pixels for YOLOv12 and DocLayout-YOLO.

For Qwen3-VL, the dataset was converted from the standard COCO JSON format into a specialized Grounding prompt format (JSONL). The model is trained to generate JSON-formatted outputs containing a list of objects with their respective category labels and 2D bounding boxes. To maximize detection performance, we implemented a dual-query strategy:

General Queries: The model is prompted to identify and locate all layout elements simultaneously (e.g., "Identify and locate all drawing layout elements...").

Per-category Queries: The model focuses on localizing a specific target class (e.g., "Locate the Legend region...").

Training Strategy

Training was conducted using the AdamW optimizer coupled with a Cosine Learning Rate Scheduler. A warm-up period was implemented during the first 500 iterations to stabilize the initial gradients. All architectures were initialized with pre-trained weights mentioned above and fine-tuned according to their respective default loss configurations. During model training, we implemented selective parameter freezing strategies tailored to the specific architecture of each model. Specifically, for Qwen3-VL, we employed Parameter-Efficient Fine-Tuning via LoRA (Low-Rank Adaptation) to achieve efficient adaptation.

Table 2: Overall Performance Comparison of Evaluated Models on the FELD Dataset.

Evaluation Metrics

Accuracy Metrics

To assess the detection performance, we utilize standard COCO-style metrics and classification statistics. The core benchmarks are the mean Average Precision (mAP), specifically mAP_{50} and $mAP_{50:95}$. The precision (P), recall (R), and F1-score are calculated at a confidence threshold of 0.25 to evaluate the balance between prediction accuracy and coverage.

Model Complexity and Efficiency

Beyond accuracy, we quantify the computational requirements and real-time performance of each model. Model complexity is measured by the number of Parameters and Floating Point Operations (FLOPs). To evaluate practical deployment feasibility, we record models' Inference Time per unit (pre-processing and post-processing time excluded) and Frames Per Second (FPS) on T4 GPU.

Results and Analysis

This section presents a comprehensive analysis of the experimental results achieved by the candidate models on the FELD dataset. We first evaluate the overall performance of each architecture from the perspectives of both accuracy and computational efficiency, followed by an in-depth exploration of performance variations across different layout categories. Furthermore, an ablation study is conducted on DocLayout-YOLO to investigate how its specialized architectural innovations for general DLA, combined with pre-trained weights from general document datasets, influence the model's performance on AEC-specific drawings.

Overall Performance Analysis

Table 2 presents the overall performance of the candidate models on the FELD dataset. Throughout this paper, the best-performing results for each metric are highlighted in bold, while the second-best are indicated with an underline.

First, RF-DETR (m) achieves the SOTA performance in detection accuracy, reaching a peak mAP_{50} of 0.949, $mAP_{50:95}$ of 0.890, and a Precision of 0.985. This result demonstrates the superiority of the global attention mechanism within the Transformer architecture when processing large-scale drawings. In contrast, the traditional Faster R-CNN exhibits significant robustness, ranking second in mAP_{50} (0.930) and $mAP_{50:95}$ (0.779) while achieving the highest Recall (0.924). This validates the continued efficacy of the Region Proposal Network in identifying regular geometric layouts prevalent in AEC drawings. However, its inference speed is limited to 11.4 FPS. Regarding YOLOv12 (m), this model remains the most efficient architecture, achieving the highest frame rate of 43.3 FPS and a leading inference time of 23.1ms while its Precision (0.871) remains competitive.

The vision-language model Qwen3-VL-8B demonstrates a unique performance profile influenced by its specific evaluation methodology. During inference, the model performs per-category queries. Following the standard convention for VLM-based grounding tasks, the detection confidence for all outputs is fixed at 1.0. This could negatively impact metrics such as mAP, which rely on sorting detections to calculate precision-recall curves.

Despite this inherent disadvantage in ranking-based metrics, the model achieves the highest F1-score (0.911)

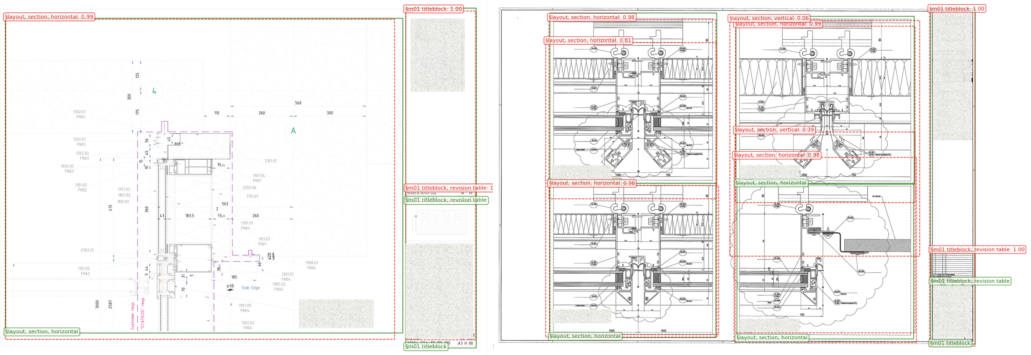

*Figure 3: Visualization of Qwen3-VL inference results. The **left** panel shows a successful layout detection; the **right** panel illustrates a failed case with redundant overlaps.*

and maintains strong performance with the second-highest Precision (0.916) and Recall (0.906). This suggests that the extensive multimodal knowledge and vision-language alignment embedded in Qwen3-VL provide superior semantic classification consistency. However, its localization precision ($mAP_{50:95}$ of 0.668) still lags behind specialized models. Moreover, its significant 8B parameter count leads to extreme latency, with an inference time of 6120.3ms per drawing, making it currently unsuitable for real-time industrial throughput.

Finally, DocLayout-YOLO, pre-trained on DocLayNet and DocSynth, fails to outperform general-purpose vision models on the FELD test set. This outcome indicates that architectural innovations and pre-trained features derived from general DLA do not effectively transfer to the AEC domain. The distinctive topological logic and the high-density, line-based graphical-symbolic logic of architectural drawings remain fundamentally different from the structural patterns found in general documents. A more granular analysis of this domain gap will be conducted in the Ablation Study section.

Category-specific Analysis

Table 3 provides a granular breakdown of the $mAP_{50:95}$ scores across nine layout categories, revealing distinct performance characteristics of the evaluated models.

First, RF-DETR (m) exhibits a dominant performance by achieving the highest precision across all categories. Its consistent lead validates the robustness of the Transformer-based architecture in managing diverse layout structures. Meanwhile, Faster R-CNN and YOLOv12 (m) alternate as the second-best performers depending on the category. Faster R-CNN maintains a competitive edge in regular geometric areas such as *GA section* (0.820), while YOLOv12 performs reliably in *Titleblock* (0.952) and *Legend* (0.910).

Second, DocLayout-YOLO† shows highly polarized results across different classes. While it achieves respectable performance in structured regions like *Titleblock* (0.894) and *Legend* (0.720), its accuracy collapses in *Notes* (0.395) and *GA section* (0.039). This disparity suggests that while its DLA-oriented architecture can recognize common document-like blocks, it struggles with the specialized graphical density and topological complexity inherent in AEC-specific sections.

Despite mAP calculation disadvantages, Qwen3-VL-8B achieved a perfect 1.000 $mAP_{50:95}$ for *Legends* and led in *Vertical Section* (0.856). While highly competitive in *Titleblocks* (0.939), its performance in *Notes* (0.560) was hampered by over-generalization, frequently misidentifying miscellaneous text as notes. This underscores the model's robust pattern recognition alongside current limitations in fine-grained textual classification.

Finally, a cross-model observation reveals that *GA section* and *Plan* generally yield the lowest scores among all categories. This trend is primarily attributed to the limited sample size for these specific classes in the current dataset, which restricts the models' ability to learn sufficient discriminative features during the training phase.

Ablation Study on DocLayout-YOLO

To further investigate the impact of architectural innovations and pre-training weights of DocLayout-YOLO on model performance within the FELD dataset, we conducted a comprehensive ablation study.

DocLayout-YOLO is a variant of the YOLOv10m baseline. Its primary structural modification involves replacing the standard C2f and C2fCIB modules in layers 4, 6, and 8 with specialized G2L_CRM modules designed for DLA. Additionally, the standard DocLayout-YOLO leverages large-scale pre-training on general document layout datasets, specifically DocLayNet and DocSynth. We designed this ablation study to specifically examine how these DLA-centric modifications and pre-training weights respond to the unique graphical nature of AEC drawings.

We evaluated three specific configurations to isolate these variables:

1. YOLOv10m (COCO pre-trained): The baseline general-purpose object detector with COCO weights.
2. DocLayout-YOLO (COCO + Random Init): Incorporates the G2L_CRM architectural changes but utilizes COCO weights for common layers and random initialization for the new modules, effectively testing the architecture without DLA-specific pre-training.
3. DocLayout-YOLO (DocLayNet&DocSynth pre-

Table 4: Ablation Study on Model Architecture and Pre-training Weights of DocLayout-YOLO

Model / Configuration	$\mathbf{mAP}_{50:95}$	$\mathbf{mAP}_{50}$	P	R	F1	Params
DocLayout-YOLO (DocLayNet&DocSynth Pre-trained)	0.589	0.675	0.736	0.602	0.662	19.97M
DocLayout-YOLO (COCO + Random Init)	<u>0.727</u>	<u>0.854</u>	<u>0.921</u>	<u>0.695</u>	<u>0.792</u>	19.97M
YOLOv10m (COCO pre-trained)	**0.772**	**0.900**	**0.954**	**0.826**	**0.885**	16.46M

trained): The full model incorporating both architectural changes and large-scale document-domain pre-training.

The results presented in Table 4 revealed a surprising trend: both the architectural innovations and the document-specific pre-training weights of DocLayout-YOLO resulted in a performance degradation on the AEC dataset compared to the baseline.

Moving from the YOLOv10m baseline to the DocLayout-YOLO architecture (COCO + Random Init) led to a decrease in $mAP_{50:95}$ from 0.772 to 0.727. This suggests that while G2L_CRM modules may excel at hierarchical text layouts, they are less effective at capturing the high-density, purely graphical symbolic logic of architectural drawings. While the most significant drop occurred when applying the DocLayNet pre-trained weights, which caused the $mAP_{50:95}$ to plummet to 0.589.

This confirms a strong "domain interference" effect, indicating that the structural priors learned from general documents like newspapers and academic papers are fundamentally incompatible with AEC drawings. The features optimized for general documents act as a negative prior, preventing the model from adapting to the complex graphical logic of architectural drawings.

Conclusion and future work

This research identifies and addresses a critical "missing link" in the automated interpretation of AEC engineering drawings: layout detection. We systematically evaluated the performance of five deep learning architectures on this task, revealing how different modeling paradigms navigate the unique structural constraints of AEC layouts.

Our experimental results demonstrate that RF-DETR (m) is the most effective technical pathway for this task, achieving a superior mAP_{50}. The success of RF-DETR highlights the necessity of global attention mechanisms in capturing the intricate spatial dependencies inherent in large-format engineering drawings. Notably, Qwen3-VL-8B also performed excellently, achieving the highest F1-score, which demonstrates the significant potential of VLMs for interpreting AEC engineering drawing. Conversely, the benchmarking of DocLayout-YOLO revealed a significant "domain gap". Our ablation study specifically proved that architectural priors and pre-trained weights optimized for text-centric documents can act as a negative prior, hindering the model's ability to adapt to the high-density graphical-symbolic logic of AEC layouts.

Despite these advancements, the FELD dataset's limited scale and facade-specific focus restrict broader generalisability. To address this, future work will enhance robustness via domain-specific augmentation and evaluate cross-domain generalisation through a dual-metric framework: quantifying "domain shift" via zero-shot testing and measuring "adaptation velocity" through few-shot transfer learning across structural and MEP sectors.

Furthermore, the inherent high-resolution nature of AEC drawings poses a significant challenge for standard deep learning pipelines; our current methodology simply relies on standard resizing, which inevitably leads to the loss of fine-grained textual features and thin geometric lines. This factor likely constrained the localization precision of RF-DETR and prevented Qwen3-VL from fully leveraging its native capacity for dynamic, native-resolution visual inputs.

Future research efforts will focus on three primary dimensions to achieve more holistic drawing understanding. First, we aim to expand the FELD dataset into a multi-domain AEC layout benchmark to enhance cross-domain generalization and address current class imbalances. Second, in this work, ADIRO is used primarily as a layout-centric schema to support consistent dataset construction and annotation, rather than as a full reasoning layer; in future work, we plan to integrate ADIRO more deeply into the pipeline by leveraging its structure in model design and training, and by using it as a foundation for ontology-based reasoning, knowledge graph construction, and potential integration with BIM models. Finally, we will leverage recognized layout boundaries as "middleware" to guide Main Drawing Content Layer extraction, implementing semantic-aware tiling to ensure that downstream symbol recognition and geometric analysis are performed within a coherent logical context.

Abstract

Accessing Building Information Model (BIM) data encoded in Industry Foundation Classes (IFC) remains difficult for non-expert stakeholders due to heterogeneous property sets and nested relationships. This paper presents a constrained text-to-graph querying framework that transforms IFC data into a labeled property graph, queried via Cypher, while project-specific Information Delivery Specification (IDS) requirements define admissible entity labels, relationships, and property keys. A regular-expression grammar restricts Large Language Model (LLM) generation to executable, schema-compliant queries. Evaluation shows grammar constraints eliminate schema hallucinations, achieving 100% Semantic Compliance and improved execution accuracy, with competitive performance from smaller open-weights models.

Introduction

BIM workflows increasingly presume that building information can be accessed on demand to support coordination, compliance checking, and decision-making. In practice, however, obtaining a first correct and verifiable answer from an IFC model remains costly (Hellin et al., 2025). This cost extends beyond computation to include the time and expertise required to translate an information need into a formal query, execute it on an IFC-derived representation, and validate the results against both the model content and project-specific modelling conventions. This initial problem typically involves multiple iterations of identifying relevant entities and relations, selecting appropriate properties and value types, and refining queries until defensible results are produced. The burden is most evident for information needs that exceed direct attribute lookups and require combinations of property constraints and topological reasoning. Common quality and compliance checks, such as isolating spatially contained elements or verifying classification and completeness requirements, remain technically demanding, as they require detailed knowledge of IFC structures and querying mechanisms. Prior research consistently identifies an intent-to-query gap in BIM information access and proposes abstractions and natural-language interfaces to mitigate direct interaction with raw IFC schemas (Mazairac and Beetz, 2013; Yin et al., 2023a; Hellin et al., 2025). However, query verbosity and representational overhead remain pragmatic obstacles, particularly where relevant information is accessible only through long navigation paths and reified relationship structures. IFC, as an open and vendor-neutral standard (International Organization for Standardization, 2024), encodes semantics indirectly, leading to complex multi-hop queries across relationship entities and nested value representations. Linked Data approaches, including ifcOWL and higher-level ontologies such as the Building Topology Ontology (BOT) and BimSPARQL, improve expressiveness and topology-centric querying (Beetz et al., 2009; Rasmussen et al., 2020; Zhang et al., 2018). Nevertheless, semantic variance across projects, arising from custom property sets, naming conventions, heterogeneous datatypes, and tool-specific export practices, limits query robustness and reuse (Yu et al., 2023). IDS addresses this by formalising project-specific information requirements and constraints in a machine-interpretable manner (buildingSMART International, 2024).

Recent advances in LLMs demonstrate strong capabilities in natural-language-to-structure translation (Jiang et al., 2023), yet their probabilistic nature poses reliability risks when applied to deterministic, schema-bound engineering data. Hallucinations and invalid query generation remain critical concerns (Huang et al., 2023). Building on recent BIM research that combines LLMs with graph-based grounding (Iranmanesh et al., 2025), this paper proposes a reliability-oriented framework that translates natural-language questions into constrained graph queries over IFC-derived representations, informed by IDS constraints. A key objective is to enable the framework to run privately on local machines, preserving data confidentiality and substantially reducing the energy and operational costs associated with reliance on commercial, cloud-based LLM services. By combining graph abstractions, explicit project constraints, and constrained decoding, the approach aims to improve the correctness and verifiability of results for topology- and constraint-dependent BIM checks.

Background and Related Work

Querying BIM models

BIM models integrate geometry, spatial relations, material properties, quantities, and semantics in one digital structure. In practice, this richness creates large datasets that are difficult to interrogate without specialized tools. Most exchanges rely on IFC (currently version 4) (build-

ingSMART International, 2024), which provides interoperability but also substantial complexity due to broad entity vocabularies, heterogeneous property sets, and deeply nested relations (Borrmann et al., 2018). As repositories grow, efficient BIM search becomes increasingly important (Khademi and Behan, 2017). Early efforts introduced domain-specific query languages such as BIMQL (Mazairac and Beetz, 2013) and QL4BIM (Daum and Borrmann, 2014). BIMQL focuses on class- and attribute-based filtering, whereas QL4BIM emphasizes spatial and topological queries. Both approaches improve expressiveness but still require users to understand formal query syntax and IFC internals, including indirect relationship encoding. Database-based approaches have also been explored. SQL is mature and efficient, but less suited to IFC-style hierarchical and multi-hop relations. SPARQL over ifcOWL maps IFC into RDF triples and supports linked-data querying (Zhang et al., 2018), yet this representation is often verbose and large (Pauwels et al., 2017). As an alternative, labeled property graphs (LPGs) represent relations more directly and support efficient traversal in systems such as Neo4j (Neo4j, 2026), queried with Cypher (Zhu et al., 2025). The RDF–LPG choice remains use-case dependent, but LPGs are often preferred for storage and query efficiency (Zhu et al., 2023). Prior work shows the value of LPG-based BIM querying. Ismail et al. (2017) demonstrated IFC-to-LPG transformation for graph analyses (e.g. emergency routes and model comparison), while later studies reported benefits for change tracking (Esser et al., 2022), semantic enrichment (Wang et al., 2022), and code compliance (Bloch et al., 2023). With recent LLM advances, graph representations are increasingly relevant as a grounding layer for natural-language BIM interaction and hallucination reduction.

LLM based BIM query

Natural-language BIM querying lowers the barrier for non-expert users by avoiding direct interaction with formal query syntax. However, LLMs alone do not reliably query IFC data: without grounding, they hallucinate entities, properties, and relations. Du et al. (2026) identify three recurring causes: long prompt context, limited global spatial understanding, and cumulative errors in multi-agent pipelines. The spatial reasoning gap is particularly critical for BIM querying. Accordingly, prior work introduces external constraints. Ontology-based approaches translate natural language into SPARQL over RDF/OWL models, as in Yin et al. (2023b). Tool-augmented pipelines instead couple LLM planning with deterministic BIM operations; for example, Hellin et al. (2025) use a ReAct-style workflow with Python tools over IFC, reporting good results for direct queries but weaker performance for indirect and relational questions. As also discussed by Du et al. (2026), graph representations can improve structural grounding for spatial and topological reasoning. Retrieval-augmented generation (RAG) provides another grounding strategy by injecting retrieved context at inference time (Gao et al., 2023). In BIM, this can supply IFC documentation and project-specific metadata (Iranmanesh et al., 2025). Yet text-centric RAG does not fully capture relational model structure. Graph-RAG improves this by retrieving connected nodes and edges, but still underperforms on complex multi-hop queries with multiple entity references and ambiguity (Iranmanesh et al., 2025). Formal project specifications offer a complementary constraint layer. IDS (buildingSMART International, 2024) defines expected IFC entities, properties, value domains, and vocabularies in machine-readable XML, primarily for automated compliance checking. In query generation, IDS can constrain allowable query patterns across IFC-, RDF-, or LPG-based representations, grounding LLM output in explicit project rules. This study therefore examines whether project-specific IDS constraints reduce hallucinations in LLM-mediated BIM querying, a direction that remains largely unexplored.

Appropriate use cases and study scope

From a theoretical perspective, model checking activities can be classified into three categories (Solihin and Eastman, 2015; Hjelseth and Nisbet, 2016). Simple checks involve the verification of the existence of specific property sets, the presence of assigned values, and the correctness of those values. Elaborated checks address design, spatial, or technical characteristics that are not explicitly stored as IFC properties but can be derived through relatively straightforward algorithms or mathematical relationships. A representative example is the verification of regulatory requirements governing the minimum ratio between window surface area and room floor area, as prescribed by Italian building codes. Complex checks, by contrast, focus on performance-based assessments and require advanced simulations, such as those used for evaluating building energy performance.

For simple checks, established rule-based approaches (e.g. IDS frameworks and commercial tools like Solibri) are likely to remain more efficient and reliable than LLM-based solutions. In this context, the primary advantage of LLMs lies in their usability, as they lower the technical barrier for non-specialist users. The suitability of LLMs for elaborated checks is clearer, however, concerns remain regarding computational accuracy and the risk of hallucinated outputs (Huang et al., 2023). In these cases, LLMs may be a useful interface between the complexity of rule-based checking software and end users, providing the ability to perform elaborated checks without needing to learn the software's query grammar. With respect to complex checks, neither traditional rule-based tools nor LLM-based approaches currently offer adequate capabilities.

Beyond model checking, greater value may be found in leveraging LLMs as intuitive interfaces for querying BIM data (Yin et al., 2023b). Their accessibility enables meaningful interaction with BIM models by non-technical stakeholders, including building occupants, maintenance personnel, municipal officers involved in digital permit-

ting, and senior decision-makers within organizations. This work focuses on elaborated checks, where the key challenge is reliably translating natural-language intent into verifiable, executable queries over IFC-derived data.

Research Questions

To structure the study, three research questions are formulated, each addressing a key design choice of the proposed pipeline:

RQ1 (text-to-query over direct QA): Can LLM-mediated text-to-graph querying produce correct results for IFC-based information needs where Direct QA over serialized data fails?

RQ2 (graph representation): How does representing IFC as a graph affect the correctness and robustness of answers generated from queries over the model?

RQ3 (IDS as a constraint layer): Does integrating IDS improve the semantic correctness of LLM-generated Cypher queries over IFC-derived graphs?

Together, these questions assess whether a constrained graph query workflow can provide predictable, auditable access to BIM information for non-expert stakeholders, while remaining practical for real project models.

Proposed Method

System overview

A Constrained Natural Language to Cypher (NL2Cypher) framework is proposed to ground LLMs in project-specific constraints defined by the IDS. An IFC file is transformed into a Neo4j (Neo4j, 2026) LPG and an IDS file is compiled into a formal grammar. This grammar restricts the LLM's decoding process, ensuring that generated Cypher queries are syntactically valid and semantically compliant with the project schema.

The architecture consists of three primary layers:

a) The data ingestion layer transforms the IFC model into a flattened property graph and scans the model for available vocabulary.

b) The constraint layer parses the IDS to extract enforced constraints (entities, properties, enums) and merges them with the model vocabulary to build a strictly typed schema.

c) The generation layer uses constrained decoding to guide the LLM, masking invalid tokens at each generation step based on a regular expression derived from the schema.

IFC-to-graph mapping

To enable efficient graph transit, the system simplifies the complex IFC schema into a LPG. The mapping process involves three transformation rules. First, every `IfcProduct` becomes a graph node. The node label corresponds to the IFC class (e.g., `IfcWall`). Then, the relationships hosted in `IfcPropertySet` entities linked via `IfcRelDefinesByProperties` are flattened and embedded directly onto the entity node as key-value pairs. Finally, the complex relationship entities (e.g., `IfcRelAggregates`, `IfcRelContainedInSpatialStructure`) are converted into directed edges. The relationships most commonly required for property- and topology-based queries are prioritized: CONTAINS (from `IfcRelContainedInSpatialStructure`), DECOMPOSES (from `IfcRelAggregates`), and HAS_MATERIAL (from `IfcRelAssociatesMaterial`). Relationship types that serve different querying needs—such as `IfcRelVoidsElement` and `IfcRelFillsElement` (opening and infill associations), `IfcRelConnectsPathElements` (wall connectivity), and `IfcRelSpaceBoundary` (thermal envelope geometry)—are not mapped in the current implementation. The mapping is extensible: supporting additional relationship types requires adding the corresponding extraction logic and registering new edge labels in the grammar.

IDS parsing and constraint compilation

The core innovation of this method is the translation of the IDS "semantic contract" into a generative grammar. Solely relying on the IDS can be insufficient if the model contains valid data not covered by the specification. At the same time relying only on the model allows the LLM to hallucinate on dirty data. Therefore a Hybrid schema merging two sources is constructed.

Enforced Vocabulary from IDS defines strict constraints. The system parses the IDS XML structure, extracting entities from `applicability` clauses and required properties from `requirements` clauses. It captures domain-specific constraints defined via XML Schema Definition (XSD) restrictions (e.g., `xs:enumeration`), ensuring that sensitive properties (e.g., `FireRating`) are strictly limited to their defined enums.

Available Vocabulary from IFC is extracted by scanning the model file for existing labels and properties. Conflicts are resolved by giving precedence to the IDS. Properties are categorized into two tiers: **strict** (constrained to the IDS-defined enums) and **open** (inferred from the model with data types like Boolean, Numeric or String). This ensures regulatory compliance without rendering valid non-standard model data unqueryable.

This hybrid vocabulary is then compiled into a Regular Expression (Regex) that guides the LLM's decoding process via Outlines library (dottxt-ai, 2026).

Query generation

Instead of fine-tuning the model or relying on "soft" prompt engineering, constrained decoding is utilized. The hybrid schema is translated into a regex pattern that defines the set of all possible valid Cypher queries for that specific building. For a schema with entities E and properties P, a regular expression $r = \texttt{build_cypher_regex}(E, P)$ is compiled to act as a grammar for valid Cypher. r is assembled from (i) an entity alternation group E_{alt} (e.g., `(IfcDoor|IfcWall)`), (ii) a property alternation group P_{alt} (e.g., `(FireRating|Height|Name)`), and (iii) a small set of admissible literals and operators. Property access is restricted to the bound match vari-

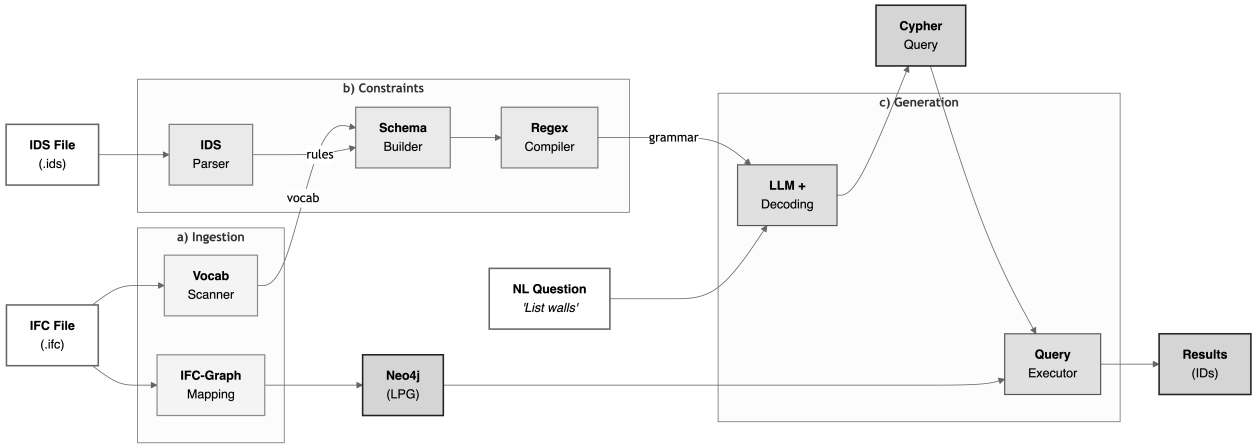

Figure 1: System overview of the NL2Cypher framework. The three layers correspond to (a) data ingestion, (b) constraint compilation, and (c) grammar-constrained query generation.

able (e.g., v.`Name`) with optional type conversions (e.g., `toInteger`(v.`FireRating`)). The grammar supports semantic string matching (e.g., $CONTAINS$) and null-safety checks ($ISNOTNULL$) which are essential for handling natural language ambiguity. The `WHERE` clause is optional and bounded to a fixed maximum number of boolean conditions to avoid overly long or incomplete queries.

$$
\begin{aligned}
r &= r_{\text{MATCH}}\, r_{\text{REL}}^{?}\, r_{\text{WHERE}}^{?}\, r_{\text{RETURN}}, \\
r_{\text{MATCH}} &:= \texttt{MATCH}\,(v : E_{\text{alt}}), \\
r_{\text{REL}} &:= -[: R_{\text{alt}}] \rightarrow (v_2 : E_{\text{alt}}), \\
r_{\text{WHERE}} &:= \texttt{WHERE}\; c_1\, \big((\texttt{AND}|\texttt{OR})\, c_2\big)^{\leq 4}, \\
c_i &:= \big(f^{?}(v.P_{\text{alt}})\ \text{op}\ \text{val}\big) \mid \big(v.P_{\text{alt}}\ \texttt{CONTAINS}\ \text{str}\big), \\
f &\in \{\texttt{toInteger}, \texttt{toFloat}, \texttt{toString}\}.
\end{aligned}
\tag{1}
$$

Note that R_{alt} represents the relationship alternation group (e.g., (CONTAINS|HAS_MATERIAL)). Furthermore, the return clause r_{RETURN} is constrained to return the node variable v. This is strictly enforced to guarantee that the execution engine retrieves the element's `GlobalId` for evaluation against the Gold Standard, preventing the generation of queries that return unidentifiable scalar values.

During inference, the constrained decoder only allows tokens that keep the partial output compatible with r (invalid next tokens are masked by setting their logits to $-\infty$). As a result, generated queries are (i) executable (high SVR - Syntactic Validity Rate) and (ii) limited to entity labels and property names present in the hybrid schema (high SCR - Schema Coverage/Compliance Rate).

Experimental Design

Baselines and datasets for demonstration and validation

To evaluate the efficacy of IDS grounding and graph-based querying, four experimental settings are compared in a 2×2 matrix of Direct Question Answering (QA) versus Text-to-Cypher, crossed with baseline versus IDS-constrained configurations (Table 1.)

Table 1: Experiment settings.

	Direct QA	Text-to-Cypher
Baseline	**S1** Naive QA **Input:** IFC text dump **Output:** JSON `GlobalIds`	**S3** Soft Cypher **Input:** graph schema **Output:** Cypher → IDs
With IDS	**S2** Grounded QA **Input:** IFC + IDS rules **Output:** JSON `GlobalIds`	**S4** Strict Cypher (proposed) **Input:** hybrid schema (IDS + model) **Output:** Cypher → IDs

Settings 1&2 simulate a RAG approach where the model reasons over raw text. To ensure comparability, the LLM is instructed to output a JSON list of `GlobalId` strings rather than the natural language. Settings 3&4 generate executable Cypher code. Setting 3 represents the current state-of-the-art in Text-to-Cypher (prompting), while Setting 4 represents our proposed method.

Dataset and Preprocessing

A sample project from Autodesk (Autodesk, 2026), exported as an IFC model, and a corresponding IDS requirement file are utilized. For the Direct QA settings (1, 2), the IFC model is serialized into a condensed JSON format. For the Graph Settings (3, 4), the model is loaded into a Neo4j (Neo4j, 2026) instance using the mapping de-

scribed above.

The IDS file defines seven specifications that constrain naming conventions, required properties, and material assignments for the principal IFC entities (Table 2). Properties such as `FireRating` are limited to enumerated values (0, 30, 60, 90 minutes), while `LoadBearing` and `IsExternal` are enforced as Boolean indicators. Material constraints require both presence (for structural elements) and specific content (concrete for load-bearing columns). These specifications form the enforced vocabulary layer in the hybrid schema.

Table 2: Summary of IDS specifications used in the evaluation.

Applicable Entity	Required Properties	Value Constraints
`IfcBuildingStorey`	`Name`	Level naming pattern
`IfcDoor`	`Name`, `IsExternal`, `FireRating`	`FireRating` ∈ {0, 30, 60, 90}
`IfcSpace`	`NetFloorArea`, `Reference`	Controlled room-type vocabulary
`IfcWall`	`LoadBearing`, `IsExternal`	Boolean
`IfcWindow`	`Name`	Component naming pattern
Structural†	`Material`	Presence required
`IfcColumn`*	`Material`	Must contain ''Concrete''

*Load-bearing only. †`IfcStair`, `IfcBeam`, `IfcSlab`, `IfcPile`, `IfcRamp`, `IfcColumn`.

Task design and use cases

The evaluation consists of 16 natural-language queries, categorized into three levels of increasing complexity:

- **Level 1 – Class retrieval** (6 queries, Easy): direct entity lookups that test the ability to identify correct IFC classes. Example: *''List all doors''* → `MATCH (n:IfcDoor) RETURN n`.
- **Level 2 – Property filtering** (5 queries, Medium/Hard): queries that add attribute constraints, Boolean checks, numeric comparisons, or null-safety tests. Examples: *''List all external walls''* → `MATCH (n:IfcWall) WHERE n.IsExternal = true RETURN n`; *''List all doors that have a fire rating defined''* → `MATCH (n:IfcDoor) WHERE n.FireRating IS NOT NULL RETURN n`.
- **Level 3 – Topology and relationships** (5 queries, Medium/Hard): multi-hop graph traversals combining relationship patterns with property constraints. Example: *''List spaces on Level 2 larger than 12 m^2''* → `MATCH (s:IfcBuildingStorey)-[:DECOMPOSES]->(n:IfcSpace) WHERE s.Name CONTAINS '02' AND n.GrossFloorArea > 12 RETURN n`.

Each query is paired with a gold-standard Cypher query whose result set defines the ground-truth `GlobalId`s used for evaluation.

Evaluation

Three metrics are employed to evaluate performance. To enable a common comparison across all settings, the primary metric is the accuracy of the returned `GlobalId`s:

- **Execution Accuracy (EA):** Jaccard similarity between the set of `GlobalId`s returned by the system and the ground-truth set.

$$EA = \frac{|R_{\text{gen}} \cap R_{\text{gold}}|}{|R_{\text{gen}} \cup R_{\text{gold}}|} \tag{2}$$

  For Direct QA (Settings 1&2): ground truth is parsed from the JSON output.
  For Text-to-Cypher (Settings 3&4): ground truth is obtained by executing the generated Cypher query against the database.
- **Syntactic Validity Rate (SVR):** for Direct QA, the percentage of responses that are valid, parseable JSON; for Cypher, the percentage of generated queries that execute without syntax errors.
- **Semantic Compliance Rate (SCR):** the percentage of generated schema elements (entity labels, property names) that exist in the hybrid schema (reported for the Cypher-generating settings).

Results and Discussion

Comparative performance

Phase 1: Cloud baselines and data access

To establish a performance ceiling and verify the necessity of structured data access (RQ1), the framework was first evaluated using state-of-the-art cloud models: Google Gemini 2.5 Flash and Gemini 3.0 Flash Preview. These models were tested on the unconstrained settings: Naive QA (S1), Grounded QA (S2), and Soft Cypher (S3).

Table 3 presents the results of the cloud-based evaluation. Both Direct QA settings (S1 and S2) achieved near-zero EA across all models and runs (Gemini 2.5 Flash: 0.09 ± 0.08; Gemini 3.0 Flash: 0.05 ± 0.06). Despite the advanced reasoning capabilities of the Gemini models, the system failed to reliably identify correct elements. The size of the IFC model chosen for tests exceeds 1M tokens both as a .ifc and as a .json dump, so the truncation of the input plays an important role in such a low performance, too. This confirms that without structured access to the underlying model data, LLMs cannot reliably retrieve specific BIM elements. The unique nature of IFC identifiers (22-character encoded strings) prevents probabilistic guessing, and schema knowledge alone (S2) proved insufficient for identifying specific instances.

In contrast, the graph-based approach (S3: Soft Cypher) demonstrated significant potential even without grammar constraints. Gemini 2.5 Flash achieved a mean EA of 0.67 ± 0.03 across three runs, successfully translating natural language into executable Cypher queries for the majority of test cases.

This disparity supports the hypothesis that the ''Text-to-Graph'' abstraction is superior to ''Direct QA'' for engineering tasks. The LLM excels at logic generation (constructing the query pattern) but struggles with direct information retrieval when denied an explicit index.

While Setting 3 (Soft Cypher) performed well, it was not flawless. Gemini 2.5 Flash achieved a mean SVR of 0.83 ± 0.07, meaning that on average roughly 17% of generated

Table 3: Phase 1 Results: Cloud-based Models (Unconstrained). Values reported as mean ± std over n independent runs.

Model	Setting	SVR	SCR	EA
Gemini 2.5 Flash	S1 (Naive)	0.54 ± 0.14	–	0.09 ± 0.08
($n = 3$)	S2 (Grounded)	0.60 ± 0.10	–	0.08 ± 0.07
	S3 (Soft Cypher)	0.83 ± 0.07	0.99 ± 0.01	0.67 ± 0.03
Gemini 3.0 Flash (Preview) ($n = 3$)	S1 (Naive)	0.44 ± 0.17	–	0.05 ± 0.06
	S2 (Grounded)	0.44 ± 0.06	–	0.02 ± 0.04
	S3 (Soft Cypher)	0.67 ± 0.03	0.99 ± 0.02	0.62 ± 0.03

queries were invalid Cypher and could not be executed. Detailed analysis of the error logs revealed two primary failure modes in the ''Soft'' setting:

1. **Hallucinated properties:** the model occasionally queried properties that did not exist in the graph (SCR < 1.0), despite the schema being provided in the system prompt.
2. **Complexity degradation:** performance dropped sharply as query complexity increased. For ''Hard'' queries (involving relationships and multi-hop traversals), the mean EA for Gemini 2.5 Flash dropped from 100% (Easy) to 22% (Hard).

These limitations in the unconstrained "Soft" approach (specifically a non-perfect SVR) motivate the need for the grammar-constrained generation (S4) explored in the subsequent phase of this study.

Phase 2: Efficacy of grammar constraints

To evaluate the proposed grammar-constrained generation (S4), Qwen2.5-Coder was utilized as a state-of-the-art open-weights model family. Unlike the prompt-based approaches in Phase 1, Setting 4 requires direct intervention in the decoding process to enforce adherence to the hybrid schema; this requirement motivates the use of local, open-weights models rather than API-based cloud services.
Table 4 summarizes the performance impact of the constraints. S3 results are reported as mean ± std over multiple independent runs ($n = 5$ for 7B, $n = 9$ for 3B); S4 results are deterministic (greedy decoding with grammar constraints) and therefore reported from a single run.

Table 4: Phase 2 Results: Open-weights models (constrained vs. unconstrained). S3 values reported as mean ± std over n runs; S4 is deterministic (single run).

Model	Setting	SVR	SCR	EA
Qwen2.5-Coder-7B Instruct	S3 ($n = 5$)	0.88 ± 0.04	0.87 ± 0.01	0.34 ± 0.03
	S4 (Strict)	**1.00**	**1.00**	**0.63**
Qwen2.5-Coder-3B Instruct	S3 ($n = 9$)	0.95 ± 0.03	0.94	0.62 ± 0.02
	S4 (Strict)	**1.00**	**1.00**	**0.64**

The effect of grammar constraints varied markedly between the two models. For the 7B model, which achieved only $EA = 0.34 \pm 0.03$ under unconstrained prompting (S3), grammar constraints nearly doubled accuracy to $EA = 0.63$, while also raising SCR from 0.87 ± 0.01 to a perfect 1.00. In this case, constrained decoding compensated for the model's weaker query-generation logic by narrowing the output space to valid schema elements.

The 3B model tells a different story. It already achieved $EA = 0.62 \pm 0.02$ ($n = 9$) under Soft Cypher—comparable to the 7B model's *constrained* result—with low variance across runs. Grammar constraints (S4) brought EA only marginally higher to 0.64, a difference well within the S3 standard deviation. The benefit of S4 for the 3B model was therefore not in accuracy but in *reliability*: SVR improved from 0.95 ± 0.03 to 1.00 and SCR from 0.94 to 1.00, guaranteeing that every generated query is syntactically valid and schema-compliant. This distinction matters in production settings, where even a 5% rate of invalid queries can erode user trust.

These results suggest that grammar constraints serve two distinct roles depending on model capability: for weaker models, they act as an accuracy amplifier by restricting the search space; for stronger models that already generate correct logic, they act as a safety net that eliminates the residual tail of schema hallucinations and syntax errors.

To further verify the effect of grammar constraints (S4) relative to the prompt-based baseline (S3), results were decomposed by query complexity: Level 1 (Class Retrieval), Level 2 (Property Constraints), and Level 3 (Topology/Relationships).

- **Level 1: Class retrieval (easy).** Under Strict Cypher (S4), both the 7B and 3B models achieved perfect performance ($EA = 1.00$, $SCR = 1.00$, $SVR = 1.00$). In the unconstrained S3 setting, the 3B model already performed strongly ($EA = 0.98 \pm 0.06$), while the 7B model showed more variability ($EA = 0.30 \pm 0.07$). The transition to S4 eliminated all remaining instances of invalid entity labeling.
- **Level 2: Property value retrieval (medium).** The 3B model showed high resilience in this category already under Soft Cypher ($EA = 0.79 \pm 0.02$). However, constraints ensured that property keys were strictly mapped to IDS- and model-derived vocabulary, maintaining $SCR = 1.00$ across both models and avoiding confusion between similarly named attributes.
- **Level 3: Topology and relationships (hard).** Multi-hop traversals remained challenging. While the 7B model under S4 constraints achieved only marginal correctness ($EA \approx 0.03$), the 3B model under S4 provided the only successful executions in this category ($EA \approx 0.13$). This suggests that by narrowing the search space to valid relationship types and property keys, grammar constraints can occasionally assist smaller models in constructing complex graph patterns that would otherwise fail under unconstrained prompting.

Overall, grammar constraints substantially improve reliability for class and property retrieval by mitigating schema hallucinations, but they cannot compensate for limited logical reasoning in complex topological queries.

Limitations and implications

The results indicate that constrained NL2Cypher generation can substantially improve the reliability of natural-language querying over IFC-derived graphs, particularly for class retrieval and property-level queries. In practice, this can make BIM information more accessible to non-expert stakeholders by reducing the need to learn specialist query languages and by limiting common failure modes such as schema hallucinations and non-executable queries.

Several limitations must be acknowledged. First, the evaluation constitutes an initial validation on a single sample project with one IDS file and 16 queries; broader replication across IFC files from real projects, with different modelling conventions, varying data quality, and larger query sets, is required before generalisability claims can be made. Second, the hybrid schema is only as effective as the underlying IDS and the extracted model vocabulary; incomplete or overly permissive specifications may still allow ambiguous queries, while overly strict specifications can reduce coverage of valid (but unspecified) information. Third, and most critically, the framework exhibits near-total failure on Level 3 topology queries ($EA \approx 0.03$–0.13), demonstrating that grammar constraints—while effective at eliminating schema-level errors—cannot compensate for the multi-step logical reasoning that complex graph traversals require. Time and cognitive effort were not measured in this study; future work should include user studies to quantify usability gains.

Fourth, IDS availability is still uneven in current practice. The proposed framework is most effective in projects where at least a partial IDS already exists. When the IDS is incomplete, the hybrid schema can still enforce the entities and properties that are specified and rely on model-derived vocabulary elsewhere. When the IDS is missing entirely, the method loses its project-specific grounding and should be interpreted as a query-assistance setup rather than a full compliance-oriented one; grammar-constrained generation remains possible over the model-only vocabulary, but without the strict property typing and enumeration controls that prevent hallucinations on ambiguous or inconsistent data. The approach therefore does not replace careful IDS authoring, but it can benefit from gradual IDS formalisation: because the grammar makes explicit which entities and properties are queryable, project teams receive immediate feedback on specification gaps, turning IDS creation from a retrospective compliance exercise into a proactive step that directly improves query reliability.

Conclusions

This paper presented an IDS-constrained text-to-graph querying framework that addresses the reliability gap when applying LLMs to BIM information retrieval. By transforming IFC data into a labeled property graph and compiling project-specific IDS requirements into a hybrid schema, the approach enables grammar-constrained decoding that eliminates schema hallucinations and guarantees syntactically valid Cypher queries. The experimental results confirm that LLMs are most effective when used to generate query logic rather than retrieve information directly, and that combining graph-based representations with formal semantic constraints improves accuracy.

These findings have practical implications for the Architecture, Engineering, Construction and Operators (AECO) industry. First, LLM-mediated BIM querying should be treated as a query generation problem with hard constraints, not a prompt engineering problem. Second, IDS can serve proactively to reduce variability in query formulation, beyond its traditional role in retrospective compliance checking. Third, by offloading syntactic precision to the constraint engine, smaller open-weights models can achieve reliability levels previously reserved for large cloud models, enabling privacy-preserving, local deployment without uploading sensitive project data to external APIs.

Future work will (i) scale experiments across additional domains and IDS complexities, (ii) investigate robustness under non-compliant or inconsistent IFC models, and (iii) extend the graph schema to better represent spatial context (e.g., second-level space boundaries) for queries about connectivity, adjacency, and energy-relevant relationships. Beyond accuracy, future evaluations should consider deployment factors such as latency and the environmental footprint. Two promising directions are interactive self-correction, where execution feedback (e.g., "query returned 0 nodes") drives iterative refinement, and hybrid graph-vector retrieval for unstructured data. Nevertheless, the results demonstrate that this NL2Cypher technique provides a practical and effective pathway toward democratizing BIM information access in a reliable way.

AUTOMATED SCHEDULE ENRICHMENT FROM DAILY PROGRESS REPORTS: A BI-DIRECTIONAL NEURO-SYMBOLIC AI APPROACH

Sudheer Kumar Nanduri, Venkata Santosh Kumar Delhi
Indian Institute of Technology Bombay, India

Abstract

Construction progress monitoring requires integrating daily progress reports (DPRs) with baseline schedules for productivity analysis and risk management. Manual integration is unscalable due to heterogeneous formats and inconsistent terminologies. This paper presents a neuro-symbolic system that enriches schedules from the DPR files utilizing the large language models and knowledge graphs. The system learns construction terminology from schedule and DPRs, adapts confidence weighting, and validates outputs against project constraints. Tested on a real construction project with 173 DPRs and 1000 validation activities, it achieved a median confidence of 0.825 and zero constraint violations.

Introduction

Construction schedules are central to project planning, monitoring, and control (Project Management Institute, 2021), yet they are rarely updated using the execution data collected during the construction (Olawale & Sun, 2015). Intermittent and partial schedules are used in the routine project communications, losing the golden thread of workflow information across multiple digital documents (Adekunle et al., 2022). Daily progress reports (DPRs) capture detailed fieldwork plans, completed and delayed activities, and exact quantities, resources, and locations. But they typically remain disconnected from the baseline schedules.

Automating the integration of DPRs with schedules, referred to as schedule enrichment in this work, remains a challenge due to heterogeneity arising from document origins. DPRs are semi-structured documents, and the terminology used varies significantly across projects, contractors, and engineers. In contrast, schedules are more formal, structured, and governed by strict temporal and precedence constraints. Field implementations may sometimes relax the strictness, but the precedence information remains logical. Bridging these two information sources requires both semantic flexibility and logical consistency.

Existing automated approaches address part of the problem. Language models can recognize semantic similarity between activity descriptions, but cannot reliably enforce temporal or causal constraints. Rule-based systems provide logical rigor but fail when faced with vocabulary variations and incomplete ontologies. Sequential combinations of these approaches remain brittle, as validation occurs after matching decisions are made.

This paper proposes a neuro-symbolic approach that integrates neural semantic reasoning with symbolic constraint validation during inference. The system learns construction vocabulary automatically from successful alignments and adaptively balances neural and symbolic contributions as knowledge accumulates. The approach is validated on real project data and demonstrates that bi-directional neuro-symbolic integration enables scalable, interpretable, and constraint-aware schedule enrichment.

Related Work

Project monitoring and automated schedule updating are actively researched topics in the construction automation domain (Turkan et al., 2012). Existing approaches rely heavily on building information modeling (BIM) with visual data analytics (Golparvar-Fard et al., 2015) or point clouds (Park & Cho, 2022). While model-based approaches are effective in geometric progress tracking, they are less suited for capturing workflow semantics and also face adoption challenges (Saka & Chan, 2020).

These limitations motivate a shift towards knowledge-based approaches that operate directly on documents. Natural language processing (NLP)- based approaches were explored for extracting activity information from schedules (Zhao et al., 2020) and for bridging schedule activities to the Uniformat (Jung et al., 2024) standard, thereby standardizing the ontology.

Transformer-based approaches were found to be valuable for aligning schedules with field reports and for generating look-ahead planning (Amer et al., 2021, 2023). Large Language Models (LLMs) have demonstrated strong performance in understanding domain-specific vocabulary with minimal task-specific engineering. From generating schedules autonomously (Al-Sinan et al., 2024) to identifying constraints from field meeting transcripts (He et al., 2024). Although LLMs have shown generative capabilities in semantics, the ontology is the primary driver of the logic and validation, which LLMs do not explicitly model.

In contrast, graph-based methods (C. Wu et al., 2023) provide a structured mechanism for enriching existing knowledge, either from schedules or from constraints. Domain-specific knowledge graphs are graph-based

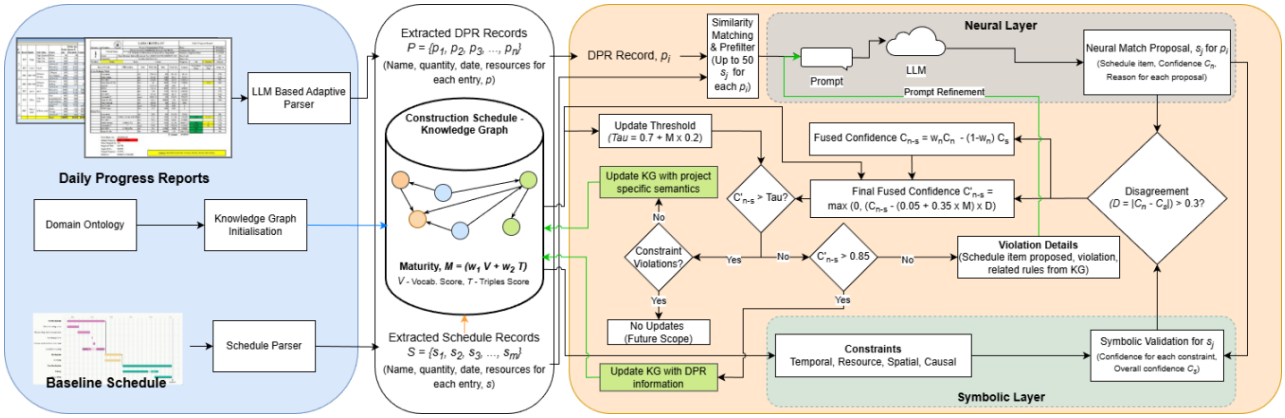

Figure 1 Overall System Architecture

approaches that simultaneously store the project information and allow for constraint application mapping very easily with a construction schedule (S. Wu et al., 2024).

Further, LLMs are shown to work well with knowledge graphs (KG) (Cai et al., 2025), even within the domain of construction automation (Li et al., 2024). However, most current efforts remain unidirectional flows that allow a neural system to extract data for a symbolic system to process, limiting the system's ability to incrementally gather knowledge from daily changes in the field.

Neuro-symbolic AI offers a more robust approach. Recent work in neuro-symbolic AI has proposed multiple integration strategies ranging from loose coupling to tightly embedded symbolic reasoning (Kautz, 2022). The current methods of NLP lack the logical rigor needed for understanding schedules and field documentation without engineering. Language model approaches demonstrate strong semantic understanding of unstructured information but lack mechanisms to enforce constraints required for schedule correctness. Rule-based and ontology-driven approaches enable constraint checking and logical consistency but depend on manually curated vocabularies and struggle with heterogeneous, informal field terminologies.

Thus, the specific research gap lies in the absence of a Type 6 (Neuro[Symbolic]) framework that embeds symbolic reasoning as a subroutine within a neural process loop. Existing research does not address automated vocabulary learning or adaptive integration, in which the system transitions the governance as domain knowledge evolves. As a result, there is currently no method that enables scalable, constraint-aware alignment of DPRs with schedules while continuously learning project-specific terminology.

Methodology

To address the identified research gap, this paper proposes a neuro-symbolic methodology for automated construction schedule enrichment from daily progress reports. The method integrates neural semantic reasoning with symbolic constraint validation in a unified inference process, enabling robust alignment between DPR data and schedule data.

System Architecture

The proposed methodology, structured and presented in Figure 1, is designed as a Bi-directional Neuro[Symbolic] (Type 6) (Kautz, 2022) architecture. This approach balances the semantic capabilities of LLMs and the validation capabilities of KGs in an iterative loop. The overall architecture has three interacting layers:

1. Data preparation layer responsible for parsing DPR files, scheduling data, and initializing the knowledge graph.
2. The Knowledge graph layer, which gets enriched through the processes, can be used to enrich the schedule after processing DPR.
3. Neuro-Symbolic matching layer responsible for candidate DPR-schedule alignment proposal, validation, and refinement.

Problem formulation

Let

$P = \{p_1, p_2, p_3, \dots, p_n\}$ denote the set of extracted DPR records,

$S = \{s, s_2, s_3, \dots, s_m\}$ denote the set of baseline schedule tasks, and

Each DPR activity p_i is associated with observed attributes, including execution date, quantity, location, and resource usage. Each scheduled task s_j is associated with planned attributes, including time windows, locations, quantities, and precedence relationships.

The objective is to determine a mapping function.

$$F : P \rightarrow S$$

that aligns the DPR activities with corresponding schedule tasks while maintaining logical consistency and enabling schedule enrichment. Constraint information used during alignment is derived from schedule-defined constraints and from observed constraints inferred from DPR execution data. The system validates proposed vocabulary and alignments against available constraints and incrementally augments the knowledge graph with newly observed data when sufficient evidence is present. These learned mappings are subsequently used to refine future alignments and to enrich the baseline schedule without manual ontology engineering.

Data Preparation Layer

Daily Progress Report Parsing

In this work, we utilised DPR files generated at the project level by the contractor's planning office and submitted to the cost consultant. All reports originate from a single organizational source and use a common spreadsheet template, reducing the heterogeneity of file type choices and broader design choices. However, different engineers introduced varying column ordering, multiple data regions per sheet, mixed data types, merged cells and colours, comments along with the data, and hidden row data, apart from progress details. In case DPRs originate from multiple sources with different formats, the same parsing pipeline described below can be applied to each source.

We followed a semi-automated approach for parser scripting. The first 3-5 DPR files are sampled for inspection to read raw cell values. Known patterns of the document structure that can be ignored are coded to allow focusing on the header, data presence, and hierarchy markers from merged cells. The extracted details are used to construct a detailed prompt for Large Language Models (LLMs) to generate code for targeted data parsing.

The LLM-generated script is run on all the DPR files for data parsing and extraction. Each parsed record is checked for activity name, quantity, date, and location hierarchy, and missing data is used to calculate a quality score for the LLM-generated script. The quality score is used to generate new code versions for improved data extraction, with details of the previous run's errors and additional directions added to the prompt.

Schedule Loading and Knowledge Graph Initialisation

The baseline schedule is parsed for task definitions, structure, temporal constraints, quantities, and relationships. Simple natural language processing steps, such as case correction, punctuation removal, and lemmatization, are applied to the extracted textual data. The scheduled tasks and their relationships are represented as entities and relations within the knowledge graph.

The knowledge graph is initialised as a formal RDF graph. Base ontology is created with domain-specific semantics comprising 16 common activity types (excavation, PCC, etc.), 12 logic-based precedence constraints (reinforcement before shuttering, etc.), and 4 base synonyms (shuttering synonym of formwork, etc.), forming around 80 triples.

For each schedule task, the graph instantiates a unique entity, mapping it to its corresponding activity type and its temporal predecessors as graph edges. One project-specific problem was that the baseline schedule is activity-based but not delineated by location, whereas DPRs present activity and location hierarchy. At the initial schedule ingestion phase, enforcing location is not useful, and so the location constraint is kept for semantic hinting to LLMs and only soft matching in the KG.

Since we do not have the project-specific knowledge at the start, the knowledge graph is set up with a maturity score to guide the transition from purely neural to neuro-symbolic. This setup allowed us to achieve better semantic performance without encountering cold-start issues. The equations below represent the maturity formula built for the purpose.

$$Maturity\ Score, M = w_1 * V + w_2 * T \quad (1)$$

$$Vocabulary\ Score, V = min\left(1.0, \frac{v_l}{v_T}\right) \quad (2)$$

$$Triples\ Score, T = min\left(1.0, \frac{t_l}{t_T}\right) \quad (3)$$

Where,

v_l = Learned mappings beyond the baseline KG initialisation (0 mappings),

v_T = Threshold mappings (200 mappings) – considered to be fully mature,

t_l = Learned triples beyond the baseline KG initialization (86 triples),

t_T = Threshold triples (10,000 triples),

w_1, w_2 = Weightage for vocabulary score and triples score. (0.7, 0.3 respectively)

The weights are empirically determined, specific to the project, based on the available data. The thresholds are considered based on domain knowledge. Roughly 200 unique activities and 10,000 triples can be considered for the construction activities.

The KG is considered immature when its score is less than 0.1, and most subsequent layers tend to use the neural system in such cases. As the KG becomes more enriched, its maturity increases, and the dependency on the symbolic component also increases.

Neuro-Symbolic Layer

This process follows each DPR activity in a multi-step alignment process.

Neural Proposal Stage

The activity description of each task pi, a list of leaf tasks (non-summary tasks), and a prompt to select the best matching task based on semantic, spatial context, and hierarchy are sent to an LLM.

One specific detail of the task list is the workflow based on the KG's maturity. If the KG is immature, the top 50 schedule tasks are utilised. If the KG is mature, then a symbolic pre-filtering stage is applied. The filters include activity type match, keyword overlap, and trade separation, which are used to filter the tasks. The schedule data lacked separation of MEP concerns, whereas the DPR provides detailed separation. So, immature KG will not know the correct MEP trade for pre-filtering by activity type, and so this part is explicitly added. If filtering is successful, the top 50 tasks are considered for similarity matching.

The LLM returns a scheduled task that matches the prompt, along with its confidence and reasoning. The confidence value is the neural system confidence (C_{neural}), ranging from 0 to 1.

Symbolic Validation Stage

The proposed schedule element is validated against four constraints in the KG.

1. Temporal constraint: The DPR task must fall within a temporal window with ±7 days over the scheduled start and end dates of the task. Additional validation regarding the completion of the prerequisite tasks before the activity's date
2. Resource constraint: The DPR task achieved cumulative quantity must fall within a 30% range of the scheduled task
3. Spatial constraint: The DPR task overlaps with activity locations in the KG
4. Causal constraint: The DPR task preceding activities must be completed. Check if earlier matched DPR activity exists.

All violations are treated as soft violations, as weather issues, resource constraints, scope changes, and other factors can occur during field execution. We assigned empirical confidence penalties (0.9 when valid, 0.3-0.4 when invalid), calibrated on a held-out subset of 50 DPR records.

To assess sensitivity, the penalties were uniformly varied by 20%. The median fused confidence ranged from 0.61 (for -20%) to 0.78 (+20%). A span of 0.17 points. The high-confidence alignment rate varied from 1.5% to 11.0%. This moderate variation suggested that exact penalty calibration is not a critical operation, and the system remains stable under reasonable parameter changes. The mean aggregated confidence across all four constraint dimensions is considered the symbolic system confidence ($C_{symbolic}$), ranging between 0 and 1.

Disagreement Resolution

The absolute difference between the neural and symbolic system confidence is considered Disagreement (D) if it exceeds 0.3. If there is a disagreement, a fused confidence score is calculated for processing.

$$D = \left|C_{neural} - C_{symbolic}\right| \quad (4)$$

$$C_{n-s} = w_{neural} * C_{neural} + (1 - w_{neural}) * C_{symbolic} \quad (5)$$

$$w_{neural} = 0.85 - (\mathrm{M} * 0.35) \quad (6)$$

Where,

D is the disagreement between neural and symbolic components,

C_{n-s} is the Fused Confidence Score of the system,

w_{neural} is the weight for the neural component, derived from the Maturity Score, M, described in (1)

C_{neural} & $C_{symbolic}$ are the neural and symbolic confidence values

The KG maturity score is inversely correlated with the symbolic system confidence. Thus, when KG is immature, the neural system is preferred for fused confidence. If the KG is mature, and there is a disagreement between the two components, the fused score is calculated with a penalty term based on the KG maturity score.

In practical terms, an immature KG keeps the workflow neural-heavy, the candidate selection remains broad, and the fused confidence is driven more by the LLM. As the KG matures, the workflow shifts towards symbolic governance through pre-filtering and stronger constraint weighting, typically producing lower but more reliable confidence scores.

$$Penalty_strength, p = 0.05 + (M * 0.15) \quad (7)$$

$$Penalty, P = Penalty_strength, p * Disagreement, D \quad (8)$$

$$C'_{n-s} = \max(0.0, (C_{n-s} - P)) \quad (9)$$

Where,

p is the penalty strength calculated over the Maturity Score S described in (1),

P is the penalty value, and

C'_{n-s} is the Final Fused Confidence Score.

The final fused confidence score is the decisive variable for the iterative refinement step.

Iterative refinement

If the fused confidence exceeds 0.85, the DPR is aligned with the schedule activity and updates the KG.

A variable threshold, τ, as detailed in (10), is used to determine whether to map the vocabulary and enrich the KG.

$$\tau = 0.7 + M * 0.2 \quad (10)$$

Where,

τ is the variable threshold calculated from the Maturity Score M mentioned in (1).

The final fused confidence score (C'_{n-s}) is compared against the threshold τ. If the confidence exceeds the threshold and there are no constraint violations, the DPR element is utilised for vocabulary mapping and for the DPR entry as a record of the progress of the actual schedule. Even if the confidence is below the threshold but greater than 0.85, the DPR entry is still recorded as a progress entry, but no vocabulary mapping will be made. If there are violations, but the confidence score is high, the constraints can be updated. But this step will require a detailed study of which constraints can be safely updated and which should be left for future work.

Both the above steps of threshold verification and updating the KG form the core of forming a $Neural -> Symbolic$ learning system. For the DPR activity p_i and the proposed schedule activity s_i, the fused confidence scores, with breakdowns, constraint violations, and other relevant details, are collected and sent back to the LLM for the next alignment suggestion, forming a $Symbolic -> Neural$ constraint enforcement system. To prevent the system from entering an infinite loop, iterative refinement stops after 3 rounds.

Experimental design

System Design Validation

To validate the model, the pipeline is run on the schedule and applied to 1000 activities from the DPRs. Six validation tests were conducted on the research claims. In

addition, 105 DPR-schedule alignments (from the ground truth dataset, stratified across all three buildings) were manually verified by a domain expert. Metrics like precision and F1 score were computed at four evaluation levels: Strict task-UID match, building-aware match for correct activity type and building, activity type-only match, and coverage, where any match is produced when one is expected.

1. Neuro-Symbolic Integration – Integration logs were used to count events by direction between neural and symbolic systems, and measured the refinement success rates by comparing confidence scores. Considered a pass if we observe > 100 events with > 70% refinement success.
2. Bidirectional Learning – Alignment confidence scores were split into early (first 50%) and late (last 50%) groups, and the mean confidence change was calculated; improvement at the late stage was considered a pass if it exceeded 1%. Also, the vocabulary counts are fit to linear regression to detect trends.
3. Knowledge Accumulation – KG statistics before and after pipeline execution were measured as the growth factor in triples relative to the initial stage. If the growth factor is > 10 and the vocabulary mappings increase by> 50, then it is considered a pass. If the growth factor increases by 50, it is regarded as strong evidence
4. Entity Resolution Effectiveness – Entity counts before and after deduplication are compared. If the ratio is more than 50%, it is considered a pass, and it is considered strong if the ratio > 70%.
5. Symbolic Inference Performance – Triples discovered by the reasoning system and logical conflicts found are measured. The validation passed if inferred triples are >1000, and conflicts < 5%.

Baseline and Ablation Studies

For baseline studies, we implemented the same three approaches from scratch and executed them on the sample.

1. Pure Neural (LLM) – Direct LLM matching without KG validation or iterative refinement. We performed 10 LLM calls, each aligning one DPR activity to the full schedule. A smaller random sample of DPR activities is chosen to isolate and assess the LLM behaviour for relative trends rather than a full-scale evaluation.
2. Pure Symbolic (Rules) – String matching (and Jaccard similarity of keyword overlap executed on all 100 activity samples.
3. Traditional NLP (TF-IDF) –Vectorization and cosine similarity matching-based approach on all 1000 activities.

For ablations, we adopted an analytical approach. Each component's contribution is used to compute the degraded confidence if it were absent.

Learning Trajectory Verification

To verify the learning trajectory, we rerun the pipeline on the dataset 10 times, with a sample size of 10 in each run. In each iteration, the activity batch is randomized. The KG maturity, average confidence, and vocabulary learned are extracted at each iteration, and the final KG serves as the starting point for the next. We computed the maturity growth between the final and first iteration, and the confidence improvement ratio. Successful learning must show at least a 1% increase in confidence and a monotonically increasing level of maturity.

Results

System Design Validation

Table 1. System Design Validation Results

Test	Evidence	Metrics
Neuro-Symbolic Integration	Moderate	775 integration events, 100% refinement
Bi-directional Learning	Weak (single pass)	-7.7% confidence change (0.838 to 0.774); 0 vocabulary at pre-populated KG; 375 vocabulary mappings acquired during processing
Knowledge Accumulation	Strong	KG grew from 86 ontology triples to 39,620 (456x); alignment-driven growth: +4660 triples from 34,600 post-schedule baselines
Entity resolution	Strong	1139 activity variants reduced to 134 canonical entities (88% compression); 760 resolution events across exact (58%), LLM (34%), and similarity (3%) methods
Symbolic inference	Strong	28,975 triples inferred; 0 logical conflicts detected

On the manually verified subset, the precision and F1 scores for activity-type match are 0.930 and 0.815; for building-aware match, 0.338 and 0.400; for Strict task-UID matches, 0.141 and 0.189; and for coverage matches, 1.000 and 0.850. Across all 1000 alignments, 769 were matched, yielding a 76.9% match rate. Most strict-UID errors were not semantic failures. 56 of 61 wrong matches still identified the correct activity type, with errors dominated by cross-building confusions (42) and granularity mismatches (14). These results indicate strong semantic recognition, with the remaining difficulty concentrated in spatial disambiguation.

The bidirectional learning row in Table 1 reflects an early vocabulary saturation. The confidence decrease reflects the KG maturity (Eq. 6), penalizing matches that lack full constraint support. Thus, the negative confidence change reflects a calibration effect rather than evidence against bidirectional learning. The broader evidence for

bidirectional learning comes from the same run's 375 vocabulary mappings acquired during DPR processing.

Details of the symbolic inference validation suggest that the symbolic reasoning primarily generated triples of transitive closure over the precedence relationship (about 73.8% of the total KG content), suggesting that implicit knowledge discovery amplifies explicit data. However, the absence of conflicts indicates the need to reexamine the precedence graph derived from the validated schedule. Further verification is needed using synthetic, contradictory data.

Baseline & Ablation Comparison

The baseline comparison across approaches is presented in Figure 2. The median confidence is higher than the mean, indicating a bimodal distribution with many high-quality matches. The pure LLM approach performs comparably but has lower mean and median values than the proposed approach. Higher confidence (10% compared to 4.3% of ours) in the LLM approach might suggest the lack of constraint validation, which is derived from the symbolic component in our system. The purely symbolic approach, understandably, fails to handle vocabulary variation. Still, the traditional NLP implementation treats pairs as minimal datasets to measure similarity and cannot be applied directly. However, this doesn't affect the overall implementation and results.

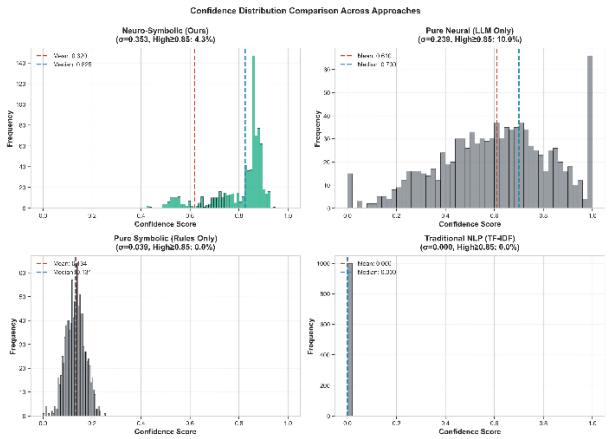

Figure 2 Baseline Comparison Results

The ablation study results are presented in Figure 3. The top contributors are KG validation, vocabulary learning, and iterative refinement, which together account for nearly 70% of the system's performance. All three are mechanisms of the neuro-symbolic system, confirming the system's synergy. Of the 769 alignments requiring refinement, KG validation successfully identified inconsistencies and is the most valuable component.

Qualitative Analysis

Representative examples from the evaluation illustrate the system's practical behaviour. A DPR entry reporting "Waterproofing" activity for Building C (Terrace Floor, Super-Structure section) was matched to the schedule task "Terrace Floor water proofing", with a fused confidence of 0.949 (neural 0.95, symbolic 0.947), indicating semantic agreement, temporal validity, spatial consistency, and precedence satisfaction. In a contrasting case, the DPR entry "Sunk Area Filling" (for building B) was matched to "PCC" with a fused confidence of 0.758 (neural 0.90, symbolic 0.0), resulting in a disagreement and flagging for expert review. 188 such cases were identified of the 1000 processed alignments, demonstrating the system's ability to surface uncertain matches rather than silently accepting them. The KG also learned 375 vocabulary mappings, including synonyms such as shuttering for formwork, typographical errors like conctere for concrete, and field-specific terms like UGWT Raft, mapped to the canonical Underground Water Tank activity type, which persisted in the KG without requiring further LLM calls.

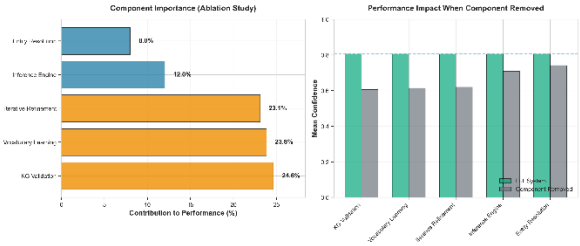

Figure 3 Ablation Study Results

Learning Trajectory Verification

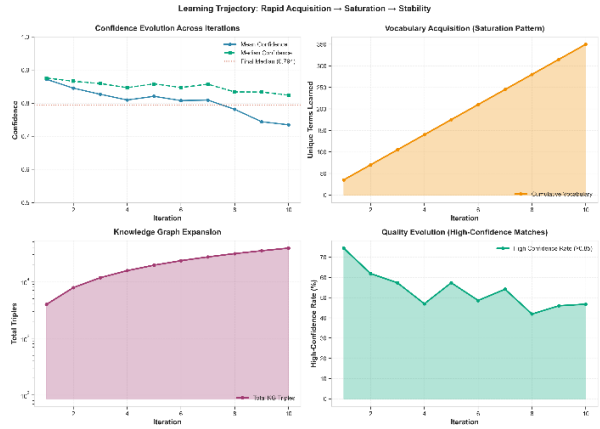

Figure 4 Learning Trajectory Verification

The learning trajectory results over 10 iterations are presented in Figure 4. Overall, the KG maturity shows a +68% increase, with 7 terms and 44 KG triples learned. The confidence decreases by 1.7%, with intermittent dips, possibly due to adaptation to edge cases. The initial iterations also show high values, suggesting that the initial sending with the schedule and the first iteration itself rapidly accumulates valuable project-specific knowledge.

Figure 5 shows that most KG growth comes from schedule-derived structural scaffolding, while DPR alignment provides a smaller but semantically important set of learned mappings and observations.

Discussion

The results demonstrate that the proposed neuro-symbolic system can appropriately align daily progress reports with baseline schedules and regulate confidence in logically

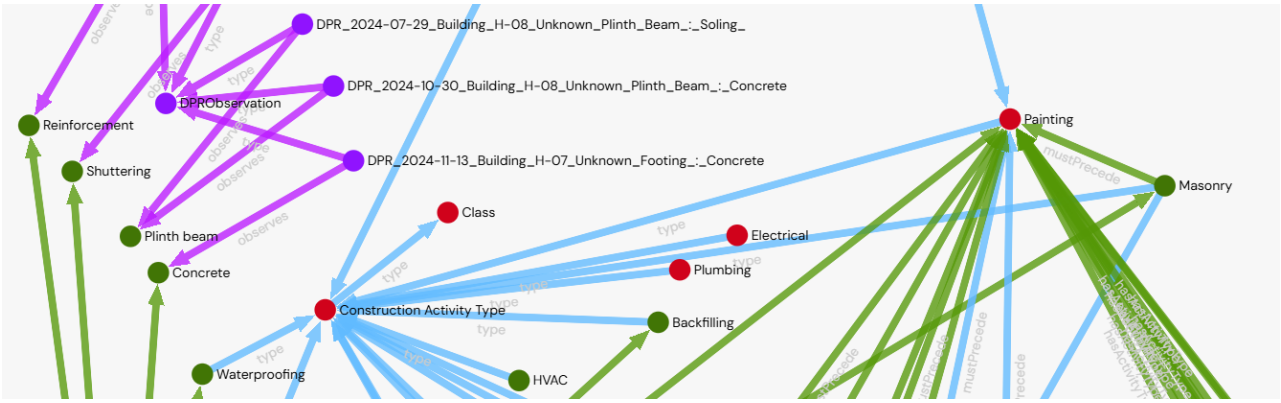

Figure 5 Knowledge Graph Evolution Across Pipeline Stages. Baseline nodes and edges are in red; schedule parsing-based nodes and edges are in green, DPR parsing-based nodes and edges are in violet.

invalid matches. This result is reflected in consistently higher median confidence values and the absence of constraint violations, even when operating on the DPR files. Of the 1000 activities, 769 alignment matches passed all constraint validation, and the remaining 231 activities were left unmatched, achieving zero logical conflicts in the inferred knowledge graph. Relative to the LLM baseline, the main gain is better confidence calibration rather than higher peak scores.

A key observation from the experiments is that system performance is driven by the ability to calibrate confidence. The LLM baseline occasionally produced higher peak confidence values, but these were not supported by symbolic validation. In contrast, the proposed approach is more robust, limiting the extreme confidence, since incorrect high-confidence updates can distort the KG for downstream applications.

The presence of 775 recorded interaction events with successful refinements suggests that embedding symbolic reasoning within the inference loop enables systematic reconciliation rather than post-hoc filtering. This behavior directly supports the effectiveness of a Type 6 neuro-symbolic integration as discussed earlier. The ablation study further reinforces this observation, showing that knowledge graph validation, vocabulary learning, and iterative refinement mechanisms account for nearly 70% of the system's performance contribution.

Error analysis shows that most strict UID failures were cross building or granularity confusions rather than semantic misunderstandings, indicating that the main remaining limitation is spatial disambiguation. Knowledge accumulation was substantial with KG growth dominated by precedence closure and 375 vocabulary mappings acquired during DPR processing. Validation on a single project remains a limitation, although the dataset spans 173 DPR files (i.e., 173 days of data) and 1000 activities, and the initial ontology is domain-general. The current validation does not stress-test contradictory schedules, leaving multi-project and synthetic conflict evaluation as future research directions. Overall, the findings indicate that the value of the proposed approach lies not in outperforming the neural baselines on isolated similarity metrics but in delivering a scalable, interpretable, and constraint-aware mechanism for schedule enrichment under realistic field conditions.

Conclusion and Future Work

This paper presented a bi-directional neuro-symbolic framework for automated construction schedule enrichment using daily progress reports. By embedding symbolic constraint reasoning within a large language model-driven inference loop, the proposed system enables semantically flexible, logically governed alignment between heterogeneous field documentation and formal schedules. Validation on a real construction project demonstrated that the framework achieves robust alignment performance, characterized by high median confidence, zero accepted constraint violations, and substantial growth of project-specific knowledge without manual ontology engineering.

Comparative baseline and ablation studies confirmed that the system's effectiveness arises from neuro-symbolic synergy rather than isolated neural or rule-based components. Symbolic validation and iterative refinement were shown to actively govern inference, preventing logically invalid schedule updates while allowing the language model to adapt to informal terminology and evolving field context. The learning trajectory analysis further indicated that the system transitions from rapid vocabulary acquisition to stable, conservative alignment behavior as domain knowledge matures, a desirable property for operational deployment.

Several directions for future work naturally follow from this study. First, while the current validation focused on a single project, extending the framework to multi-project datasets would enable systematic evaluation of generalizability across different schedule structures and documentation practices. Second, stress-testing the system with synthetic or adversarial contradictions, such as intentionally inconsistent precedence or delayed prerequisite activities, would provide deeper insight into its conflict-detection and resolution capabilities. Third, the current symbolic constraints rely on empirically defined thresholds. Adaptive or data-driven thresholds could further improve the robustness under varying data quality conditions. Finally, tighter integration with BIM may enable more explicit reasoning about spatial

dependencies, thereby enhancing the system's ability to interpret fine-grained execution workflows.

Overall, the results suggest that the neuro-symbolic integration offers a promising and practical pathway towards scalable, interpretable, and optionally safe automation of construction schedule management. By balancing semantic adaptability with explicit domain constraints, the proposed framework establishes a foundation for future research on intelligent, learning-driven planning systems in construction.

Acknowledgements

The authors would like to thank Mr. Divyansh Gupta for his extensive support in data collection and coordination with the project field team. The authors also gratefully acknowledge the Indian Institute of Technology Bombay for facilitating access to project data and supporting this research.

Abstract

The complexity of building codes and variations in Building Information Modelling (BIM) practices have long challenged Automated Compliance Checking (ACC). The success of Large Language Models (LLMs) in code generation opens new opportunities for this domain. Unlike previous work relying on machine-readable rules or LLMs using hard-coded tools that limit scalability, this paper examines whether LLMs, using the Code-Act pattern, can generate scalable compliance logic for regulations up to Solihin and Eastman's complexity class 3. We show that iterative refinement with a strong verifier evolves reusable checking functions for consistently modelled BIM data, while geometric reasoning requiring auxiliary constructions remains challenging.[1]

Introduction

The digitalization of building permit processes promises faster, more consistent reviews of construction projects. Accelerating these processes is particularly relevant given the pressing demand for housing in many regions, where lengthy approval cycles contribute to construction delays, and increased costs and uncertainty (Bloch and Fauth, 2023). At the center of this effort lies ACC, which refers to the automatic verification of building designs against applicable codes and standards. If realized effectively, ACC offers a dual benefit: architects can pre-check their building models prior to submission, leading to higher-quality designs, while authorities can review submissions faster and more thoroughly.

Eastman et al. (2009) proposed a widely adopted four-step process for automated rule-based checking: (1) rule interpretation, which involves translating regulatory text into a machine-readable format; (2) building model preparation, including semantic enrichment to make information that is implicitly present in the model explicitly available; (3) rule execution, encompassing spatial checks, simple property checks, and more complex calculations; and (4) reporting of compliance results.

The ACC process has seen substantial evolution over time. For example, for rule interpretation, early approaches relied on hard-coded implementations, resulting in opaque black-box systems that were difficult to modify or extend (Solihin, 2004). Subsequent work shifted toward machine-readable intermediate representations, such as the RASE (Requirement, Applicability, Selection, and Exception) semantic markup methodology (Hjelseth and Nisbet, 2011). Such representations offer greater transparency but prove difficult to author and often fail to capture the full complexity of regulatory language. Natural language processing (NLP) techniques were applied to assist this translation, initially, through rule-based methods that required considerable manual effort and were difficult to scale (Zhang and El-Gohary, 2017). Machine learning and deep learning approaches improved scalability across different types of regulatory texts but introduced a dependency on high-quality, labeled training data (Fuchs et al., 2024). LLMs have further reduced data requirements and enabled human-in-the-loop workflows, for example, to apply RASE markup utilising YAML-based representations (Al-Turki et al., 2024). More recent work has explored feeding regulations directly into LLMs for ACC, bypassing intermediate representations entirely (Iversen and Huang, 2026). However, most LLM agent-based approaches required manually authored tool functions that the LLM can invoke, a process that reintroduces significant manual effort. Allowing LLMs to generate the checking code themselves addresses this limitation, but the resulting functions have generally not been reusable across different building models (Madireddy et al., 2025). Achieving reusability would make these functions independently deployable as transparent, reproducible compliance checks, shareable as plain code across practitioners and tools.

In this paper, we assess whether LLM agents can generate reusable compliance checking functions for building regulations with complexity up to Class 3 in the classification by Solihin and Eastman (2015), which require extended data structures such as geometric helper elements. The LLM agent uses the Code-Act architecture (Wang et al., 2024), where the agent interleave reasoning with code generation and execution. By employing a strong verifier, i.e., ground-truth compliance results for multiple Industry Foundation Classes (IFC) models against which generated functions are iteratively tested, we investigate whether this process enables the development of verifiable, deterministic, and reusable compliance checking functions. Accord-

[1]Source code and data available at: `https://github.com/stefan-1992/ACC-function-generation`

ingly, we address the following research questions (RQs):

- **RQ1:** To what extent can LLM agents generate reusable compliance checking functions that generalize across building models?
- **RQ2:** What difficulties arise when scaling across diverse building models?
- **RQ3:** Up to what regulation complexity class can LLM agents reliably generate checking functions?

These questions are investigated through a systematic training and evaluation framework applied to 16 compliance rules across 12 building models. The generated functions are evaluated for correctness and generalization, with a detailed analysis of failure modes and the impact of regulation complexity.

Related work

The challenge of translating building regulations into executable checks has been addressed through two contrasting paradigms. Deterministic, machine-readable representations offer transparency and reproducibility but require substantial manual authoring effort and struggle to capture the full complexity of regulatory language. For example, Solibri, one of the most used commercial tools, provides significant functionality for general model checking and compliance checking. Existing rule templates can be parametrised, but checks beyond the available templates require custom Java development through Solibri's API. The inner workings of built-in rules remain a black box, and the proprietary format makes keeping rules up-to-date with regulatory amendments difficult (Solibri Inc., 2026). Moreover, many regulations cannot easily be transformed into parameterised rule templates or other machine-executable formats, particularly when they involve complex spatial relationships or context-dependent conditions (Hjelseth and Nisbet, 2011). Information availability poses an additional challenge: approaches such as Singapore's IFC-SG standard (Government of Singapore, 2026) specify precise information requirements, validated through Information Delivery Specifications (IDS), but this shifts the burden onto the modeller. Semantic enrichment can partially alleviate this burden by automatically deriving missing information from the model (Bloch, 2022), yet it remains an open research problem. LLM-based approaches offer a more dynamic alternative that can work directly with natural language regulations and heterogeneous model data, yet they often lack the determinism and reusability needed for production use.

Agent-based approaches to automated compliance checking

Several recent studies have explored LLM-based agents for ACC. Ying and Sacks (2024) proposed a framework with different LLM techniques, such as Retrieval-Augmented Generation (RAG), ReAct (reasoning–action) agents, and tool usage, which cover the full ACC pipeline: retrieving relevant regulations from PDF documents, executing compliance checks through switching between reasoning and action phases with predefined tool functions, and resolving non-compliance issues. While this approach demonstrates the feasibility of end-to-end agent-based checking, it relied on manually authored tool functions, and the compliance checking was only tested on one building requirement.

Zheng et al. (2026) and Iversen and Huang (2026) showed that LLMs can identify which predefined functions to orchestrate for a given rule check, but in Iversen and Huang (2026) only a limited number of functions were actually implemented, restricting the approach's practical applicability. While Zheng et al. (2026) used LLMs for function implementation in a case study, they did not systematically evaluate the LLMs' capability for this task. Shi et al. (2025) explored fine-tuning LLMs specifically for automated code compliance, indicating that domain adaptation can improve checking accuracy. However, they did not generate fully executable functions but high-level function calls, which removes the LLM's ability to receive feedback from the rule execution and adjust the generated functions accordingly. Madireddy et al. (2025) advanced the concept by having LLMs generate Python scripts for compliance checking; however, the scripts required manual transfer to Revit and human-in-the-loop verification, limiting automation. Furthermore, several rule-specific hints were required, implying extensive manual analysis.

BIM question answering as a foundation

A related field is BIM question answering, where LLM agents generate code to extract information from building models. Zheng and Fischer (2023) introduced BIMS-GPT, a virtual assistant that dynamically generates queries against BIM data. However, this approach is limited to information directly available in the BIM database. Hellin et al. (2025) developed a multi-agent system for natural language-based BIM question answering. The agents can invoke multiple IfcOpenShell-based tools to explore the BIM model until it has enough information gathered to answer the question. Nithyanantham et al. (2025) proposed MCP4IFC (Model Context Protocol), providing tools to query, edit, and create IFC elements, including dynamic code generation when the existing toolkit is insufficient. Li et al. (2025) demonstrated an LLM agent capable of retrieving data from multiple sources and generating code for spatial queries on building models. These systems address similar technical challenges to ACC, i.e., interpreting domain-specific queries and invoking functions or generating executable code, but typically evaluate results on individual models, where the logic can be adapted to the model at hand. Furthermore, the geometric complexity of such queries is typically lower than in ACC.

Our work extends tool generation to compliance checking functions that must generalize across multiple building models, necessitating a more scalable evaluation framework. Crucially, LLMs are used only during function generation, not at inference time: the resulting checking functions are deterministic, reusable, and execute without LLM

involvement, combining the authoring flexibility of LLMs with the auditability of conventional rule logic.

Methodology

We adopt a machine learning-inspired training strategy in which LLM agents iteratively write, refine, and validate compliance checking functions operating on BIM models in IFC format (Figure 1), which are then tested on unseen models. This strategy is inspired by the evolutionary code optimization strategy of AlphaEvolve (Novikov et al., 2025), where a strong verifier guides iterative improvement. At the center of the approach lies the function creation, which draws on the Code-Act pattern to iteratively generate and refine checking functions.

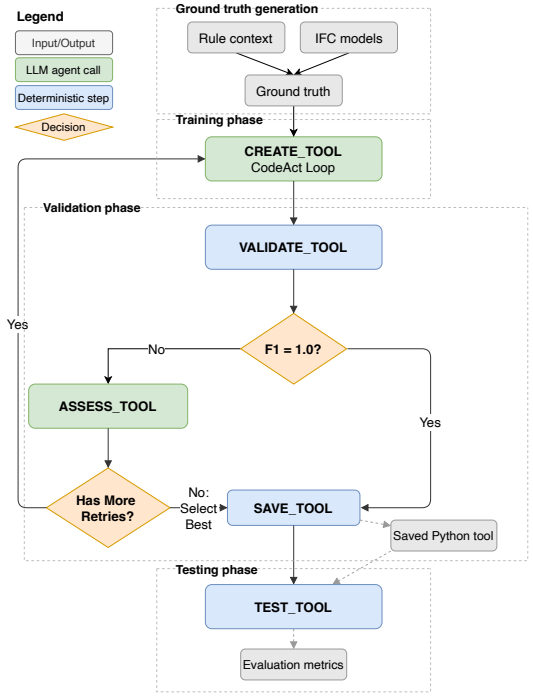

Figure 1: Overview of the agent pipeline for generating compliance checking functions.

Ground truth generation

While in AlphaEvolve, a test function was used to evaluate the generated code, our framework relies on ground-truth compliance results for each building model. These can be produced manually, through coded reference implementations, or using existing rule-checking tools, as long as each element receives a definitive pass or fail label.

The dataset should comprise at least three building models to support separate training, validation, and test splits, with violations present across most or all models, and a mix of compliant and non-compliant elements. Having more BIM models with rule violations increases generalisability of the generated functions, as the agent must handle diverse geometric and semantic configurations rather than overfitting to a single case. We use the Globally Unique Identifier (GUID) to identify and compare violating building elements, producing a deterministic binary signal per element that remains stable throughout the experiment.

Training phase

The training phase begins by selecting a *primary* training BIM model, selected as the model containing the highest number of non-compliant issues, to provide the most informative training model as context for testing the developed functions. The code-generation agent (CREATE_TOOL) then receives the natural-language rule text, including any relevant thresholds and exceptions, along with the expected answers for each training BIM model (Figure 2). It synthesizes a candidate checking function in Python, using `IfcOpenShell` for IFC access and `trimesh`/`shapely` for geometric operations where needed.

Rule: This rule checks that doors and windows in the model are located in the same floor as the wall they are related to. The rule also checks that the model does not contain any orphan doors or windows (a door or window without a relation to any wall).

Parameters: Check Orphan Doors and Windows: True

Question: What doors or windows in the current IFC model are not located in the same floor as the wall they are related to, or are orphan doors/windows without a relation to any wall? Return a list of IFC GUIDs of all elements that violate this rule.

Ground Truth:

`Model: 146` – pass (no violations, return `[]`)

`Model: duplex (primary)` – 2 violations:

Required GUIDs: `[1hOS...lSFK, 1hOS...lSDm]`

Issue 1: *''Door.1.7 And Wall.0.10'': Door components are included in Level 2, but Wall components are included in Level 1. Door components should be included in the same floor as the component they belong to.*

Issue 2: *''Door.1.8 And Wall.0.13'': [...]*

Figure 2: Condensed example of the agent prompt for the ''doors and windows'' rule.

During the code-generation phase, visualised in Figure 3, the agent operates in a CodeAct loop of up to $n_{\text{max_iter}}$ iterations. The agent's task is to iteratively develop a function that identifies the same violations as the ground truth for all training models. At each iteration, it returns either a *CodeAction* or the final *ACC Function*. The *CodeAction* contains reasoning traces and Python code that is executed in a Python sandbox where imports and runtime tools are pre-loaded. Multiple BIM models are used for training to encourage generalization from the outset, ensuring that the function does not overfit to a single building's characteristics. The agent commonly developed strategies to first test functions on only the primary model, before including test cases for all training models. The agent can decide at any point to return the final implementation of the *ACC Function*, which terminates the loop. On the last permitted iteration (i.e., $n_{\text{max_iter}}$), the agent is prompted to return its best implementation. Before proceeding to validation, a pre-check executes the function against all training models to verify the absence of runtime errors; if it crashes, the agent re-enters the loop with the error log appended (up to three consecutive pre-check failures were permitted).

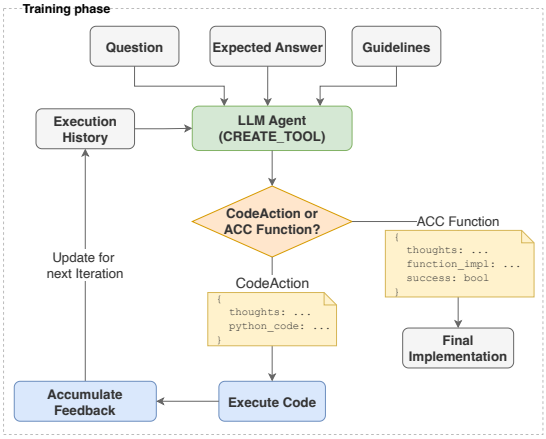

Figure 3: Overview of the code act training loop for generating compliance checking functions.

The agent's prompt specifies a function contract; the generated function must accept a single IFC file path and return a list of non-compliant element GUIDs. Beyond the geometric libraries, the agent has access to `query_ifcopenshell_docs` as runtime tool, which retrieves up-to-date IfcOpenShell documentation and code examples for a given topic.

Validation phase

Once the agent has converged on a function during training, the function is executed against a separate set of validation building models. A dedicated assessment agent interprets the training and validation results. This agent receives the tool's source code, its execution logs, aggregated performance metrics (true-positive, false-positive, and false-negative counts), and a comparison of expected versus predicted element counts. We use an LLM because the diagnosis requires correlating source code logic with per-model error distributions, which involves too many interacting factors for simple heuristic rules. The agent determines the likely cause of failure from five diagnostic categories (overfitting, missing generalisation, implementation bug, model difference, or unknown) and outputs a concrete, GUID-free improvement hint for the code-generation agent. Critically, the assessment agent is prompted not to disclose ground-truth results from the validation set to the code-generation agent; only this high-level diagnostic feedback is provided, discouraging information leakage. Exposing validation GUIDs would allow the code-generation agent to reverse-engineer element-specific properties, or worse, hard-code the GUIDs, undermining generalisation beyond the training distribution.

The assessment result is checked against a retry budget (default: 2 retries). If retries remain and the diagnosis suggests a fixable error, the improvement hint is injected into the next CREATE_TOOL prompt. If the budget is exhausted or the error is deemed negligible, the best-performing implementation is saved. This mechanism bounds computational cost while still allowing targeted refinement.

Testing phase

Functions that pass validation are evaluated on a held-out test set of building models, measuring how well the generated functions transfer to unseen buildings. The separate test set ensures that neither the agent's prompts nor the tooling are optimised against it. We apply this process to 16 compliance rules spanning multiple complexity classes as detailed in the next section.

Experimental setup

We evaluate our approach using 12 building models, divided equally into training, validation, and test models (4 models each), as shown in Table 1. All models are freely available: three originate from the GNI BIM Dataset - 2025_BIMfundamentals (Wang et al., 2026), and the remaining models are sourced from IFCBench (Hellin et al., 2025). The data split ensures that each compliance rule exhibits non-compliant elements in the training set, with test and then validation sets prioritised where possible.

Table 1: Building models used in each data split.

Training	Validation	Test
146*	106*	4351
AC20	172*	Digital Hub
Dental Clinic	FZK House	S. MacAlister
Duplex	Smiley West	WBDG Office

*From GNI BIM Dataset (Wang et al., 2026).

Ground-truth compliance labels are produced using Solibri (Solibri Inc., 2026). We executed predefined rule sets against each IFC model using Solibri's autorun. From the resulting BIM Collaboration Format (BCF) reports, we identified issues with single (or well separable) constraints and defined how to automatically locate them and distinguish the GUIDs that violate the rule from contextual reference elements. Where rules depend on semantic classifications (e.g., space usage types), we applied them through importable Solibri pattern rules. To keep the agent on equal footing with the verifier, we provided it with the `classify_spaces` tool, which assigns semantic labels (e.g., circulation, habitable) to IFC spaces by matching names against the predefined patterns.

Compliance rules

We select 16 compliance rules spanning the complexity classes defined by Solihin and Eastman (2015), summarized in Table 2. These range from simple property checks (Class 1) through rules requiring derived attributes or geometric relationships among multiple objects (Class 2) to rules requiring extended data structures and geometric helper elements (Class 3). In practice, Class 1 and 2 rules may behave as higher-complexity checks when the required properties or relations are absent from the IFC model and must be derived geometrically.

Table 2: Compliance rules grouped by Solihin & Eastman complexity class, with non-compliant element counts across data splits.

Rule	Class	Ruleset	Description	Train	Val	Test
Slab thickness	1	BIM Validation	Slab thickness within 0.30 m–1.0 m range	14	–	3
Riser height	1	ADA/ABA - 504.2	Risers between 100 mm and 180 mm high	5	37	3
Tread length	1	ADA/ABA - 504.2	Treads at least 280 mm deep	2	45	2
Non-uniform risers/treads	2	ADA/ABA - 504.2	Uniform riser heights and tread depths per flight	2	21	–
Stair–slab connection	2	ADA/ABA - 504.2	All stairs connected to slabs	3	–	2
Doors and windows	2	BIM Validation	Doors/windows on same floor as host wall; no orphans	7	8	18
Large spaces ≥ 2 doors	2	Adv. Space Check	Spaces ≥ 50 m^2 have at least 2 doors	22	9	25
Same-storey elevation	2	Gen. Space Check	Spaces in same storey share bottom elevation	180	110	124
Space validation (inside)	2	Gen. Space Check	No components incorrectly inside spaces	17	7	17
Space validation (intersect)	2	Gen. Space Check	Spaces do not intersect with slabs/walls	24	55	22
Circular space	3	ADA/ABA - 304.3.1	Wheelchair turning space ≥ 1525 mm diameter	2	22	2
Clear floor space	3	ADA/ABA - 305.3	Clear floor/ground ≥ 760 × 1220 mm	18	23	1
Two doors in series	3	ADA/ABA - 404.2.5	≥ 1220 mm between hinged/pivoted doors in series	8	–	2
Clearance front of doors	3	BIM Validation	Sufficient clearance on both sides of doors	28	30	11
Slabs guarded against falling	3	BIM Validation	Slab edges protected by barriers or acceptable drop	34	11	8
Unallocated areas	3	BIM Validation	Floor area must be assigned to a space ≤ 0.50 m^2	6	–	23

Evaluation metrics

Evaluation is performed at the building element level using unique element identifiers (i.e., GUIDs). For each model, we compare the set of GUIDs returned by the generated ACC function against the ground-truth set. For violations involving multiple elements, each GUID is counted once. We compute precision, recall, and F1 score per model. The *average* F1 score ($F1_{\text{avg}}$) is the arithmetic mean of the per-model F1 scores (macro-average over models). As a special case, if a model is fully compliant (no non-conforming elements) and the function correctly identifies it as such, this yields Precision, Recall, and F1 score of 1.0. As an alternative, the *aggregated* F1 score ($F1_{\text{agg}}$) is computed by pooling all true-positive, false-positive, and false-negative counts across models before calculating precision, recall, and F1 score (micro-average over models). This provides a more balanced measure, as fully compliant models receive proportionally less weight compared to $F1_{\text{avg}}$. In Table 3, per-class and overall averages are macro-averaged over the rules within each class and over all 16 rules, respectively.

Agent configuration

The agents are powered by GLM-4.7 by Z.ai[2], chosen for its competitive performance on SWE-Bench Verified[3] and favourable performance-to-cost ratio. The function creation agent is permitted up to 15 internal coding iterations per attempt ($n_{\text{max_iter}} = 15$). The validation loop allows up to 2 feedback-driven retries before the best implementation is saved. The agent has access to `IfcOpenShell` for IFC model traversal, and `shapely` and `trimesh` for 2-D and 3-D geometric operations, respectively. The libraries are preloaded and briefly described within the prompt. Documentation retrieval is currently only supported for IfcOpenShell; extending this to cover `trimesh` and `shapely` is left for future work.

Results

Table 3 summarises the per-rule performance across the three data splits. We use the aggregated F1 score ($F1_{\text{agg}}$) as the primary evaluation metric. Overall, the LLM agent shows moderate capability for implementing ACC functions, with $F1_{\text{agg}}$ values of 0.55 on training, 0.54 on validation, and 0.40 on test. The near-identical training and validation scores suggest that the validation feedback loop generalises to the validation models. The subsequent drop on the unseen test set, however, indicates that many generated functions still overfit to assumptions about how geometry, properties, and relationships are represented in the training and validation IFC models. Performance varies by complexity class. Class 1 rules achieved near-perfect validation scores ($F1_{\text{agg}} = 0.96$), yet dropped sharply on the test set (0.38). Class 2 rules achieved the strongest test results ($F1_{\text{agg}} = 0.57$). The strong Class 2 average is driven by three rules that generalised fully to the test set, whereas the weak Class 3 average (0.21) reflects the continued difficulty of rules that require auxiliary geometric constructions or richer rule logic.

Rules that achieved perfect or near-perfect training scores showed varying degrees of degradation on test, from none (*doors and windows*, *same-storey elevation*, and *stair–slab connection*: $1.00 \rightarrow 1.00$) to complete failure (*slab thickness*: $1.00 \rightarrow 0.00$). The validation feedback loop improved some rules: for *tread length*, the validation $F1_{\text{agg}}$ reached 0.89, and the function still achieved 0.67 on test. For more complex rules, however, the feedback loop could not compensate for missing geometric detail, incomplete IFC relationships, or ambiguous rule semantics. The gap between $F1_{\text{avg}}$ and $F1_{\text{agg}}$ on the test set (0.59 vs. 0.40) suggests that performance remains uneven across models, with several rules receiving inflated average scores because some test models are fully compliant.

Table 4 shows the execution metrics for each rule. Total duration ranges from 4.3 minutes (slab thickness) to 56.9 minutes (clear floor space). Token usage spans 116 k

Table 3: Per-rule $F1$ scores across data splits. $F1_{\text{avg}}$: macro-average over models; $F1_{\text{agg}}$, P_{agg}, R_{agg}: micro-average over models (pooled counts). Class and overall rows: macro-average over rules.

† All models were compliant; the scores reflect false-positive control only.

(slab thickness) to 2.4 M (clearance front of doors), with geometry-heavy Class 2 and 3 rules consistently consuming the most time and tokens. *Doors and windows* converged quickly and achieved perfect scores across all three splits, suggesting that the agent performs well when the rule can be expressed through relatively direct relationship checks. By contrast, *clear floor space* (56.9 min), *space validation (intersect)* (45.4 min), and *clearance front of doors* (45.3 min) were among the longest-running rules, reflecting the cost of repeated geometric exploration without strong generalisation.

Discussion

The results indicate that reusable compliance checking functions can be generated when IFC semantics are consistent, but generalisation remains fragile across heterogeneous models. The perfect test performance of *doors and windows*, *same-storey elevation*, and *stair–slab connection* shows the approach is viable when the relevant semantics are explicitly represented and stable across models. The broader decline from training to test suggests that many functions encode assumptions about properties, relationships, or geometry that do not transfer reliably. Manual error analysis of the test set explains this gap. Geometry-based heuristics were the dominant failure mode, affecting seven rules: *clearance front of doors*, *slabs guarded against falling*, *space validation (inside)*, *space validation (intersect)*, *non-uniform risers/treads*, *clear floor space*, and *unallocated areas*. The agent often produced plausible but coarse approximations based on bounding boxes, convex hulls, perimeter sampling, or random point placement. Such heuristics succeed on training models but may fail on unseen IFC geometries, where Solibri uses richer geometric reasoning and internal tolerances.

Relationship traversal is a second major source of error. The clearest examples are *large spaces ≥ 2 doors* and *two doors in series*, where the generated functions rely on `IfcRelSpaceBoundary` to associate spaces, walls, and doors. When these relationships are incomplete or absent, the functions fail to identify the relevant door pairs or counts. Property lookup is similarly brittle: *slab thickness* fails because the relevant property is stored under the German label `Dicke`, while *riser height* is affected by inconsistent property interpretation, for example when `Pset_StairCommon.RiserHeight` reports 0.55 m while the Revit-derived maximum riser height is 0.18 m. These examples show that the core challenge is not only code generation, but also learning robust strategies for handling heterogeneous IFC conventions.

Many of these issues could be reduced by increasing the number and diversity of training and validation models. A larger dataset would expose the agent to more variants of relationship structures, property naming conventions, unit systems, and geometric edge cases, making it less likely to overfit to a single export implementation. Realising that benefit would require longer exploration budgets, since the agent would need more iterations to inspect a broader range of failure cases. At the same time, scaling to a broader model set would require automating Solibri object classification, which is currently provided through manually prepared pattern rules. Without such automation, the approach does not scale cleanly to new models

Table 4: Execution metrics per compliance rule: retry count, coding iterations per attempt, and time/token breakdown.

		Iterations per attempt			Agent (min)		Execution (min)			
Rule	**Retries**	**Att_0**	**Att_1**	**Att_2**	**CREATE**	**ASSESS**	**Tr+Val**	**Test**	**Total (min)**	**Tokens**

Unallocated areas	1	15	15	–	11.6	0.3	2.0	0.5	14.3	1,033,179

because both the ground-truth generation and the agent's auxiliary classification tool depend on handcrafted semantic mappings.

Geometric reasoning poses a barrier that current LLMs cannot overcome reliably. The weak Class 3 scores confirm this. The circular space result demonstrates that geometry per se is not the barrier: because fitting a circle inside a polygon requires no model-specific assumptions, the agent achieved a perfect test score ($F1_{\text{agg}} = 1.00$) despite the check's geometric nature. In contrast, rules that require helper elements such as door swing arcs, clearance zones, or barrier envelopes remain difficult, and the resulting implementations often fall back on heuristics that are too coarse to match Solibri consistently.

Another difficulty is that several Solibri checks combine multiple sub-rules within a single template. We partly addressed this by passing rule parameters to the agent, but their exact operational meaning often remains opaque from the prompt alone. This is visible in *space validation (inside)*, where Solibri flags both, components inside spaces and cases where a space does not properly touch the slab or surface below itself. Access to Solibri rule documentation via RAG could help the agent interpret these composite checks and checking parameters more faithfully and reduce the need to infer hidden sub-rules from sparse examples. Without visual feedback on intermediate geometry, the agent cannot verify whether helper elements such as clearance zones are correctly positioned.

We note several limitations. The 12-model evaluation limits statistical robustness. The GUID-level evaluation counts each element once, regardless of its involvement in multiple violations of the same type, potentially overestimating quality for rules that affect many similar elements. The ground truth was established through Solibri rule checks; differences in rule interpretation between the ground truth and the generated ACC functions cannot be excluded. A future dataset should include checks from multiple sources and different methods for generating (or manually creating) the ground-truth violations. Semantic labels for spaces and doors had to be provided via the `classify_spaces` tool, applying pre-defined name-matching patterns. Simple name-matching is effective in controlled settings but produces false positives when naming differs across building types, and introduces a manual dependency that does not scale to new models. Automating object classification is therefore important for scaling the evaluation pipeline and giving the agent access to consistent semantic categories. Integrating more dynamic components, such as semantic similarity or auxiliary agents for edge cases, might improve generalisation but would also weaken the deterministic character of the generated functions, which is central to their reusability across design tools.

Conclusions

This study investigated whether LLM-based agents using the Code-Act paradigm can generate reusable compliance checking functions from building regulations. The results show that such functions are achievable for a subset of Class 1 and Class 2 rules when IFC representations are consistent and the required relationships or properties are explicitly available. However, checks that depend on geometry-heavy heuristics, incomplete relationship traversal, non-standard property lookup, or composite Solibri rule semantics remain difficult, especially for Class 3 rules.

Several directions for future work emerge from these findings. First, larger and more diverse datasets are needed so that the agent can cope with variation in IFC exports, property names, unit conventions, and relationship completeness. Therefore, Solibri object classification should be automated so that semantic labels can be generated consistently at scale rather than supplied through manual pattern rules. Additionally, a curriculum-based generation strategy, in which agents reuse and compose previously veri-

fied functions, might reduce the search space for complex rules. Finally, the generated functions can be integrated into design tools and further enable extended use cases, including reinforcement learning-based design adaptations.

Abstract

National residential retrofit is essential for meeting climate targets, making Whole-Life Carbon Assessment (WLCA) critical for balancing operational and embodied emissions. However, fragmented datasets and incomplete material inventories limit its application at scale. This study proposes a multi-agent, Retrieval-Augmented Generation (RAG)–enabled Knowledge-Based System (KBS) for national-scale WLCA of residential retrofit scenarios. Domain-specific LLM agents retrieve, interpret, and explain carbon metrics with full data provenance, improving transparency and reducing manual effort. Case studies on Irish semi-detached dwellings achieve 88% feasibility, 81% nDCG, 70% Precision, and 79% Mean Reciprocal Rank, confirming the system's potential for evidence-based national decarbonisation planning.

Introduction

Global population growth and the associated demand for housing and infrastructure continue to increase the built environment's climate impact. Recent demographic projections estimate the world population will approach ∼9.7–9.8 billion by 2050 (INED, 2024). At the same time, international and regional policy frameworks are tightening requirements on building energy and carbon performance. In the European Union, the recast Energy Performance of Buildings Directive (EPBD) has strengthened the pathway toward a zero-emission building stock and explicitly advances whole-life thinking, including requirements to calculate and disclose life-cycle global warming potential for new buildings according to a phased timeline (European Commission, 2025). These developments increase the need for decision-support tools that quantify carbon impacts consistently and transparently across large residential portfolios.

Residential retrofit programmes are widely recognised as an effective near-term strategy for reducing operational emissions in existing housing stocks, yet they also introduce embodied emissions that can materially influence net carbon outcomes over the assessment horizon. National-scale and case-study analyses consistently identify this operational–embodied trade-off, showing that retrofits optimised for operational performance may increase whole-life impacts when embodied effects are excluded (McGinley et al., 2022). Whole-life carbon assessments across diverse residential contexts further indicate that an exclusive focus on operational reductions can shift emissions toward materials and construction activities as retrofit depth and deployment scale increase (Hegarty and Kinnane, 2023). Simulation-based LCA studies of residential retrofits similarly demonstrate that conclusions regarding optimal retrofit strategies are highly sensitive to methodological assumptions, including system boundaries, replacement cycles, grid decarbonisation pathways, and uncertainty treatment (Aghamolaei et al., 2025). The broader retrofit LCA literature highlights persistent challenges in translating existing guidance into routine practice, with analyst judgement and modelling choices continuing to drive substantial variability in reported outcomes (Hurst and O'Donovan, 2025).

National-scale complexity has been addressed through the use of building archetypes, building-stock models, and parametric simulation pipelines. Reviews indicate that archetype-based approaches enable scalable analysis but remain sensitive to data quality, representativeness, and calibration decisions (Shen et al., 2024). Bottom-up building-stock frameworks capture heterogeneity and support targeted strategies when detailed inputs are available, although fragmented and incomplete datasets remain a major limitation (Penaka et al., 2024). Parametric life-cycle approaches enable systematic exploration of retrofit options under uncertainty, but their application at scale depends on robust inventories, consistent life-cycle boundaries, and transparent assumptions (Arbulu et al., 2024).

Recent advances in large language models (LLMs) and Retrieval-Augmented Generation (RAG) frameworks present an alternative pathway for scaling whole-life carbon assessment while maintaining traceability. RAG approaches ground model outputs in retrieved evidence, reducing hallucination risk (Lewis et al., 2020), while multi-agent RAG architectures decompose complex analytical workflows into specialised agents, improving robustness and interpretability (Xie et al., 2025). These developments are increasingly discussed within sustainability assessment research as mechanisms for improving scalability and reducing expert workload, alongside continued emphasis on transparency, auditability, and governance.

This study introduces a novel national-scale WLCA framework for residential retrofits that integrates parametric simulation with a retrieval-augmented, multi-agent knowledge-based system to address challenges posed by

fragmented data, limited transparency, and poor scalability. The core contribution lies in the tight coupling of ISO-consistent operational and embodied carbon accounting with a domain-specific multi-agent RAG architecture, where dedicated Operational, Embodied Carbon, and Whole-Life Carbon Agents retrieve, validate, and synthesize results directly from an authoritative knowledge base, ensuring full numeric grounding and traceable provenance. The framework further advances current practice through an orchestrated interface and interactive dashboard that present complex WLCA results in a clear, explainable form suitable for stakeholders and policy decision-making. This design enables scalable exploration of retrofit pathways, transparent evaluation of operational–embodied trade-offs, and reproducible decision support for residential decarbonization planning at regional and national scales.

The paper follows a structured format, with Section 2 presenting the research methodology. Section 3 examines a comprehensive Irish case study, providing real-world context for the study's findings. Finally, Section 4 concludes the paper and outlines potential avenues for future research.

Methodology

This study proposes a scalable framework for whole-life carbon assessment of national residential building stocks by integrating data-driven archetype modeling, parametric simulation, and standardized life-cycle assessment. Representative dwelling archetypes are constructed from geometric, material, and operational data, with key parameters systematically varied to generate realistic retrofit scenarios and evaluate both operational and embodied carbon impacts. All simulation outputs and life-cycle results are stored in a structured, version-controlled knowledge base that preserves numerical consistency, provenance, and traceability, while a domain-specific, multi-agent retrieval-augmented generation layer enables auditable, constraint-aware querying and transparent trade-off analysis. Together, the framework translates high-dimensional WLCA evidence into explainable, policy-relevant insights and supports robust, reproducible evaluation of residential retrofit strategies at scale.

Data acquisition

The framework establishes an integrated data infrastructure that can be populated from nationally available statistics, open databases, or project-specific surveys. Geometric inputs describe spatial and envelope characteristics such as envelope U-values (W/m^{2}K), floor area (m^2), glazing ratio (WWR in %), and orientation (θ in $^\circ$), which govern heat transfer and solar gains. Non-geometric data capture operational conditions including occupancy schedules, internal gains, ventilation behaviour, and system efficiencies (Ali et al., 2019).

Embodied-carbon assessment relies on material and product-level information drawn from recognized life-cycle inventories and environmental product declarations. Typical sources include international or national databases such as ICE, ecoinvent, CIBSE TM65, or equivalent regional inventories; however, the framework allows substitution with any dataset providing transparent emission factors and system boundaries (Chartered Institution of Building Services Engineers (CIBSE), 2021; Circular Ecology, 2025; Ecoinvent Association, 2025). Climate data consisting of hourly temperature, solar irradiance, and wind profiles are incorporated to enable climate-sensitive operational modelling.

Archetype development

The methodology employs building archetypes representing dominant residential typologies to enable national-scale analysis without modelling individual dwellings. Each archetype encapsulates typical geometry, construction, and operational characteristics derived from national housing statistics and empirical studies. Baseline specifications include envelope assemblies, material composition, thermal performance (U-values in W/m^{2}K), building services, and occupant behaviour assumptions across age bands and dwelling forms. These attributes are formalized within the *ArchetypeData* table of the WLCA Knowledge Base System (KBS), where stable identifiers enable consistent linkage to operational simulations, embodied material records, and scenario states across the pipeline (Ali et al., 2019).

Archetypes are implemented in validated dynamic building simulation environments, such as EnergyPlus or IES VE, or equivalent tools capable of hourly energy modelling (Erdogan, 2019). Simulation outputs are benchmarked against national or measured datasets to ensure realistic performance. Once validated, archetypes function as flexible templates for systematic variation of materials, systems, and operating conditions in retrofit and whole-life carbon analyses.

Operational and embodied parametric feature selection

Parametric feature selection defines the multidimensional design space explored within the WLCA framework. Parameters are identified through literature review, data availability, and preliminary sensitivity testing, rather than expert judgement alone. Selected variables demonstrably influence energy demand, thermal behaviour, or material-related impacts and are registered in the WLCA Parametric KBS with metadata specifying domain relevance, allowable ranges, default values, and dataset versions.

Parameters are categorized into geometric, operational, and material groups. Geometric variables influence envelope exposure and solar gains; operational parameters capture use patterns and system performance; material parameters affect heat transfer and embodied carbon intensity. Together, these parameters bound the parametric space feeding simulation, LCA calculation, and retrieval. Centralized storage enables the *Interface Agent*

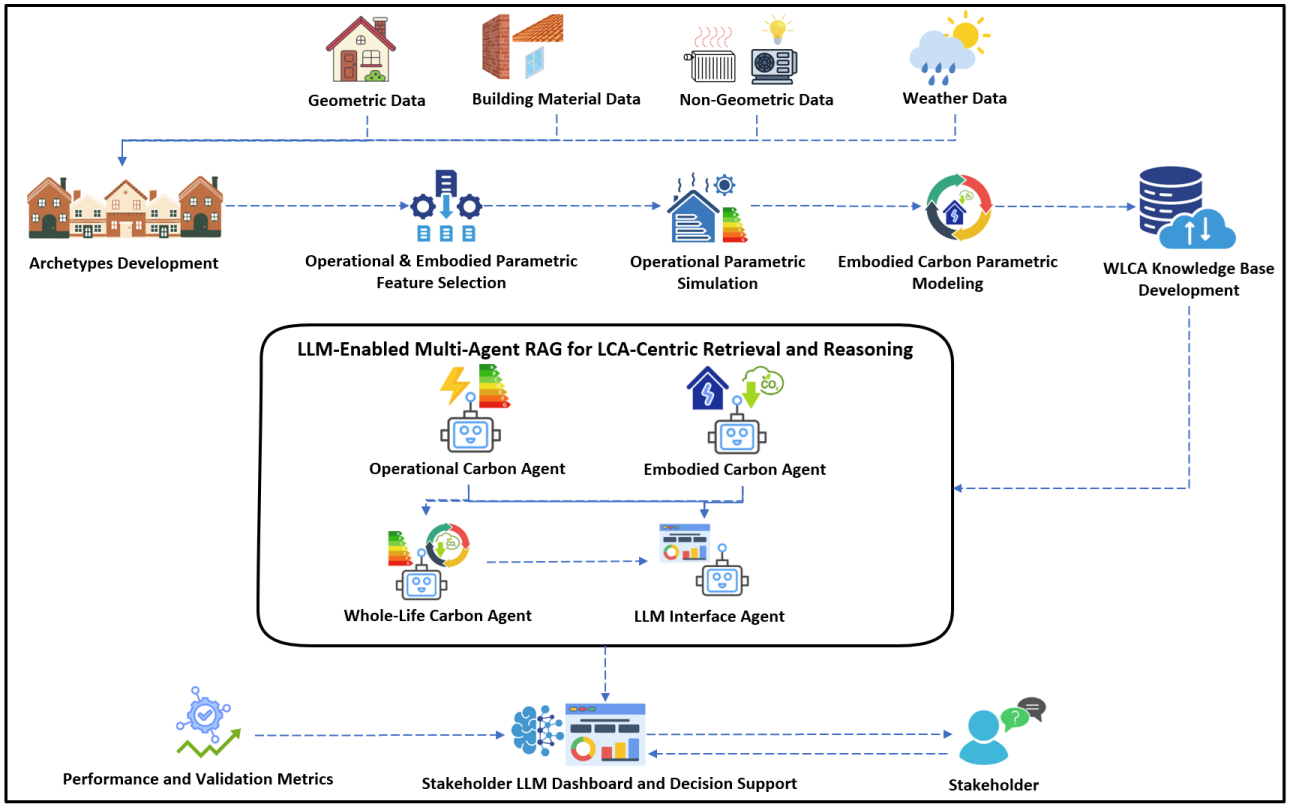

Figure 1: Methodology for Multi-Agent RAG-Enabled Knowledge System for national-Scale Whole-Life Carbon Assessment of Residential Retrofits.

and *Query Interpretation* process to consistently translate natural-language queries into structured retrieval constraints.

Operational parametric simulation

Operational simulation evaluates the effects of variations in form, systems, and building type on energy demand through an ensemble of scenarios generated by perturbing selected parameters. High-throughput execution is achieved using parametric automation tools such as jEPlus, Python-based workflows, or equivalent batch-processing environments (Zhang and Korolija, 2010). Each simulation is associated with a specific archetype identifier, parameter set, climate file, and scenario state, with results stored in the *OperationalData* table of the KBS.

To manage computational cost in high-dimensional spaces, statistical sampling methods such as Simple Random Sampling, Latin Hypercube Sampling, or Sobol sequences are employed. Simulation outputs include annual energy use intensity, heating and cooling loads, system consumption, and comfort metrics. These results form the primary evidence used by the *Operational Agent* within the RAG architecture. Post-processing normalizes outputs and structures them for integration with WLCA calculations, producing a reusable, queryable synthetic dataset that supports consistent reuse without re-running simulations.

Embodied carbon parametric modeling

For each parametric configuration, a cradle-to-grave life-cycle assessment is conducted in accordance with ISO 14040/14044 standards (ISO, 2006). The assessment follows the A–C life-cycle structure, covering product and construction stages (A1–A5), operational energy use (B6), and end-of-life processes (C1–C4). Lifecycle boundaries and assessment horizons are aligned within the WLCA Parametric KBS to ensure consistent integration of embodied and operational impacts by the *Whole-Life Carbon Agent*.

Material emission factors are sourced from established inventories such as ICE, ecoinvent, and CIBSE TM65, or equivalent national datasets. Where project-specific data are unavailable, transparent proxy selection is permitted based on material function and composition, with uncertainty and provenance explicitly recorded. All material quantities, emission factors, and uncertainty annotations are persisted in the *EmbodiedData* table, enabling full auditability during retrieval.

An automated calculation pipeline links simulation outputs, material quantities, and emission factors to compute embodied and operational impacts across large scenario sets. Results are expressed as total life-cycle emissions ($kgCO_2e$) and normalized by floor area to enable

cross-scenario comparison. This integrated dataset underpins the knowledge base and is consumed by the *Whole-Life Carbon Agent* to compute total WLCA values, savings, and baseline–post-retrofit comparisons within the auditable RAG pipeline.

WLCA knowledge base development

The Whole-Life Carbon Assessment Knowledge Base System (KBS) functions as the authoritative, version-controlled data backbone of the proposed multi-agent, retrieval-augmented framework. All user queries, agent reasoning, and dashboard outputs resolve directly to records stored in the KBS, which persists not only final whole-life carbon indicators but also the intermediate parameters, scenario states, and modeling artifacts required to reconstruct any reported value. This design ensures that WLCA results remain traceable, auditable, and reproducible across software environments and jurisdictions, while preserving numerical consistency and provenance throughout the assessment workflow.

At the data layer, the KBS is organized into normalized tables that store archetype descriptors in *ArchetypeData*, operational simulation outputs in *OperationalData*, embodied material inventories in *EmbodiedData*, and higher-level assessment parameters in the WLCA Parametric KBS, all indexed by explicit scenario and state identifiers. Baseline and post-retrofit conditions are encoded as distinct scenario states, enabling consistent before–after comparisons and trade-off analysis without duplicating archetype definitions. To support retrieval-augmented generation, the KBS exposes both structured access for deterministic constraint filtering and semantic representations for contextual retrieval, allowing the system to combine semantic relevance with strict numeric grounding and ensuring that all returned WLCA outputs are anchored in authoritative, auditable records.

LLM-enabled multi-agent RAG for LCA-centric retrieval and reasoning

The proposed system implements a domain-specific, multi-agent retrieval-augmented generation (RAG) layer that mediates between a stakeholder-facing dashboard and an underlying WLCA Knowledge Base System (KBS) (Table 1). The architecture is explicitly designed for research-grade life cycle assessment, where numerical correctness, scenario consistency, and full provenance traceability are mandatory. Rather than allowing a large language model to generate estimates directly, the system decomposes query handling, data retrieval, validation, domain reasoning, and output persistence into explicit agents and deterministic process steps.

To support transparency and interpretability, the operation of each architectural component is explained using the same representative retrofit query that is traced end-to-end in Table 1. The example considers a dwelling constructed in 1965, originally heated by a boiler, with the user seeking to upgrade to a heat pump, achieving a BER A2 rating while minimizing embodied carbon impacts.

User Query and Interface Agent The process begins when the user submits a natural-language query via the dashboard, such as: *"I have a house built in 1965 with a boiler and would like to upgrade to A2 rating with a heat pump and lower embodied carbon."* As shown in the first row of Table 1, this raw query is persisted verbatim in the *UserQuery* table, ensuring that the original user intent is preserved for audit and traceability.

The Interface Agent then performs query normalization. Informal expressions such as "house built in 1965," "boiler," and "A2 rating" are mapped to standardized domain concepts, including the 1950–1966 age band, a baseline boiler heating system, and a post-retrofit BER A2 performance target. The resulting normalized query string (Table 1, second row) removes linguistic variability while preserving semantic intent and provides a stable input for deterministic interpretation and retrieval.

Query Interpretation and Constraint Encoding. The normalized query is translated into a structured representation of intent and constraints. As illustrated in Table 1, this step extracts the retrofit action (boiler to heat pump), the target post-retrofit energy rating (BER A2 or better), the optimization objective (minimize embodied carbon), and the building context (constructed in 1965, corresponding to the 1950–1966 age band). These elements are encoded in a *RetrievalConstraints* record, which governs all subsequent retrieval and filtering operations and ensures that the user's intent is expressed in a fully specified and reproducible form.

Semantic Retrieval and Candidate Set Generation. Guided by the encoded constraints, the RAG layer initiates semantic retrieval over the WLCA KBS. This step identifies archetypes, retrofit scenarios, and related records that are contextually similar to the interpreted query. The results are stored as a ranked *CandidateSet* (Table 1), in which multiple mid-century dwelling archetypes with low-carbon retrofit characteristics are initially considered. This stage prioritizes recall and ensures that potentially relevant records are not prematurely excluded.

Structured Filtering and Compatibility Enforcement. The candidate records are then subjected to structured filtering using the explicitly encoded constraints. The candidates are retained only if they support a heat pump retrofit and achieve a post-retrofit BER A2 or better (Table 1). This step enforces methodological and scenario compatibility, eliminating records that are semantically similar but technically or contextually invalid for the query.

Join, Re-ranking, and Retrieved Record Bundling. Filtered records are joined across the *ArchetypeData*, *OperationalData*, *EmbodiedData*, and WLCA parametric tables to align operational simulations, material inventories, and assessment assumptions under a common archetype and scenario definition. The joined records are then re-ranked according to the optimization objective in this example, lowest embodied carbon per square metre, yielding

Table 1: End-to-end processing of a natural language retrofit query using the proposed retrieval-augmented, agent-based whole life carbon assessment framework.

Process Step	Input / Context	Example Output for the Query
1. User Query Capture	Raw user input	*"I have a house built in 1965 with a boiler and would like to upgrade to A2 rating with a heat pump and lower embodied carbon."*
2. Interface Agent (Normalization)	Raw query text	Normalized query string used for interpretation and retrieval: *"house built 1965 boiler upgrade heatpump a2 rating lower embodied carbon"*
3. Query Interpretation	Normalized query	Extracted intent and constraints: – Retrofit from boiler to heat pump – Target post-retrofit energy rating: BER A2 or better – Optimization objective: minimize embodied carbon – Building context: constructed in 1965 (Age Band D: 1950–1966)
4. Semantic Retrieval	Interpreted query and parametric knowledge base	Candidate archetypes ranked by semantic similarity to the query, e.g.: 1) 1950–1966 dwelling with heat pump retrofit 2) Post-war detached dwelling with insulation upgrade 3) Retrofit archetype with low-carbon heating
5. Structured Filtering	Candidate set and extracted constraints	Records filtered to retain only those that: – Achieve BER A2 or better after retrofit – Are compatible with heat pump systems
6. Join and Re-ranking	Filtered candidate set and optimization objective	Remaining records re-ranked by lowest embodied carbon per square metre, yielding a top-K shortlist
7. Grounding and Validation	Top-ranked records	Selection of the best-matching archetype with full provenance: – Document identifier – Dataset version – Fields used for energy and carbon calculations
8. Operational Carbon Agent	Grounded archetype	Before/after operational performance estimates, e.g.: – BER before retrofit: C2 – BER after retrofit: A2 – Primary energy intensity reduced from 210 to 75 kWh/m^2/yr
9. Embodied Carbon Agent	Grounded archetype	Embodied carbon breakdown by components (walls, windows, roof, floor, heat pump) and total embodied carbon per m^2
10. Whole Life Carbon Agent	Grounded archetype	Combined 60-year whole life carbon result including operational and embodied emissions, e.g.: – Operational: 540 kgCO_2e/m^2 – Embodied: 390 kgCO_2e/m^2 – Total WLCA: 930 kgCO_2e/m^2
11. Auditable Output Storage	Agent outputs and provenance	Persisted auditable record containing retrieval preview, operational results, embodied results, WLCA results, and dataset version

a bounded Top-K shortlist. This shortlist is materialized as a *RetrievedRecordBundle*, representing the best-supported interpretation of the user query.

Grounding and Validation. Before numerical reasoning occurs, the retrieved records undergo grounding and validation. This step verifies that the selected archetype is fully parameterized, that all required operational and embodied data are present, and that dataset versions and source documents are explicitly identified. Only records that pass these checks are exposed to downstream agents,

ensuring that all reported results are fully grounded and reproducible.

Operational Carbon Agent. The Operational Carbon Agent consumes the grounded records to report on pre- and post-operational performance. In the example, this includes changes in BER rating and primary energy intensity, with reductions from a pre-retrofit C2 level to a post-retrofit A2 level, and a corresponding reduction in energy use intensity. All values are linked to underlying simulation outputs stored in the *OperationalData* table.

Embodied Carbon Agent. In parallel, the Embodied Carbon Agent computes embodied emissions associated with the retrofit measures. For the running example, this includes a component-level breakdown of embodied carbon contributions from walls, windows, roof, floor, and the heat pump system itself, aggregated into a total embodied carbon intensity per square metre. Factor sources and dataset versions are explicitly documented.

Whole-Life Carbon Agent. The Whole-Life Carbon Agent integrates operational and embodied results over a 60-year assessment horizon to compute total whole-life carbon impacts. The combined operational and embodied emissions enable direct comparison between baseline and retrofit scenarios and the quantification of net carbon savings (Table 1).

Auditable Output Storage. Finally, all agent outputs and associated provenance metadata are consolidated into a persistent *AuditableOutputs* record. This record includes a retrieval preview, operational results, embodied results, whole-life carbon results, and dataset version identifiers. Persisting these outputs ensures that all reported values can be reproduced by re-running the same pipeline against the same WLCA KBS snapshot.

Stakeholder LLM dashboard and decision support

The stakeholder-facing LLM dashboard is the primary interface to the multi-agent RAG system and is tightly integrated with its architecture. It performs no independent computation, acting instead as a thin interaction layer that submits user queries, presents grounded outputs, and exposes audit information generated by the backend. Each interaction corresponds to a *UserQuery* record and follows the same retrieval, validation, and agent-reasoning workflow.

Using natural language, users can explore archetypes, compare retrofit strategies, and analyze embodied–operational trade-offs across assessment horizons. Queries are routed through the *Interface Agent*, which coordinates retrieval and agent execution and returns structured results with narrative explanations. Quantitative outputs are displayed as tables and charts, while an embedded audit view provides dataset versions, document identifiers, factor sources, and scenario states. When evidence is incomplete, uncertainty flags and provenance gaps are shown instead of unsupported values.

The dashboard supports exporting results in CSV or JSON formats and generating auto-formatted reports with embedded audit metadata. Because outputs are derived from persisted *AuditableOutputs* records, all exported artifacts are reproducible outside the system. Portability across regions and jurisdictions is achieved by substituting local archetypes, material inventories, and climate datasets within the KBS while preserving schemas, retrieval logic, and audit guarantees, allowing the dashboard and methodology to be reimplemented in new contexts without modifying the core pipeline.

Performance and validation metrics

The evaluation framework assesses retrieval quality, answer faithfulness, and numerical correctness within the LCA-centric multi-agent RAG system to ensure transparency and methodological compliance. Retrieval performance is measured using standard information-retrieval metrics, including Recall@k, Precision@k, Mean Reciprocal Rank (MRR), and normalized Discounted Cumulative Gain (nDCG), computed on a labeled query set linking stakeholder questions to authoritative KBS records. High Recall@k and nDCG indicate that relevant WLCA evidence is retrieved and correctly ranked, while MRR captures how quickly usable evidence appears, which is particularly important in multi-agent workflows. In addition, feasibility-oriented checks evaluate whether at least one constraint-satisfying retrofit option is retrieved within top-k results, reflecting the decision-search nature of stakeholder queries (Sharma, 2025).

Faithfulness and numerical correctness are enforced through strict grounding of all reported values to versioned KBS records, with citation coverage, provenance completeness, and contradiction checks used to audit responses. WLCA outputs are further validated against ISO 14040/14044 system boundaries and accounting conventions, with spot checks ensuring that reported whole-life totals are consistent with the sum of operational and embodied components within defined tolerances (ISO, 2006). All evaluations are tied to dataset version tags and audit metadata, enabling reproducibility across regions by substituting local archetypes, material inventories, and climate data while preserving retrieval logic and guardrails.

Case study and results

This case study demonstrates how a proposed whole-life carbon (WLC) methodology can be applied to the Irish residential sector using nationally available datasets, regulatory conventions, and realistic retrofit pathways. Focusing on semi-detached dwellings as a representative housing typology, it shows an end-to-end workflow from stock characterization and archetype definition to dynamic operational energy simulation and embodied-carbon accounting (Table1). The national Energy Performance Certificate (EPC) database underpins the analysis by providing standardized dwelling attributes, which are translated into physically interpretable archetypes aligned with Ireland's Dwelling Energy Assessment Procedure (DEAP). These

Table 2: Summary of dashboard results for retrofit query on Irish semi-detached dwellings (roof built 2000).

Attribute	Result
Query constraints	I have a house built in 1965 with a boiler and would like to upgrade to A2 rating with a heat pump and lower embodied carbon.
BER (Pre → Post)	C2 → A2
Primary EUI	177.1 → 49.7 (kWh/m^2/yr)
WLCA 60y total	1620.8 → 211.6 (kgCO$_2$e/m^2)
WLCA savings	1409.2 (kgCO$_2$e/m^2)
Operational carbon 60y	1554.2 → 108.1 (kgCO$_2$e/m^2)
Embodied carbon 60y	66.6 → 103.5 (kgCO$_2$e/m^2)
Post-retrofit carbon split	Operational 51% / Embodied 49%

archetypes capture age-dependent construction practices, baseline thermal performance, and window characteristics, forming a consistent basis for simulating pre- and post-retrofit operational energy demand under controlled climate and occupancy assumptions.

Operational and embodied carbon impacts are evaluated through a parametric simulation and whole-life carbon assessment pipeline that systematically explores retrofit scenarios, including envelope upgrades and low-carbon heating systems. Dynamic simulation outputs are combined with Irish and international embodied-carbon factors to account for initial construction, retrofit measures, component replacements, and end-of-life processes over the assessment horizon. Results are stored in a structured knowledge base that supports auditable, reproducible analysis and retrieval-augmented generation, enabling stakeholders to query and compare retrofit options by operational, embodied, or total life-cycle carbon. Together, the case study illustrates how an integrated, data-driven framework can support transparent whole-life carbon assessment and decision-making for residential decarbonization in the Irish context.

The framework enables stakeholders to enter constraint-based queries through the dashboard to analyse existing buildings and evaluate retrofit outcomes. The system identifies a transition from a current BER C2 dwelling to a post-retrofit A2 option with heatpump upgrade, reducing WLCA_{60y} from 1620.8 to 211.6 kgCO$_2$e/m^2, corresponding to a saving of 1409.2 kgCO$_2$e/m^2 (approximately 86%). In parallel, Primary EUI decreases from 177.1 to 49.7 kWh/m^2/yr (a reduction of 128 kWh/m^2/yr, or 72%), while the post-retrofit carbon contribution shifts to 51% operational and 49% embodied, demonstrating transparent quantification of operational–embodied trade-offs (Table 2).

The study is evaluated using the multi-axis protocol described in the methodology, combining retrieval effectiveness, decision relevance, numerical faithfulness, and LCA correctness. Assessment is conducted on a stratified 20% sample of the 1.6 million parametric configurations (approximately 320,000 cases) using 30 stakeholder-style queries representing typical retrofit constraints. Each query yields on average 118 feasible designs after structured filtering, confirming that the design space remains highly multi-modal even under BER and envelope requirements, while the ten lowest-WLCA options form the reference set for decision-oriented metrics.

Table 3: Summary of retrieval performance across feasibility, ranking quality, and decision relevance metrics.

Method	Metrics at $K = \{1,3,5,10\}$
Full multi-agent system	Hit: 0.78/0.82/0.85/0.88 nDCG: 0.81/0.76/0.74/0.71 Precision: 0.74/0.72/0.71/0.70 Recall: 0.70/0.71/0.70/0.69 MRR: 0.74/0.76/0.77/0.79
Hybrid candidates	Hit: 0.61/0.69/0.73/0.79 nDCG: 0.69/0.67/0.65/0.63 Precision: 0.58/0.56/0.55/0.53 Recall: 0.57/0.55/0.54/0.52 MRR: 0.58/0.61/0.63/0.66
Semantic-only retrieval	Hit: 0.21/0.33/0.38/0.46 nDCG: 0.41/0.38/0.35/0.32 Precision: 0.24/0.21/0.20/0.19 Recall: 0.23/0.20/0.19/0.18 MRR: 0.24/0.27/0.29/0.31
Random (20% pool)	Hit: 0.10/0.11/0.18/0.32 nDCG: 0.16/0.17/0.17/0.18 Precision: 0.11/0.11/0.10/0.13 Recall: 0.11/0.10/0.10/0.12 MRR: 0.11/0.12/0.14/0.17

Feasibility discovery shows that the multi-agent framework reliably identifies valid retrofit options under strict constraints, achieving HitFeasible@1 of 0.78 and HitFeasible@10 of 0.88, far exceeding semantic-only retrieval (0.46 at $K = 10$) and random sampling (0.32). Hybrid candidate filtering improves feasibility (0.79 at $K = 10$) but remains inferior to the full WLCA-aware reranking, underscoring the value of objective-driven ordering in sparse solution spaces (Table 3).

Decision relevance and ranking quality further demonstrate the system's effectiveness. The framework attains PrecisionTop10@10 and RecallTop10@10 of 0.70, with strong early-rank performance (Precision@1 and MRR@1 of 0.74), indicating that optimal low-carbon designs typically appear at the top of the list. Ranking alignment with ideal WLCA ordering is high, with nDCG@1 of 0.81 and nDCG@10 of 0.71, while hybrid and semantic-only methods show substantially weaker performance.

Faithfulness checks confirm that all reported results remain numerically grounded and auditable, with citation coverage of 0.98, a numeric mismatch rate of 0.01, and universal compliance with WLCA boundary arithmetic. Together, these results demonstrate that the framework can navigate large parametric retrofit spaces while preserving LCA rigor, transparency, and interactive usability, making it suitable for stakeholder-facing decision support and transferable to other national building stocks.

Conclusion and future work

This study presents a scalable framework for estimating whole-life carbon emissions across national residential building stocks by integrating parametric simulation, standardized WLCA, and a multi-agent retrieval layer. Heterogeneous inputs, including archetype definitions, operational simulation outputs, material inventories, and life-cycle calculations are consolidated within a structured knowledge base to support transparent, query-driven analysis. Application to the Irish residential sector demonstrates that the framework can explore more than one million retrofit configurations while preserving numeric grounding, data provenance, and interactive performance, with structured filtering and WLCA-aware re-ranking significantly improving the identification of feasible low-carbon options over semantic retrieval alone.

The framework delivers three key contributions: it unifies operational and embodied carbon assessment within a single parametric pipeline to enable consistent before and after retrofit evaluation; it provides versioned, auditable records that support reproducible national-scale WLCA without embedding assumptions in the language layer; and it enables natural-language access to complex WLCA evidence through multi-agent orchestration with enforced numeric guardrails. Future work will extend the approach to additional building typologies and integrate dynamic occupancy, monitored energy data, and spatial datasets to enhance realism and support neighbourhood- and stock-scale decarbonization planning.

Abstract

To enable building energy flexibility, sensor networks play a critical role in building energy management. However, comprehensive sensor network deployment is hindered by high Capital Expenditure (CAPEX) and retrofitting complexities. This study proposes a graph theory-based framework to address these limitations by exploiting the physical consistency inherent in building systems. By modeling the system topology using a bipartite graph, the framework identifies unknown variables given existing measurements via physical laws (e.g., thermodynamics). The proposed framework can also be used as virtual sensing for anomaly detection and sensor network design for both existing and new buildings.

Introduction

The global energy landscape is undergoing a shift, moving the system from centralized toward decentralized with high penetration of renewable energy sources. As a major participant in the energy system, the building sector is transitioning from a passive consumer role to an active prosumer, which provides energy flexibility via Demand-Side Management (DSM) (IEA, 2019; European Environment Agency, 2024). In this context, sensor networks play a central role in monitoring physical properties in the energy system and transmitting the real-time information to Building Management System (BMS) for further optimal control (Bae et al., 2021).

While the benefits of sensor networks are well-established, the practical deployment of comprehensive sensor networks faces significant barriers. Specifically, the high Capital Expenditure (CAPEX) associated with purchasing hardware and the complexity of retrofitting wiring infrastructure into the existing BMS hinder the practical deployment of sensors in buildings. These challenges occur in both design and renovation phases.

To address these limitations, there is a need to move beyond brute-force sensor deployment and instead exploit the potential of non-intrusive virtual sensing (Aguilar and R-Moreno, 2025). Although virtual sensing could be set up manually by experts, that is time-consuming, especially for identifying complex relationships between physical sensors and virtual ones. Building energy systems possess inherent physical consistency, for instance, the thermodynamic relationships between temperature, mass flow rate, and heat transfer. Thus, this indicates that not every variable requires a dedicated physical sensor. If the system topology is well understood, missing variables can be estimated through physical laws.

This study addresses the gaps by proposing a graph theory-based framework designed to represent the information flow in the building energy system by leveraging the physical consistency. By modeling the system topology as a bipartite graph, the correlation between each measurement point and physical laws is identified. This approach effectively creates a layer of virtual sensing, reducing the reliance on physical hardware without compromising the measurements required for DSM.

Previous studies

Sensor networks are necessary for building energy systems to collect data, detect faults and assist control (Koo et al., 2022). To ensure operational continuity, traditional approaches rely heavily on physical redundancy to enhance fault-tolerant ability. However, excessive physical redundancy often leads to high deployment costs and resource waste (Filios et al., 2024). Under the premise of meeting the system requirements, optimizing sensor configuration and virtual sensing are becoming the research focus. On the one hand, the number of sensors can be decreased by optimizing sensor configuration to reduce the deployment costs. For detecting and reducing faults, hardware redundancy is needed by using two same sensors in the same place. This strategy leads to a waste of sensors, so Panayiotis M. Papadopoulos et al. (Papadopoulos et al., 2022) designed a local fault diagnosis agent to estimate the state of Air Handling Units (AHUs) and compare the difference between the estimated value and the measured value. When the system is in the normal operation state, the difference will be constrained in an adaptive threshold which formed an Analytical Redundancy Relation (ARR). J. Aguilar et al. (Aguilar and R-Moreno, 2025) evaluated the sensor redundancy by structural observability analysis and optimized the sensor configuration by using Genetic Algorithm (GA). However, their focus is only on minimal sensor placement for fault detection. On the other hand, for the area lacking physical sensors because of high deployment costs or technical limits, virtual sensors can be constructed using physical-mathematical correlations or data-driven models (Wang and Li, 2022). Jiteng Li et al. (Li et al., 2024) established a framework of sensor off-

set definition by using redundant sensors, which can be a theoretical basis for virtual in-situ calibration method. Jabeom Koo et al. (Koo and Yoon, 2022) proposed an in-situ virtual sensing method that enables automatic virtualization and replacement when physical sensor bias exceeds approximately 1.0 °C. By integrating data-driven modeling with calibration techniques, the approach significantly enhances sensing reliability, reducing the initial average RMSE from 0.88 °C to 0.30 °C and eliminating 44.0% of bias errors and 32.9% of random errors.

Stylianos Karatzas et al. (Karatzas et al., 2024) used the LSTM algorithm to build a virtual sensing of framework for Indoor Air Quality (IAQ) index through data from two sensors for capturing pollutants. With this framework, this model can predict IAQ without the need of new sensors and its mean absolute percentage error is around 15%. Anupama Kowli et al. (Kowli et al., 2023) proposed a data-driven virtual sensing framework that utilizes linear regression to map the spatial distribution of indoor thermal variables, achieving estimation accuracies within 1 ℃ for temperature and 3% for relative humidity. By matching the performance of physical sensors like the BME280 over 95% of the time while minimizing hardware redundancy, this approach provides a cost-effective solution for high-fidelity indoor environmental monitoring. Yejin Hong et al. (Hong et al., 2021) proposed a physical-relation-driven assistance virtual sensor based on an autoencoder, which uses physical law and equipment performance curves to make up for the lack of key data. The accuracy for temperature, pressure, and control signals of the system under this strategy is all over 98%, effectively replacing the physical sensor.

While the previous studies have investigated the sensor configuration and virtual sensing techniques in different systems, they did not address the inherent physical consistency in the sensor networks and utilize it in a generalized approach. The detailed gaps are as follows:

- Sensor redundancy is well-established in control theory; it is traditionally categorized into hardware redundancy (multiple sensors) and analytical redundancy (model-based estimation). However, the potential of analytical redundancy for investigating the redundancy of sensor networks in complex building topologies remains underexplored.
- The majority of them approached the challenges by developing a complete high-fidelity model. This approach requires an extensive amount of data to train and calibrate the model, and it cannot be generalized.
- The inherent physical consistency has not been leveraged for sensor network related studies in the building energy system.

Contribution

Given the previous graph-based approaches (Papadopoulos et al. (2022); Aguilar and R-Moreno (2025)), this study proposes a generalized framework that focuses on the inherent physical consistency mapping in building energy systems. In contrast, the proposed framework is not oriented toward fault diagnosis or sensor placement optimization, but toward systematically mapping the physical consistency of an existing sensor network as a whole. By abstracting the building energy system as a bipartite graph, the governing physical laws are bridged with the sensor points. The proposed framework is then applied to an office building in Scandinavian climate.

Methodology

This section first introduces the problem formulation. In addition, the proposed framework is explained, and that includes physical system abstraction, graph construction, and observability propagation. The overall methodology is shown in Fig 1. The core of the proposed framework is an iterative propagation algorithm designed to map the information trajectory within the building energy system. Its primary function is to determine the maximal subset of system state variables that can be analytically deduced from a limited set of physical measurements. This process effectively converts the static topological model into a dynamic evaluation of system observability.

Problem formulation

In this study, the **physical consistency** of sensor networks in building energy systems is defined as the analytical interdependence of distributed physical measurements governed by fundamental physical laws. Specifically, the measurements are mathematically coupled at system components (e.g., Heat Exchanger (HEX), fans). For example, in a district heating substation, the thermal energy extracted from the primary side equals the energy delivered to the secondary side through the heat exchanger, with constant efficiency losses. This principle implies that a sensor network is not a set of independent measurements, but an interconnected system in which each measurement directly links with the related variables.

Likewise, **physical redundancy** is defined here as the ability to deduce a system variable (v_0) using a set of interdependent measurements ($\{v_1, v_2, ...v_n\}$) connected via a governing physical law (f):

$$v_0 = f^{-1}(v_1, v_2, ..., v_n) \tag{1}$$

where, v_i is calculated by inverting the governing physical law (f^{-1}). Accordingly, if the variables $\{v_1, ..., v_n\}$ are measured, v_j can potentially become a physical redundant sensor.

The **observability** is defined as the structural capacity to uniquely determine the value of a state variable given a specific network topology and measurement points. A variable is considered structurally observable if there exists physical consistency linking it to the set of known physical sensors and components. Therefore, the system's observability is binary for each sensor point: a variable is observable if it belongs to a closed set generated by

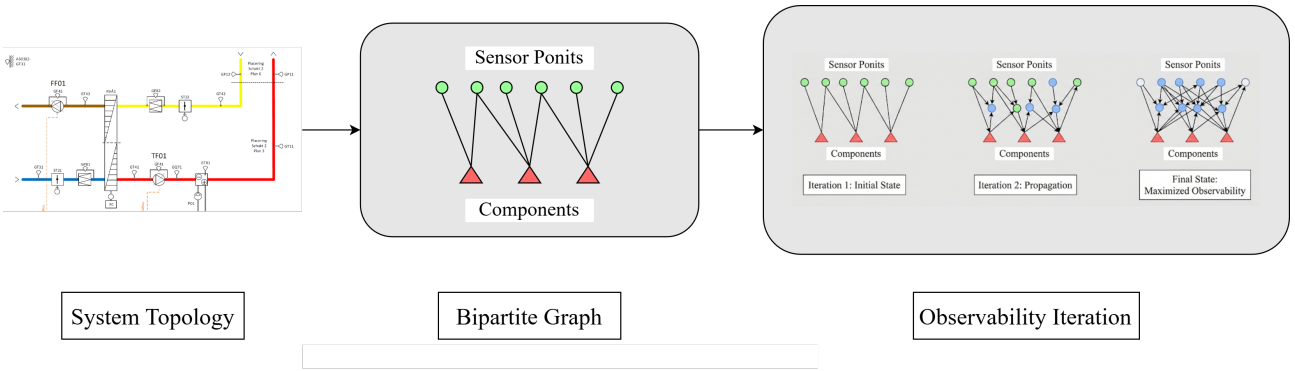

Figure 1: The overall methodology.

the propagation of known values through solvable physical laws.

Physical system abstraction

A building energy system can be decomposed into node sets of physical components (e.g., heat exchangers, pumps) and measurement variables (e.g., temperature, mass flow rate). The behavior of each component is governed by physical laws, such as mass and energy balance.

Let $\mathcal{V}$ be the set of measurement variables and C be the set of physical components. A variable $v_j \in \mathcal{V}$ represents a potentially measurable physical property, and $c_i \in C$ represents a component in the system, subject to the corresponding physical law involving a subset of variables. It is worth noting that the identification of both sets can be done by computer rather than manual work.

Maybe we should also highlight that this framework can be run by a computer to identify and set up potential virtual sensors?

Bipartite graph construction

The system can be modeled as a Bipartite Graph $G = (\mathcal{V}, C, \mathcal{E})$, where the two sets of vertices are the measurement variables $\mathcal{V}$ and the physical components C, respectively.

An undirected edge $e_{ij} \in \mathcal{E}$ exists between a variable v_j and a component c_i if and only if v_j is included as the subset variable in the physical law defined by c_i. Moreover, the $\mathcal{E}$ indicates the physical consistency of the target system.

The connectivity of the graph can also be represented algebraically by an incidence matrix $\mathrm{M} \in \{0,1\}^{|C|\times|\mathcal{V}|}$, defined as:

$$\mathrm{M}_{ij} = \begin{cases} 1, & \text{if } v_j \text{ is involved in } c_i \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

where, $|\cdot|$ denotes the cardinality of the set. Additionally, another state vector S is defined, representing the observability status of each measurement variable:

$$\mathrm{S}_j = \begin{cases} 1 & \text{if variable } v_j \text{ is known (either measured} \\ & \text{or deduced)} \\ 0 & \text{if variable } v_j \text{ is unknown} \end{cases} \tag{3}$$

Observability propagation

Initialization. To initialize the problem, the global variable set $\mathcal{V}$ is split into two mutually exclusive subsets based on their initial observability status, as shown in Equation 4, and a variable may flip membership from unknown to measured through the iterative process below. The framework develops an iterative scheme to successively deduce unknown variables to increase the set of measured variables, and the details are explained as follows.

$$\mathcal{V} = \mathcal{V}_{\text{measured}} \cup \mathcal{V}_{\text{unknown}} \tag{4}$$

where:

- $\mathcal{V}_{\text{measured}}$ represents the subset of variables directly measured by sensors (e.g., legacy BMS sensors).
- $\mathcal{V}_{\text{unknown}}$ represents the subset of unknown variables. It can be unmeasured physical variables or the measurement to be diagnosed.

Iterative Propagation. The iteration logic is grounded in the solvability of the governing physical laws. At each iteration, the algorithm evaluates the unknown degree (d_i) for every physical component c_i at iteration k:

$$d_i^{(k)} = \sum_{j=1}^{|\mathcal{V}|} M_{ij} \cdot (1 - S_j^{(k)}) \tag{5}$$

where, M_{ij} denotes if the variable v_i is involved in the components c_j; $(1 - S_j^{(k)})$ evaluates to 1 if the variable v_i is unknown ($S_j = 0$) and 0 if it is known ($S_j = 1$). Consequently, d_i only sums the unmeasured variables connected to c_i. The propagation adheres to the following:

1. **Solvable condition** ($d_i = 1$): If a component c_j is connected to exactly one unknown variable v_{unknown} (i.e., all other involved variables are members of the measured set), the component becomes solvable. The variable v_{unknown} is then moved from $\mathcal{V}_{\text{unknown}}$ to the $\mathcal{V}_{\text{measured}}$.
2. **Redundant Condition** ($d_i = 0$): If all variables associated with the component c_i are known, the equation

ceases to provide new information and instead serves as a consistency check, providing analytical redundancy useful for fault detection.

3. **Unsolvable Condition** ($d_i > 1$): If a component contains multiple unknowns, it remains unsolvable at the current iteration k. However, it may become solvable in subsequent iterations as information propagates from neighboring components.

Convergence Criteria. The iterative process repeats, updating the state vector $\mathrm{S}^{(k)} \rightarrow \mathrm{S}^{(k+1)}$, until the system reaches the redundant condition ($d_i^k = 0$), and that is, $\mathcal{V} = \mathcal{V}_{\text{measured}}$.

Use case

In order to demonstrate the implementation of the proposed framework, it is applied to a Mechanical Ventilation with Heat Recovery (MVHR) in an office building in Scandinavian climate as a use case. The schematic of the system is shown in Figure 2. The exhaust air (yellow line) passes through the rotary HEX to recover waste heat and preheat the inlet air. Then the inlet is further heated/cooled at the heating battery to a specific set point temperature, supplied by district heating/cooling via Shaunt Group (SHG).

Table 1: The tag list of sensors in the target MVHR system.

Tag	Measurement
GT	Temperature sensor [°C]
GF	Mass flow sensor [l/s]
GP	Pressure sensor [Pa]
GQ	Smoke detector [ppm]
ST	Damper position [%]
SV	Valve position [%]

In order to show the whole workflow of the proposed framework, several assumptions are made:

- This study considers only temperature and mass flow rate sensors.
- The temperature and mass flow rate losses in the duct/pipes are not considered.
- The rotary HEX efficiency is assumed to be a constant.

Graph construction

This section explains the process of constructing the bipartite graph.

Measurement Variables. Seven temperature measurement variables are included in the variable set $\mathcal{V}$: GT42 (T_1), GT43 (T_2), GT31 (T_3), GT41 (T_4), GT82 (T_5), GT81 (T_6), and GT11 (T_7). Notably, GT81 measures both the supply and return water temperatures of the SHG. In addition, two mass flow rate sensors are considered: GF42 ($\dot{m}_1$) and GF41 ($\dot{m}_2$). All variables listed above belong to the subset $\mathcal{V}_{\text{measured}}$, as they are directly measured. In contrast, no sensor is available for the mass flow rate of the hydraulic system at the heating battery. Thus, this variable is denoted by $\dot{m}_3$ and classified as $\mathcal{V}_{\text{unknown}}$.

Physical Components. In this MVHR system, the two main physical components are the rotary HEX (c_1) and the heating battery (c_1). For the HEX, the governing physical law is energy balance between the exhaust and supply air:

$$\dot{m}_2 c_{p,a} \cdot (T_4 - T_3) = \eta_{\text{hex}} \cdot \dot{m}_1 c_{p,a} \cdot (T_1 - T_2) \quad (6)$$

where, $c_{p,a}$ represents the specific heat capacity of air; η_{hex} denotes the efficiency for HEX, and is assumed to be a constant and can be estimated from the historical data. As for the heating battery, the governing equation of that is the energy balance between air and water:

$$\dot{m}_2 c_{p,a} \cdot (T_7 - T_4) = \eta_{\text{hb}} \cdot \dot{m}_3 c_{p,w} \cdot (T_5 - T_6) \quad (7)$$

where, $c_{p,w}$ is the specific heat capacity of water; η_{hb} is the efficiency, and can also be calculated from historical data.

Bipartite Graph. Based on the defined variable set and physical component set, the system is mapped to a bipartite graph $G = (\mathcal{V}, \mathcal{C}, \mathcal{E})$. The variable node set $\mathcal{V}$ comprises the $n = 10$ state variables identified above (7 temperature nodes and 3 mass flow nodes). The component set contains $m = 2$ nodes, representing the specific energy balance equations for the rotary HEX (c_1) and the heating battery (c_2). The edge set $\mathcal{E}$ is determined by the incidence of variables in the governing equations. The graph is visualized in Figure 3.

- Component c_1 (Equation 6) is connected to the subset $\{v_{\dot{m}_1}, v_{\dot{m}_2}, v_{T_1}, v_{T_2}, v_{T_3}, v_{T_4}\}$.
- Component c_2 (Equation 7) is connected to the subset $\{v_{\dot{m}_2}, v_{\dot{m}_3}, v_{T_4}, v_{T_5}, v_{T_6}, v_{T_7}\}$.

Incidence Matrix. The connectivity of the bipartite graph is formalized by the incidence matrix $\mathrm{M} \in \{0,1\}^{2\times 10}$. The rows correspond to the component set C, and the columns correspond to the variable set $\mathcal{V}$. The matrix is defined as:

$$\mathrm{M} = \begin{array}{c} \\ c_1 \\ c_2 \end{array} \begin{array}{c} \begin{array}{cccccccccc} \dot{m}_1 & \dot{m}_2 & \dot{m}_3 & T_1 & T_2 & T_3 & T_4 & T_5 & T_6 & T_7 \end{array} \\ \begin{pmatrix} 1 & 1 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{pmatrix} \end{array} \quad (8)$$

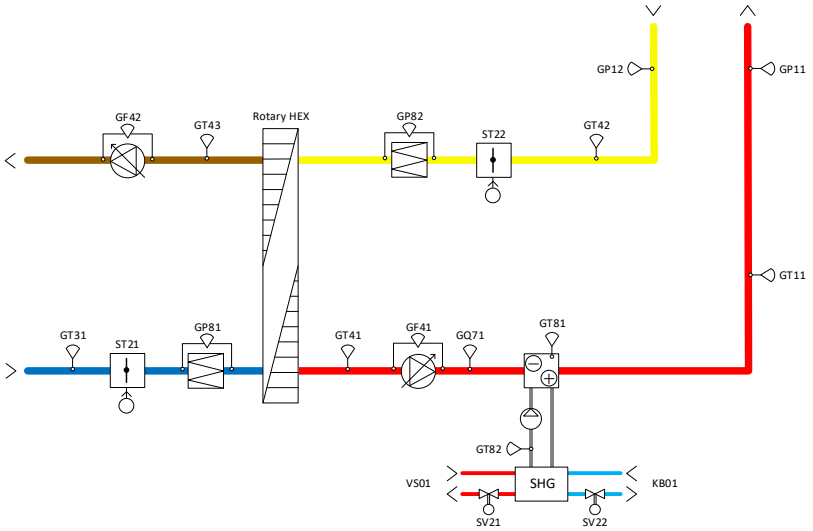

Figure 2: The system schematics of the Mechanical Ventilation with Heat Recovery system. The heat recovery from exhaust air happens at the rotary Heat Exchanger. The inlet air is further heated or cooled at the heating battery, supplied by district heating/cooling via the Shunt Group.

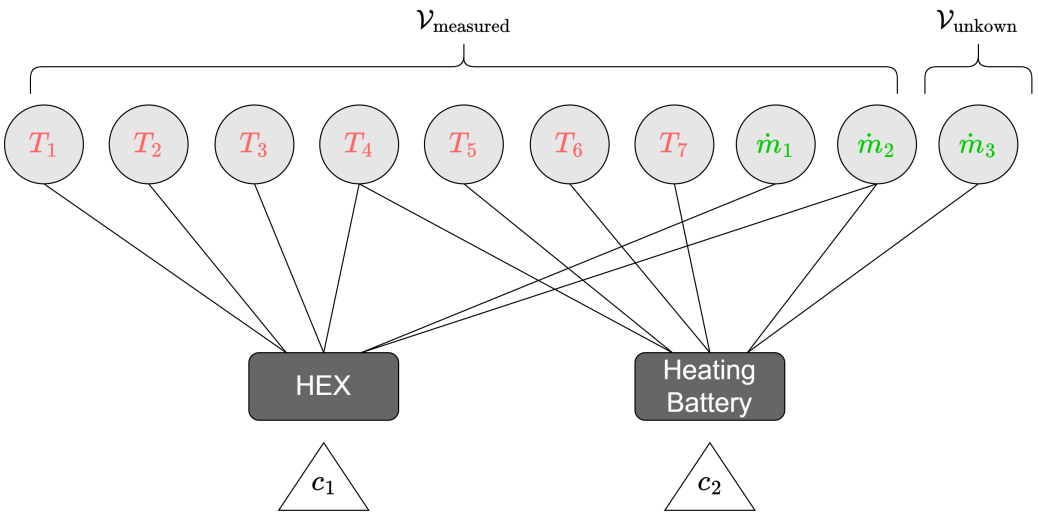

Figure 3: The constructed graph for the use case.

Observability propagation analysis

In this use case, the only unknown variable is the hydraulic mass flow rate, $\dot{m}_3$.

Step 1: Initialization ($k = 0$). The algorithm begins by populating the initial state vector $\mathrm{S}^{(0)}$ based on the sensor tag list (Table 1).

- The measured subset is initialized as $\mathcal{V}_{\text{measured}} = \{v_{\dot{m}_1}, v_{\dot{m}_2}, v_{T_1}, v_{T_2}, v_{T_3}, v_{T_4}, v_{T_5}, v_{T_6}, v_{T_7}\}$. Corresponding entries in $\mathrm{S}^{(0)}$ are set to 1.
- The unknown subset is initialized as $\mathcal{V}_{\text{unknown}} = \{v_{\dot{m}_3}\}$. The entry for $\dot{m}_3$ in $\mathrm{S}^{(0)}$ is set to 0.

Step 2: Iteration 1 ($k = 1$). The algorithm scans the constraint set $C = \{c_1, c_2\}$ to calculate the unknown degree $d_i^{(0)}$ for each component. For the rotary HEX (c_1), the incident variables are $\{v_{\dot{m}_1}, v_{\dot{m}_2}, v_{T_1}, v_{T_2}, v_{T_3}, v_{T_4}\}$. Since all these variables belong to $\mathcal{V}_{\text{measured}}$, the unknown degree is calculated as:

$$d_1^{(0)} = \sum_{c_1} (1 - 1) = 0 \tag{9}$$

According to the propagation logic, $d_1^{(0)} = 0$ satisfies the redundant condition. Consequently, c_1 does not infer new state variables.

For the heating battery (c_2), the incident variables are $\{\dot{m}_2, \dot{m}_3, T_4, T_5, T_6, T_7\}$. Among these, only $\dot{m}_3$ is in

$\mathcal{V}_{\text{unknown}}$. The unknown degree is:

$$d_2^{(0)} = (1-1)M_{c_2,v_{\dot{m}_2}} + (1-0)M_{c_2,v_{\dot{m}_3}} + \sum_{T \in c_2}(1-1) = 1 \tag{10}$$

Since $d_2^{(0)} = 1$, the solvable condition is met, c_2 is able to estimate the unknown variables.

Step 3: Resolution and Update. As triggered by the solvable condition, the algorithm algebraically inverts the governing equation of c_2 (Equation 7) to express the unknown variable $\dot{m}_3$ in terms of the measured set:

$$\dot{m}_3 = \frac{\dot{m}_2 c_{p,a}(T_7 - T_4)}{\eta_{\text{hb}} c_{p,w}(T_5 - T_6)} \tag{11}$$

In this context, $\dot{m}_3$ can be set up as a virtual sensor. The state vector is updated such that $\mathrm{S}_{\dot{m}_3}^{(1)} \rightarrow 1$, and the variable can be moved to $\mathcal{V}_{\text{measured}}$ for further propagation if needed.

Validation

In order to validate the approach, the temperature sensor GT41 (T_4) is assumed to be missing. It is used as a virtual sensor, and the prediction is compared with real measurement.

Figure 4 shows the validation results. The overall Root Mean Square Error (RMSE) of the validation results is 1.47 °C. It is worth noting that the RMSE during working hours (8:00 to 17:00) is only 0.23 °C. This can be explained by the different control strategies during working and non-working hours. During non-working hours, the building does not need ventilation, therefore, the rotary wheel is not actuated.

Discussion

The proposed graph-based framework offers a systematic approach to exploiting physical redundancy in building sensor networks. By visualizing the correlation between component topology and measurement variables, the methodology extends from complex system modeling towards modeling the inherent physical consistency in the system itself. This section discusses the potential application of the proposed methodology, along with the limitations and future works.

Potential applications

During the design phase, one potential application of the proposed framework is serving as a quantitative design tool to minimize CAPEX. Traditionally, sensor placement often follows rule-of-thumb and professional experience, which could lead to redundancy and unnecessary investments, especially in highly complex Heating, Ventilation, and Air Conditioning (HVAC) systems. By applying observability propagation during the design phase, the process of identifying a minimum set of sensors needed could be automated, thus reducing costs.

The framework could play a critical role in the retrofitting phase. As the building sector becomes proactive, a robust sensor network is required for future flexibility services. However, retrofitting robust sensor networks into old buildings is often hindered by the complex rewiring. As demonstrated in the case study, the deployment of virtual sensors, such as the inferred hydraulic mass flow rate, allows facility managers to upgrade legacy systems by using non-intrusive measurements, effectively bypassing the need for disruptive physical interventions.

Besides, the framework provides a robust foundation for fault detection. Instead of relying on static thresholds, the system can continuously cross-validate sensor readings by treating the target measurement as an unknown variable. A significant residual between the measured and virtual values serves as a high-confidence indicator of anomalies.

Limitations and future works

Although the proposed framework has shown potential strengths in different applications, there are still some assumptions that simplify the modeling. First, in the framework, the components are governed by theoretical physical laws; however, the uncertainties in the real practice are not considered. Moreover, some sensors are installed for safety reasons (e.g., sensors to prevent freezing), and this aspect needs to be taken into account when designing or calculating the redundancy of a sensor network. In addition, another limitation is that the energy loss is simplified to a parameter, which is not always constant in real practice. Therefore, stochastic modeling of the physical governing equations could be considered for future studies.

Future works could also focus on the coupling of semantic models (e.g., Knowledge Graphs and ontologies) with the framework for automating the development. One promising avenue for automating graph construction is the integration with established semantic building data models, such as Brick Schema. Brick Schema provides a standardized ontology for representing building energy systems, equipment, and sensor relationships using RDF-based knowledge graphs, where entities' interconnections are explicitly encoded as typed nodes and edges. This structured representation maps naturally onto the graph formulation proposed in this study: Brick's equipment classes (e.g., *brick:Heat_Exchanger*, *brick:Air_Handler*) correspond directly to the component set $\mathcal{C}$, while its point classes (e.g., *brick:Temperature_Sensor* and *brick:Flow_Sensor*) populate the variable set $\mathcal{V}$, and the *brick:feeds* or *brick:isPartOf* relationships define the edge set $\mathcal{E}$. Therefore, to ensure the scalability, the key focus for future studies is to identify entities' interconnections regardless of complexity of the system, from existing semantic models. Once the graph is constructed, the observability propagation algorithm could be integrated with BMS as a software toolbox.

Conclusion

This study proposed a graph theory-based framework to systematically exploit the inherent physical consistency in building energy systems, aiming to reduce reliance on

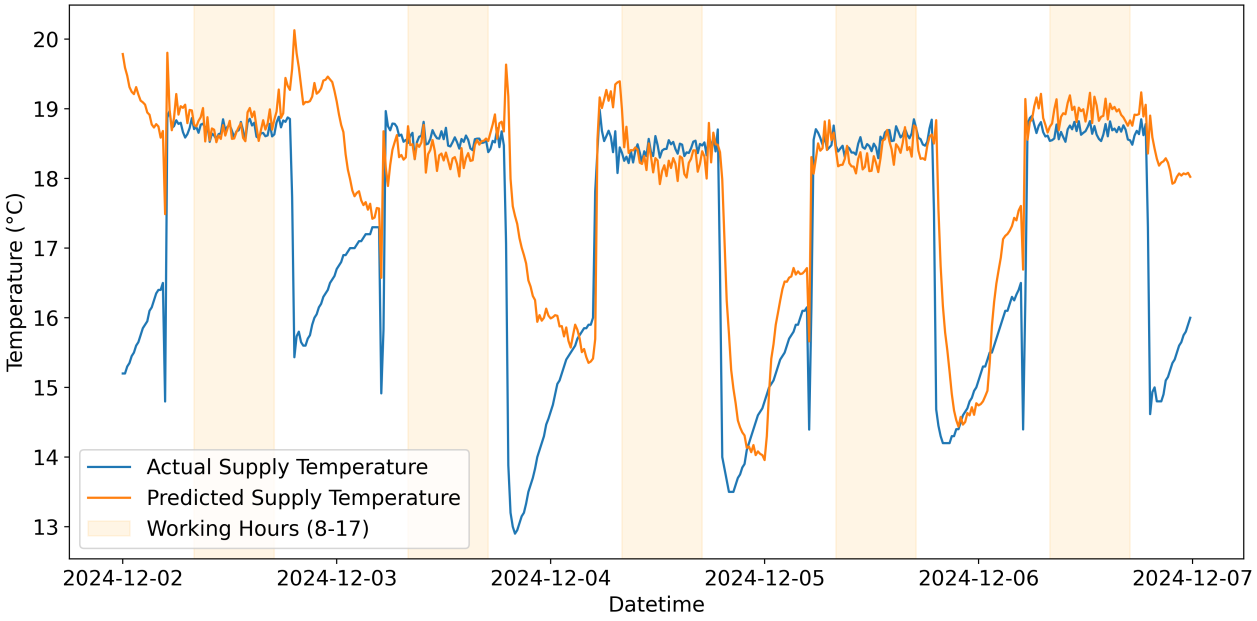

Figure 4: The validation results for 1 week.

comprehensive physical sensor networks. The main findings are as follows:

- By abstracting system topology as a bipartite graph, the framework bridges governing physical laws with measurement variables, transforming sensor networks from isolated measurement points into a physically consistent information system.
- The framework enables analytical identification of observable and redundant variables through an iterative observability propagation process. Compared to data-intensive or high-fidelity modeling approaches, the proposed framework is topology-driven, generalizable, and requires minimal calibration, making it suitable for scaling up to different Heating, Ventilation, and Air Conditioning (HVAC) systems.
- The framework provides a foundation for sensor network optimization and analytical redundancy throughout the building's lifecycle, including cost-effective sensor network design/retrofitting, and robust fault detection in building energy systems.

SEMANTIC MAPPING OF REQUEST FOR INFORMATION (RFI) TO BIM ELEMENTS WITH LARGE LANGUAGE MODELS

Limon Paul Joy, Farzaneh Zarei, and Mazdak Nik-Bakht
Department of Building, Civil & Environmental Engineering, Concordia University, Montréal, Québec, Canada

Abstract

Requests for Information (RFIs) remain a critical yet poorly integrated component of construction workflows, typically managed as unstructured text disconnected from Building Information Modeling (BIM) data. Existing studies primarily focus on reducing RFI frequency or response time, with limited focus on linking RFI content to specific BIM elements. This study presents a data-driven framework that combines large language model (LLM)-based intent extraction with BIM metadata reasoning through a staged matching pipeline. By separating semantic cue extraction from rule-based element selection, the framework enhances interpretability and robustness. Validation on experimental and real-world datasets demonstrates reliable element and family-level retrieval.

Introduction

The Request for Information (RFI) is a formal communication procedure to seek information, clarification, or resolution of uncertainties arising in construction. As an essential communication tool, RFI addresses discrepancies, prevents misunderstandings and reduces the risk of delays, claims and cost overruns. Typically, RFIs are initiated by contractors or subcontractors and directed towards designers or consultants to clarify ambiguities in designs, specifications, or constructability issues. The most common reasons for issuing an RFI are unclear specifications, design element contradictions and unforeseen field conditions (Hanna *et al.,* 2012). Despite this significance, RFIs are widely recognized as an inefficient process in project information flow and design coordination. Mohamed *et al.,* (1999) estimated a mean time of 17-person hours to process a single RFI. The cumulative impact of RFI related delays can be substantial at the project level. Total RFI response delays in a project can account for up to 10% of the overall project duration (Papajohn *et al.*, 2018). One of the primary reasons for this inefficiency is the RFI process being largely manual and document centric. Designers are often required to search through multiple sets of drawings, specifications, and revisions to identify the issue raised in an RFI, assess its implications, and issue a response. This fragmented and manual workflow contributes to elongated response times and a lack of traceability between RFIs and the affected building elements.

On the other hand, building information modeling (BIM) has reshaped the construction industry by introducing a digital framework for integrated project management. BIM is a digital representation of the physical and functional characteristics of a facility, which acts as a shared knowledge base for forming reliable decisions throughout its lifecycle, starting from the conceptual stage to its demolition (*NBIMS-USTM V3 – National Institute of Building Sciences*, 2026). Its significance in the construction industry lies within its ability to integrate data across disciplines within a collaborative environment. Furthermore, it provides a visual and spatial context that enhances the understanding of complex design information, enabling stakeholders to interpret the design more effectively than through documentation alone.

Despite their importance in construction practice, the interaction between RFIs and BIM remains limited. While BIM provides structured and spatially rich project information, RFIs are largely text-based and context-poor. Existing research has focused on improving RFIs within BIM-enabled environments, with limited attention to their systematic integration. This creates a noticeable gap in methods for semantically linking RFIs to BIM elements to support faster interpretation, more accurate responses, and improved traceability. Addressing this gap is increasingly relevant with the growth of digital project data and advances in information extraction and semantic analysis.

This research proposes an approach to link RFIs with BIM models to enhance the efficiency and effectiveness of the RFI process. It introduces a data-driven digital framework that utilizes large language models (LLMs) to semantically interpret unstructured RFI text and link it to structured BIM elements, enabling more efficient and context-aware RFI handling. The role of LLM is limited to extracting structural cues for keyword extension to guide the matching, while the core matching is driven by rule-based BIM reasoning. By establishing a direct connection between textual RFI content and BIM-based building elements, the proposed approach seeks to reduce manual effort, shorten response times, and improve information consistency across project stakeholders.

Background review

BIM use cases in RFI

Building Information Modeling (BIM) is one of the most widely adopted digitalization tools for enhancing collaboration in the Request for Information (RFI) process, as well as for identifying design and coordination issues that typically generate a high volume of RFIs. Previous studies have demonstrated that improved coordination within BIM models can significantly reduce the number of RFIs by minimizing design ambiguities and information gaps (Bhat *et al.,* 2017). Similar results were also found by Dan *et al.,* 2023,where the usage of BIM introduced better interdisciplinary design coordination, effective clash detection, and enhanced communication among project stakeholders, leading to reduced RFI frequency. Furthermore, studies investigating the combined implementation of BIM and lean construction principles reported reductions in RFI numbers of up to 70%, highlighting the potential of integrating digital modeling with process optimization strategies (Bhat et al., 2018). Beyond reducing RFI volume, BIM supported workflows also contribute to faster response times, improved design decisions, and more proactive issue resolution, thereby improving overall project efficiency. Morales *et al.,* (2022) identified reactive and proactive uses of BIM application to mitigate common issues raised in RFIs through 3D coordination, specialty design, design review and as-built modelling. BIM uses have also proved to have better financial management regarding RFI related costs. Giel *et al.,* (2013) quantified the return on investment of BIM by comparing BIM-based and non-BIM projects of similar scale, illustrating that BIM enabled projects resulted in reduced RFIs, improved coordination, fewer change orders, and faster response times, leading to significant cost improvement.

However, although substantial research has been conducted on BIM enabled environments and their impacts on the RFI process, the majority of existing studies have primarily focused on three key performance aspects of RFIs: cost, frequency, and response time. These studies have largely evaluated BIM as a coordination and visualization tool to reduce the overall burden of RFIs, rather than examining how RFI itself can be integrated within digital project environments. One of the few studies which focused on the linkage was conducted by Mao *et al.,* 2007 for generating structured RFIs by linking them to structured models such as IFC, enabling easier navigation and retrieval of relevant information for construction professionals. However, despite these early contributions, existing approaches remain largely conceptual and limited in scope, with minimal emphasis on automation. They do not adequately address automated interpretation of unstructured RFI text or its systematic linkage to BIM elements, leaving the process reliant on manual effort. The absence of explicit RFI–BIM connections limits traceability and hinders automated impact assessment.

Integration of LLM within BIM design environment

Recent advances in large language models (LLMs) have enabled new forms of interaction with BIM by enabling semantic interpretation of natural language and facilitating more intuitive interaction with complex model data. This capability has motivated growing research interest in integrating LLMs with BIM to improve accessibility, automation, and decision support. Existing research has predominantly applied LLMs to natural-language BIM querying, conversational model interaction, and parametric design generation ((Zheng *et al.,* 2023; Fernandes *et al.,* 2024; Jang *et al.,* 2024; Ko *et al.,* 2025). While these approaches demonstrate clear benefits in terms of usability, they remain largely confined to design centric use cases and do not address construction communication connections. More recent work has extended LLM applications toward regulatory and compliance-related BIM workflows. LLM-based frameworks have been proposed for automated interpretation of building codes (Yang *et al.,* 2024; Madireddy *et al.,* 2025) and autonomous compliance checking, demonstrating the potential of LLM agents to retrieve BIM data, execute rule checks, and support model revisions through natural-language interaction. Parallel to these developments, prior research has explored the application of natural language processing techniques to analyze RFI documents, focusing on extracting themes, classifying issues, and identifying key entities from unstructured text (Afzal *et al.,* 2023; Afzal *et al.,* 2024). These studies demonstrate the potential of data-driven approaches to analyze RFI datasets through automated topic discovery, issue classification, and entity extraction. In particular, unsupervised topic modelling identified recurring construction issues, while deep learning-based pipelines have been used to classify RFIs by project phase and issue type and extract key entities out of them.

Despite these advances, existing research primarily focuses on design generation, model querying, visualization, and compliance checking. Limited attention has been given to construction communication processes, and in particular, automated linkage of unstructured construction documents and texts to specific BIM elements. This gap limits traceability and automation in construction communication workflows and demonstrates the need for model centric approaches to explicitly connect construction documentation, such as RFIs, with BIM elements.

Methodology

This study proposes a data-driven framework linking unstructured RFIs to corresponding BIM elements, implemented through a Revit-based prototype. The framework integrates three components: (i) extraction of BIM element metadata, (ii) RFI preparation and intent extraction using an LLM, and (iii) a multi-stage matching and scoring pipeline combining deterministic rules with embedding-based semantic similarity to identify the best-matched elements. The LLM is used solely for intent extraction; while matching and final selection are governed by explicit rules and BIM metadata. The staged

pipeline was created based on an initial review of the RFI dataset, which indicated its unstructured and variable nature, requiring a stepwise refinement approach. This staged method evaluates high confidence cues first and progressively narrows the candidate through contextual and semantic filtering, with integrated shortlisting to maintain computational efficiency for large BIM models. *Figure 1* depicts the overall architecture of the proposed prototype. Overall, the prototype operates across three environments. BIM element extraction, visualization, and selection are performed within Revit. Structured cues extraction from RFI text is handled by a GPT-based language model. The multistage matching, scoring, and data management are executed in an external Python-based environment that coordinates interactions between the BIM model and the language model. Finally, a human-in-the-loop interface enables users to review and validate the final element selection.

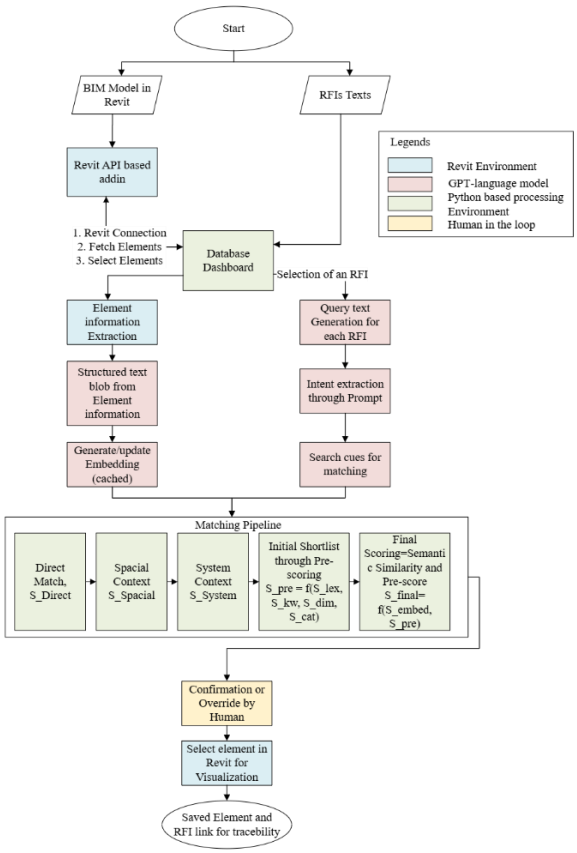

Figure 1: The overall architecture of the proposed prototype

Extraction of BIM element data from Revit model

Autodesk Revit was used as the BIM environment due to its widespread industry adoption. BIM element extraction is a critical step, enabling the transfer of structured geometric and semantic information to external components for semantic analysis and element matching.

BIM model data retrieval

To integrate the BIM model with the LLM-based matching framework, a custom C# Revit add-in was developed using the Revit API. The add-in acts as an HTTP bridge, exposing model data through endpoints for external retrieval, selection, and visualization of elements. This approach was adapted due to Revit API limitations, as API calls must run on the main thread, where computationally intensive tasks such as language processing and embedding generation would otherwise block the interface and degrade performance (*Help | Deployment Options | Autodesk*, 2026; *Help | Revit API Developers Guide | Autodesk*, 2026). The bridge supports three primary operations: Revit connection verifier, element data extraction and selection and highlighting elements.

Element metadata extraction

Using the extraction endpoint, BIM elements are retrieved in JSON format. For each element, a comprehensive set of attributes is collected to reflect how elements are typically referenced in RFIs and coordination documents. *Table 1* includes the parameters extracted from the element metadata.

Table 1: Extracted BIM element metadata parameters.

Category	Extracted attributes
Identifiers	UniqueId, Element Id
Semantic attributes	Category, Family, Instance
Contextual attributes	Level, Room, Space
Tags and Labels	Mark, Type Mark
System attributes	System of MEP elements
Spatial proxies	Nearest grid/axis reference

Structured textual representation and embedding

For text-based comparison, each BIM element's JSON data is converted into a structured textual representation (text blob), organizing key attributes into a normalized format. These text blobs support both (i) lexical/keyword-based matching and (ii) embedding-based similarity computation. Text embedding refers to the transformation of textual data into numerical vector representations that capture semantic meaning. BIM element embeddings were generated using *text-embedding-3-small* and *text-embedding-3-large* for performance comparison and are cached in the database. The embeddings are only recomputed when BIM metadata changes.

RFI data preparation and intent extraction

For semantic mapping of RFI documentation with structured BIM, RFI data is standardized and preprocessed into a consistent textual representation, making it suitable for analysis. Subsequently, structured intent cues are extracted from the normalized RFI text using LLM models.

RFI data preparation

RFIs are imported to the dashboard in a tabular format containing RFI identifier, subject/discipline, question, answer and status. For each RFI, these fields are combined into a single query text to ensure that the contextual information recorded throughout the RFI is incorporated into the matching process. Text normalization is applied to remove accents, standardize

casing, and normalize whitespace. This preprocessing of the text mitigates inconsistencies in style, abbreviations and formatting found in real-life practice.

Extract intent cues from RFI through LLM

For extracting relevant semantic cues for BIM element matching from RFI texts, two different large language models (GPT 4.1 and GPT-4.1-mini) were used to extract structural intent cues. Structured intent cues are predefined, machine-readable attributes (e.g., primary object, keywords, location) extracted from RFI text to guide downstream matching and reasoning. The normalized RFI text is fed into the model using a predefined prompt that specifies the exact structure and content of the expected output. The prompt instructs the model to return a strictly formatted JSON object containing only intent-related cues commonly expressed in RFIs, including discipline, primary object description, keywords and synonyms, spatial context (e.g., levels, grid references), and any explicitly mentioned dimensions or quantities. The model is explicitly restricted from inferring BIM element identifiers, Revit categories, or specific element instances. *Figure 2* illustrates the prompt used for intent extraction.

```
You are a construction manager.
Extract structured intent from the RFI text below.
Return ONLY valid JSON with these fields:
- action: one of [move, install, modify, remove, verify, document, clarify, other]
- primary_object: a short canonical English noun phrase (e.g., "pendant light", "skylight", "door", "circuit breaker")
- keywords: 5-12 keywords/phrases relevant to matching the correct element (include synonyms; include abbreviations)
- location: location info if mentioned (e.g., level, zone, direction, grid/axis), or empty string
- dimensions: dimensions or quantities if mentioned (e.g., 80 mm), or empty string
- discipline: one of [architectural, structural, mechanical, electrical, plumbing, general, unknown]
- confidence: number between 0 and 1
Rules:
- Do NOT guess BIM element IDs or Revit categories.
- Do NOT suggest specific element instances.
- Return JSON only. No extra text.
RFI TEXT: {RFI_TEXT}
```

Figure 2: Prompt used for intent extraction from RFI text.

In this process, the LLM does not participate in element selection; instead, extracted intent cues guide matching by expanding keywords, activating discipline-specific filters, and identifying spatial or dimensional constraints. Intent influences scoring only when supported by corresponding BIM metadata, and since the LLM cannot introduce new elements or identifiers, hallucinations have no direct impact. This design preserves transparency and limits hallucination effects through rule-based decision-making.

Multistage matching and scoring pipeline

The proposed framework employs a five-stage scoring and matching pipeline to select the best matching candidate. Early stages of this pipeline rely on explicit, high confidence cues while later stages incorporate semantic scoring. This staged design improves interpretability, computational efficiency, and robustness.

Direct identifier matching

The first stage evaluates if the RFI text explicitly mentions BIM identifiers such as ElementId, UniqueId, Mark or Type Mark. These identifiers are matched exactly against the cached BIM metadata. When the match is detected, a direct matching score S_{direct} is assigned.

$$S_{direct} = \begin{cases} 1.00 \; if \; ElementID \; match \\ 0.80 \; if \; UniqueId \; match \\ 0.60 \; if \; Mark \; match \\ 0.55 \; if \; Type \; Mark \; match \\ 0 \; if \; no \; match \end{cases} \quad (1)$$

If multiple identifiers are matched for the same element, their scores are accumulated. Because explicit identifiers provide the highest confidence linkage, if one or more candidates are identified at this stage, the pipeline terminates early and downstream stages are skipped.

Spatial context match

If the RFI contains explicit spatial references such as level, room or grid/axis identifiers, the spatial context matching is used. These references are extracted from the RFI and compared against corresponding BIM element attributes, including levels, associated room or space, and nearest axis/grid references derived from the model. Elements inconsistent with the referenced spatial context are penalized or filtered.

To compute axis/grid distance, each element represented by a point, p (location or centroid) and its distance to axis/grid, g is computed in XY plane as the minimum distance to its segment,

$$d(p, g) = \; min_{s \in g} \, dist_{XY} \, (p, s) \quad (2)$$

Here, s represents a segment of the axis/grid curve. Based on this, the nearest numeric and alphabetic axis/grid are identified and used for the matching.

Finally, A spatial context matching score, $S_{spatial}$ is computed as,

$$S_{spatial} = \begin{cases} +0.25 \; if \; match \\ -0.25 \; if \;\; conflicts \\ 0 \; if \; no \; match \end{cases} \quad (3)$$

To preserve recall, if the filter eliminates all the candidates, the unfiltered candidate set is retained.

System context match

For mechanical, electrical, and plumbing (MEP) related RFIs, system identifier provides an important functional constraint. When system related keywords are present in the RFI, alignment between the element system name and the extracted intent is evaluated. A system context matching score, S_{system} is computed as,

$$S_{system} = \begin{cases} +0.15 \; if \; match \\ -0.10 \; if \;\; system \; is \; missing \\ 0 \; if \; otherwise \end{cases} \quad (4)$$

This stage reduces cross-disciplinary mismatches that may arise from semantic similarity alone.

Prescoring for shortlist

Remaining candidates from the past three stages are ranked based on a pre-scoring process which combines multiple scoring.

First, lexical similarity within the RFI query text, Q and element text blob, E is computed as,

$$S_{lex} = \frac{|Token \; (Q) \cap Token \; (E)|}{|Token \; (Q)|} \quad (5)$$

On the contrary, intent cues derived from RFI texts are grounded against element metadata. The keyword boost score, S_{Kw} is computed as,

$$S_{kw} = \min(0.35, 0.05 x Nos\ of\ matched\ keywords \quad (6)$$

Furthermore, a dimensional match is computed if the numeric values mentioned in the RFI is a match the element metadata. The score,

$$S_{dim} = \begin{cases} +0.10\ if\ dimention\ match \\ 0\ if\ no\ match \end{cases} \quad (7)$$

Additionally, sometimes, material names exhibit strong lexical and semantic similarity with RFI text. This induces false positives giving materials as the best match. To avoid this issue and as the scope was to connect physical BIM design elements, material-level entities are explicitly penalized. The score, S_{cat},

$$S_{cat} = \begin{cases} -0.35\ if\ category\ \{\text{Materials, Analytical Surfaces}\} \\ -0.20\ if\ category = Mass \\ 0\ if\ otherwise \end{cases} \quad (8)$$

Finally, an overall prescore is calculated as a weighted sum of all the scores, as S_{pre},

$$S_{pre} = w_1 \times S_{lex} + S_{spacial} + S_{system} + S_{kw} + S_{dim} + S_{cat} \quad (9)$$

Here, the lexical similarity score was assigned a weight $w_1 = 0.35$ to reflect its role as a supporting signal rather than a dominant factor within the scoring pipeline. Lexical overlap is effective when RFIs explicitly mention element names, families, or parameters, but is sensitive to variations in terminology and phrasing. A moderate weight supports early ranking without overshadowing contextual, spatial, and semantic cues, while only top-ranked candidates are passed to the final stage, improving efficiency and accuracy.

Embedding based semantic similarity

After initial shortlisting through the prescoring, semantic similarity is computed using embedding vectors generated by text-embedding-3-small model. Both the RFI query text, Q and the element text blob, E are embedded into a shared vector space. Semantic similarity, S_{embed}, is computed using cosine similarity,

$$S_{embed} = \frac{V_Q . V_E}{|V_Q| . |V_E|} \quad (10)$$

Final ranking and user validation

The final matching score S_{final} is computed by incorporating embedding similarity with lexical similarity as well as remaining evidence-based scorings, while avoiding double counting of the lexical score. Here, a weight is used to prioritize the semantic score instead of the lexical score, as in some instances, the lexical score can overpower due to keyword matches in the element data. In this study, the weight w_2, was counted as 0.75, which can be increased or decreased depending on the user's requirement in the prototype dashboard to put more importance on either the semantic score or the lexical score. However, the weights and scorings were empirically chosen and no sensitivity analysis was conducted.

$$S_{final} = w_2 \times S_{embed} + (1 - w_2) \times S_{lex} + (S_{pre} - (1 - w_2) x\ S_{lex}) \quad (11)$$

Through the candidate final scoring, candidate elements are listed accordingly in an interactive interface. The next step includes user validation, where the user may accept the top-ranked element or select the appropriate one from the candidate list as the best. This step includes a human-in-the-loop validation mechanism that allows the user to review and confirm the prototype's suggestion. Upon confirmation, the selected element is selected in Revit and the confirmed RFI element linkage, along with all score components, is stored to support evaluation and traceability.

Evaluation of RFI-to-BIM Mapping

To determine the feasibility of this prototype, two BIM environments were considered: (i) an experimental Revit architectural Model with manually created RFIs based on the design, (ii) A real project already being completed with a set of real project RFIs.

Experimental BIM model with generated RFIs

For the first environment, an experimental architectural model was used to assess the baseline performance. Ten RFIs were manually created based on the model content to represent typical RFIs. These RFIs intentionally exclude explicit element identifiers (e.g., ElementId or UniqueId) and rely on descriptive cues commonly found in practice, such as element type, approximate location *(e.g.,* west-side skylight*),* or dimensional information *(e.g.,* timber column 228x502 mm*).* This setup ensured matching based on semantic and contextual interpretation rather than direct identifier matching. As the RFIs were created directly from the known model content, a ground-truth correspondence between RFIs and BIM elements could be explicitly defined. Figure 3 illustrates the experimental model, prototype dashboard with intents extracted from the RFI, best results found through the matching pipeline and the selection in Revit through the prototype environment. For quantitative evaluation of the performance, successful linkage was defined using two criteria: 1. Exact element match, where the top-ranked candidate corresponds to the intended BIM element, and 2. Partial match where the correct family or category is identified despite incorrect instance level selection.

The results demonstrate that the prototype successfully identified and ranked relevant BIM elements for the majority of RFIs. Out of 10 RFIs, 8 were successfully linked to the correct BIM elements, while 2 were unsuccessful. In one failed case, the correct family was identified but not the exact instance, and in the other, no element was matched. Treating exact matches as true positives yields a Top-1 accuracy of 80%, increasing to 90% when partial family or category matches are included, indicating effective narrowing of the candidate search space indicating effective narrowing of the candidate search space. From a retrieval perspective, each RFI was treated as a single query, yielding a precision and recall of 0.80. However, due to the limited sample size these metrics demonstrate feasibility rather than

generalizable performance. Analysis of the two unsuccessful cases shows reliance on room-level spatial references, where the absence of instance-level room associations prevented spatial grounding. This highlights the dependency on BIM metadata quality rather than limitations in semantic matching. Overall, the staged pipeline effectively prioritizes lexical and contextual cues, enabling accurate ranking when sufficient metadata is available.

Real project model with issued RFIs

The second environment involved a real construction project with an existing BIM model and a set of real RFIs, issued during the project lifecycle. The project had a total of 524 RFIs in disciplines from architectural, structural, building envelope, electrical, plumbing, mechanical and civil works. Unlike the experimental case, these RFIs exhibited greater linguistic variability, incomplete references, informal phrasing, and cross-disciplinary content, reflecting the complexity of real-world construction communication.

As the disciplines were modeled in separate Revit files, three were selected for implementation: architectural, structural, and building envelope, generating a total of 316 RFIs. In practice, most RFIs were communicated via emails with limited textual detail, with key context provided in separate marked drawing attachments. As this study considers only RFI text, a limited subset contained sufficient semantic information for meaningful linkage to BIM elements. After carefully screening all available RFIs, a subset of 74 RFIs was obtained where the affected design elements could be reasonably inferred. These RFIs were selected based on sufficient textual and contextual information for meaningful linkage. In most cases, identification relied on indirect spatial references (e.g., grid/axis and level information) rather than explicit element identifiers, with only a limited number of RFIs including detailed attributes such as tags, marks, or precise location descriptors that enabled direct mapping. The analysis was conducted under two language model configurations: (i) GPT-4.1 with text-embedding-3-large and (ii) GPT-4.1-mini with text-embedding-3-small, to compare the performance of higher-capacity and lightweight models. Additionally, both configurations were evaluated under two conditions: with intent extraction from RFI text and without intent extraction.

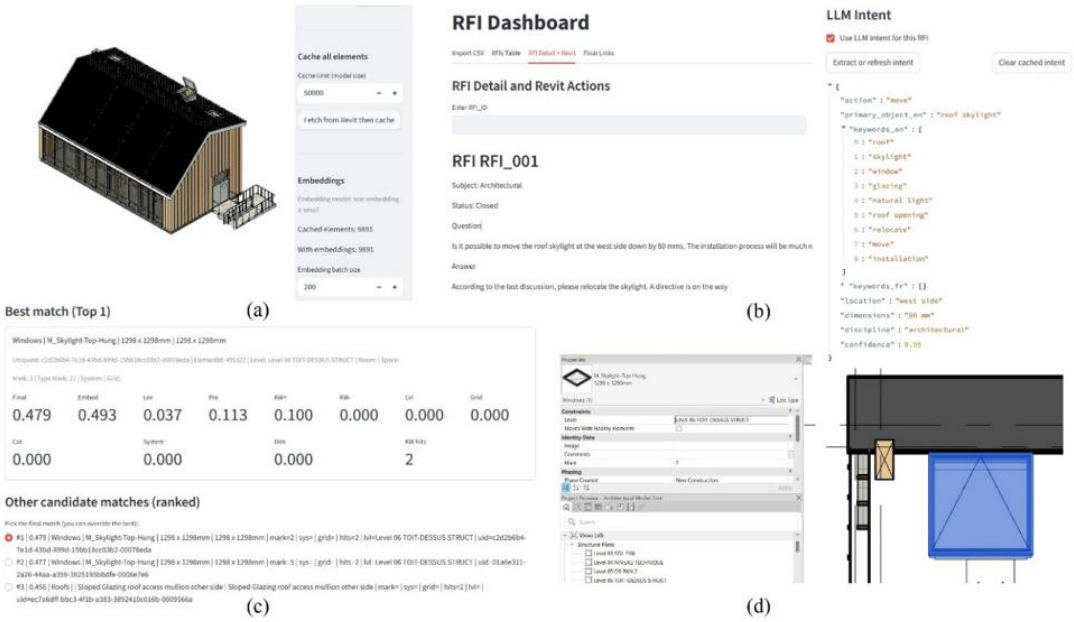

Figure 3: (a) Experimental BIM model, (b) Prototype dashboard with extracted intent from RFI text, (c)Ranked candidate list through the matching pipeline with best match element highlighted separately, (d)Best element selected in Revit

This experimental design enables a systematic evaluation of whether increased model capacity leads to measurable improvements in handling ambiguous and unstructured RFIs.

The results indicate that the framework is particularly effective in narrowing down candidate elements at the category or family level, rather than consistently achieving exact element-level matching. Exact element-level matching was achieved in a limited number of cases, with 4 RFIs correctly linked under configurations with intent extraction and 3 without across both LLM models. These cases typically involved RFIs with explicit identifiers such as element marks, tags, or clear location references. For example, the RFI *"The door supplier from Groupe Brosseau requests clarification on the door pair C-4EX6…?"*, was accurately matched by all models to the element instance due to the presence of specific mark and level information. Although exact matching was limited, the models performed well at category or family-level identification. Of the evaluated RFIs, 19 were correctly predicted by all configurations, 52 by at least one model, and only 1 was not correctly predicted by any model. This demonstrates effective narrowing of the search space by linking RFIs to semantically and functionally similar BIM elements, consistent with real scenarios where RFIs rely on indirect spatial cues. RFIs such as *"Here is a question*

for the architect. What is the window type for R01? According to the elevation and the tab..” were correctly linked by all models due to matching identifiers in both text and BIM metadata. By contrast, a failure case was observed when both the RFI text and BIM metadata lacked sufficient alignment of detail. For instance, the RFI describing parapet conditions based on multiple drawing references and attachments, the absence of explicit identifiers and insufficient corresponding BIM metadata prevented all models from achieving both element-level and category-level matches. This highlights the dependency of the approach on the availability of consistent textual and model-based information. Comparison across models shows that intent extraction does not significantly improve performance. For GPT-4.1, accuracy remains unchanged at 60.27% with and without intent. By contrast, GPT-4.1-mini shows a slight decrease when intent is used with 56.16%, compared to 58.9% accuracy with intent extraction not being used. This suggests that performance is primarily driven by rule-based matching and BIM metadata rather than LLM-derived cues. Additionally, GPT-4.1 shows more stable performance, while GPT-4.1-mini is slightly sensitive to intent inclusion, indicating greater consistency in higher-capacity models. The results indicate that although exact element-level matching is challenging due to ambiguous RFIs, the framework effectively retrieves relevant candidate elements. The high number of RFIs correctly predicted by at least one configuration demonstrates robustness, while the few unmatched cases indicate strong baseline performance even with limited context. Although the prototype shows promising feasibility by narrowing candidates to relevant categories or families, further validation with larger real-world datasets is required.

Discussion

The study demonstrates that linking unstructured RFI text to BIM elements is feasible under appropriate data and modeling conditions. The prototype contextualizes RFI information within the BIM environment by restricting the LLM to intent extraction and relying on rule-based matching with BIM metadata, ensuring transparency and minimizing hallucinations. Analysis indicates that the primary challenge in automated RFI–BIM linkage is not semantic interpretation, but the misalignment between how RFIs are authored and how BIM models represent design information. In the experimental setting, RFIs with clear element, spatial, or dimensional cues were accurately linked, whereas in the real project, references to repeated elements or design intent led mostly to category- or family-level matches with few exact matches. This observation highlights a key limitation of the current framework, which assumes a primary linkage between an RFI and a single BIM element. While this supports structured evaluation, it does not fully reflect real-world practices, where RFIs often relate to multiple elements or assemblies. Accordingly, extending the framework to support multi-element associations is an important direction for future work. A second major limitation is that many RFIs rely on marked drawing attachments for context, making textual content alone insufficient for interpretation. As the current framework operates primarily on text and does not incorporate such attachments, integrating multimodal data sources, including annotated drawings and visual inputs, is a key direction for future research to enhance contextual understanding and matching accuracy. Another limitation of this study is the dependency on the quality and completeness of BIM metadata. The framework relies in part on BIM metadata for rule-based matching, and although supplemented by semantic and lexical similarity measures, its performance may be affected in cases of incomplete or inconsistent model information. A further limitation is that matching weights were empirically selected without sensitivity analysis, which is identified as a future study.

Overall, the findings indicate that RFI BIM linkage is most effective with explicit and well-defined BIM representations. A key limitation of this study is its reliance on a relatively limited dataset, which may affect generalizability. The results underscore the importance of high-quality BIM data, where consistent categorization, complete parameters, and reliable spatial context enhance RFI grounding. In practice, family- or category-level retrieval helps narrow large models to relevant elements for efficient review. Rather than fully automating instance-level matching, the value lies in enhancing human interpretation through improved traceability and context. Future work will address multi-element linking, integration of drawing or multimodal inputs, and validation on larger, more complex real-world datasets.

Conclusion

This study presents a data-driven framework for semantically linking unstructured RFI text to BIM elements using LLM-based intent extraction and BIM metadata-driven reasoning. In the matching pipeline, the LLM is used for intent extraction, while core element matching and decision-making are governed by rule-based BIM reasoning. By combining intent extraction with a rule-based pipeline, the prototype enables context-aware linkage while limiting AI hallucination. Validation with experimental and real-world data demonstrates feasibility and its potential to improve RFI traceability and spatial understanding in BIM environments. The findings suggest that effective integration of LLMs in BIM workflows requires constraining their role to semantic interpretation, while relying on domain knowledge and BIM reasoning for decision-making. Although limitations related to BIM data completeness, vague RFIs, and single-element linkage remain, they reflect real industry conditions and guide future research. Overall, this work provides a foundational step toward more structured, transparent, and traceable RFI–BIM integration.

EXPLAINABLE AI FOR REQUIREMENT TRACEABILITY IN CONSTRUCTION SYSTEMS ENGINEERING

Timon Kuijper, Ranjith K. Soman, Tong Wang, and Sander van Nederveen
Delft University of Technology, Delft, the Netherlands

Abstract

Requirement verification in integrated contract models, such as Design and Construct, remains a manual, document-centric, and error-prone activity. While technical verification through Automated Code Compliance has advanced significantly, process requirements are typically verified through human inspection of textual documentation. This research addresses this gap by developing a novel artefact architecture that integrates general-purpose Large Language Models, the RASE mark-up language, and Knowledge Graphs to automate traceability between contractual obligations and contractor deliverables. Tested through iterative Design Science Research, the final prototype achieved a precision of 1.000 and accuracy of 0.968, offering a transparent, "white-box" framework for contractual auditability.

Introduction

Requirements traceability – the ability to track relationships between requirements and project deliverables – is essential in systems engineering and contract management for validating that project outcomes meet the specified requirements from start to finish (SixSigma, 2025). In large construction projects, the contractor must demonstrate that the delivered work complies with the Employer's requirements. Ensuring every requirement is satisfied (and providing evidence for it) is critical to project success in terms of cost, time, and quality (Hoehne, 2014). Traditionally, traceability of process-oriented requirements in construction is maintained manually through document management and version control systems (Guru, 2025). This manual approach is time-consuming, error-prone, and difficult to scale, especially given the growing volume of digital project documents and the involvement of many stakeholders. As a result, full end-to-end traceability is often impractical in current practice, and important links between requirements and evidence may be missed or lost.

Recent advances in Artificial Intelligence (AI), particularly Large Language Models (LLMs), offer new opportunities to automate requirements traceability by automatically recognizing and maintaining semantic links between textual artifacts. Research on AI-based traceability to date has focused largely on automated code compliance checking for technical requirements and on contract analysis tools, but there is a notable gap in applying AI to link process requirements with verification evidence in construction projects (Karim-Jallow et al., 2014; Ismail et al., 2017; Zheng et al., 2025). No prior work, to the authors' knowledge, has systematically explored a zero-shot LLM approach for automatically verifying process requirements in design-and-construct contracts by linking them to evidence in contractor documents. Moreover, the black-box nature of powerful LLMs raises concerns about transparency and explainability of AI-generated traceability links.

This paper addresses the above gap by presenting an AI-assisted requirement traceability approach that leverages a general-purpose LLM combined with a knowledge graph to automatically link contractual process requirements to corresponding evidence in project documents. The approach is designed to improve the efficiency and accuracy of traceability while also enhancing transparency (through a formal knowledge graph representation of the trace links). We developed and evaluated a prototype tool following a Design Science Research methodology, with iterative refinement and expert feedback. In a case study, the prototype achieved high accuracy in identifying valid requirement-evidence links, indicating that such an AI-assisted traceability system can significantly reduce manual effort and error in construction compliance verification.

The remainder of the paper is structured as follows. Background section reviews related literature on requirements traceability and AI applications in construction, identifying the research gap. Methods section explains the Design Science Research method used to develop and evaluate the solution. Implementation section describes the AI-assisted traceability tool, including its architecture and components. The following section presents the results of evaluating the tool's performance and usability. The final section discusses the findings, implications for research and practice, limitations, and future work

Literature review

Requirements traceability in construction

Requirements traceability refers to the ability to link requirements to corresponding artifacts that demonstrate their implementation or verification (Madni and Sievers, 2018). In construction projects, particularly within a Systems Engineering framework, traceability ensures

that contractual requirements are systematically verified against design documents, management plans, and other deliverables (SixSigma, 2025). Maintaining these links provides transparency, supports impact analysis, and reduces the risk of overlooked obligations.

In practice, traceability in construction remains largely manual. Engineers typically rely on traceability matrices, spreadsheets, or document annotations to map requirements to evidence (Guru, 2025). This process is time-consuming and prone to omissions, especially in large Design & Construct projects involving extensive documentation (Karim-Jallow et al., 2014). Process-oriented requirements, which describe how work must be conducted rather than what must be built, are particularly challenging to verify because evidence is often embedded in lengthy textual documents rather than structured models. As a result, complete and continuously updated traceability is difficult to achieve in current industry practice.

AI approaches to compliance and traceability

Recent advances in natural language processing and Large Language Models (LLMs) have stimulated research into automated traceability and compliance checking. In software engineering, information retrieval and machine learning techniques have been used to recover trace links between requirements and code or design artifacts (Rempel and Mäder, 2016). More recently, retrieval-augmented generation approaches using LLMs have demonstrated improved trace link recovery performance (Hey et al., 2025). In the architecture, engineering and construction (AEC) domain, AI applications have primarily focused on automated technical code compliance checking using rule-based systems, ontologies, or BIM-integrated workflows (Ismail et al., 2017; Yang et al., 2023). Parallel research has explored contract analysis using knowledge graph-enhanced LLMs (Zheng et al., 2025). While these studies show the potential of combining semantic representations with LLM reasoning, they do not directly address automated verification of contractual *process* requirements through evidence linking.

The RASE (Requirement-Applicability-Selection-Exception) methodology provides a structured way to extract normative statements from regulatory and contractual texts (Hjelseth and Nisbet, 2011). RASE has been shown to support automated processing of construction regulations by isolating enforceable requirements. In parallel, knowledge graph representations have been proposed to model requirements and compliance relationships in a transparent and queryable manner (Wang and El-Gohary, 2023). These approaches suggest that combining semantic structuring techniques with AI-driven text understanding could enable more robust verification workflows.

Research gap

Despite progress in automated compliance checking and LLM-supported document analysis, limited research has addressed the automated verification of contractual process requirements in construction projects. Existing approaches either focus on technical design compliance, require significant rule engineering, or rely on supervised training data. The use of a zero-shot LLM approach, combined with a knowledge graph to produce auditable requirement–evidence mappings for process requirements, remains largely unexplored.

This paper addresses this gap by developing and evaluating an AI-assisted verification tool that automatically links contractual process requirements to supporting evidence in contractor documentation, using a hybrid LLM and knowledge graph architecture.

Method

This study followed the Design Science Research Methodology (DSRM) (Peffers et al., 2007) to develop and evaluate the AI-assisted traceability tool. Design Science Research (DSR) is a problem-solving paradigm that iteratively designs, builds, and evaluates artifacts (in this case, a software tool) to address identified problems, thereby contributing new knowledge. The research process was structured according to the DSRM steps proposed by Peffers *et al.* (Peffers et al., 2007):

(1) Problem Identification and Motivation: Through preliminary literature review and expert interviews, we established that manual requirement traceability in large construction projects is inefficient and error-prone, and that no adequate automated solution exists. The need for an AI-based approach was justified by the increasing volume of documentation and the potential of LLMs to interpret complex texts. We defined the core problem as: "How can AI support automated traceability between contractual process requirements and contractor documentation in construction projects?"

(2) Define Objectives for the Solution: Based on the problem analysis, we set functional and non-functional objectives for the artifact. Key functional objectives included: automatically identifying requirement statements in contract documents; extracting evidence of compliance from contractor documents; and establishing trace links between them. Non-functional objectives included a high degree of accuracy and recall in link identification (targeting at least 90 % accuracy and 90% recall to be comparable with manual quality), high precision (to minimize false positives, as an incorrect assertion of compliance is unacceptable), and usability/transparency for end-users. These objectives were operationalized into measurable success criteria (e.g., performance metrics and a usability score). We also aimed for the solution to be zero-shot, meaning it should work without project-specific training, relying on prompt engineering and general LLM capabilities, to facilitate adoption in new projects.

(3) Design and Development: We designed an artifact architecture that integrates a general-purpose LLM with a knowledge graph. The design and implementation details are described in following section. Importantly,

we adopted an iterative development approach (typical in DSR): the artifact went through multiple design iterations, each adding improvements or new features to overcome shortcomings identified in the previous iteration. For example, after an initial prototype (Iteration 1) showed low recall, we refined the prompt and graph constraints to ensure all requirements would be captured (Iteration 2). Further iterations introduced a confidence scoring mechanism and automated consistency checks. Throughout this process, design decisions were informed by both literature (e.g., using RASE mark-up and SHACL constraints as derived from prior work) and practitioner input.

(4) Demonstration: We demonstrated the artifact using a real-world case study. The case involved a Design and Construct infrastructure project in the Netherlands. The input documents included a Project Requirements document (a contract appendix listing process requirements from the Employer) and a Project Management Plan (PMP) submitted by the contractor as evidence of how requirements are addressed. The tool was used to automatically generate traceability links between the requirements and the PMP. Domain experts (project engineers) observed the demonstration to validate that the identified links correspond to actual compliance evidence.

(5) Evaluation: We evaluated the artifact's performance and utility using both quantitative and qualitative methods. Quantitatively, we measured classical classification performance metrics for the trace link predictions: True Positives (TP), False Positives (FP), True Negatives (TN), False Negatives (FN), accuracy, precision, recall, and F_1 score (harmonic mean of precision and recall). These metrics were computed by comparing the AI-generated links against a ground truth traceability set established via manual verification of the case documents. We applied this evaluation after each major iteration of the artifact. Qualitatively, we gathered feedback on usability and usefulness through a focus group and a survey. After the final prototype was demonstrated, $N = 5$ construction engineering professionals used the tool on sample queries and then filled out a System Usability Scale (SUS) questionnaire. The SUS provides a standardized score out of 100 for perceived usability. We also collected open-ended feedback about what users liked and what could be improved. This multi-faceted evaluation approach follows guidance from DSR literature that emphasizes not only technical performance of artifacts but also their fit with user needs and contexts (Venable et al., 2016).

(6) Communication: Finally, we document the problem, artifact, and findings in this paper and in a companion thesis report, to disseminate the knowledge to both academic and practitioner audiences. The iterative DSR approach ensured that the research was grounded in solving a relevant practical problem while also contributing general insights (e.g., how LLMs can be combined with knowledge graphs for traceability).

Implementation of the AI-assisted traceability tool

System overview

The developed artifact is a prototype tool that supports verification of contractual process requirements by automatically producing an auditable *requirement–evidence mapping* (See Figure 1). The system combines (i) a Large Language Model (LLM) for natural-language understanding and evidence extraction and (ii) a knowledge graph (KG) to store requirement entities, evidence snippets, and their links in a structured and queryable form. The KG acts as a traceability backbone: each verification decision is represented as a link between a requirement node and one or more evidence nodes, including provenance metadata (e.g., document and section identifiers).

LLM-driven requirement extraction and evidence identification

The tool operates in two stages. First, it extracts requirement statements from the contractual requirements document. Second, for each extracted requirement, it searches for supporting evidence in the contractor document(s) (e.g., project management plan) and returns a quoted excerpt plus a document location reference. Prompting is designed to be conservative: the LLM is instructed to only propose a link when it can point to explicit textual evidence; otherwise, it returns ''no evidence found''. This design choice prioritizes avoiding false positives (incorrectly asserting compliance) over maximizing coverage.

Knowledge graph representation

All outputs are stored as RDF-like triples in a knowledge graph with a lightweight ontology. Core classes include `Requirement` and `Evidence`, with a predicate such as `hasEvidence` linking a requirement to an evidence excerpt (See Figure 2). Evidence nodes store provenance fields (document name, chapter/section identifiers) to support auditability and facilitate queries such as: ''Which requirements have no evidence?'' or ''Which document sections satisfy the most requirements?''

Design iterations (build–evaluate cycles)

The artifact was developed using a Design Science Research (DSR) approach with multiple **design iterations**. In this paper, an **iteration** is defined as one complete *build–evaluate cycle*: (1) implement a concrete change to the artifact (e.g., prompt structure, document chunking strategy, evidence provenance requirements, or KG validation rules), and (2) re-run the same case study evaluation against a fixed ground truth to quantify the impact on link-quality metrics (accuracy, precision, recall, and F_1). Each iteration was motivated by observed error patterns (false negatives/false positives) in the previous iteration and aimed to improve verification completeness while maintaining conservative, audit-friendly outputs. Table 1 summarizes the iterations and their key design changes.

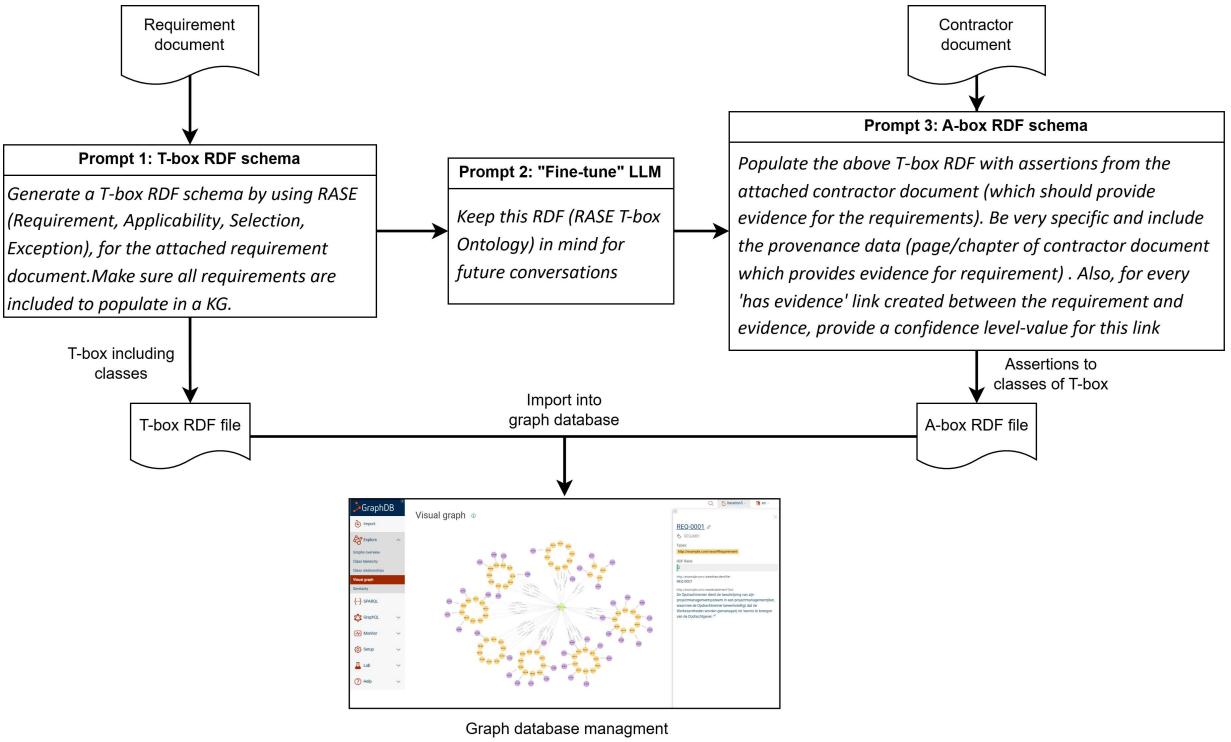

Figure 1: AI-assisted requirement traceability workflow combining T-box generation, LLM-based A-box population, and graph database integration.

Results

We evaluated the performance of the AI-assisted traceability tool on the case study project. The quantitative results demonstrate that through iterative refinement, the artifact achieved a high level of accuracy in identifying valid traceability links between requirements and evidence. Table 2 summarizes the classification performance metrics over four iterations of the artifact development. In the first iteration, the tool's recall was very low (around 17%), indicating it missed the majority of actual requirement-evidence links; accuracy was also low (17.2%). However, precision was perfect (100%) even in that iteration, meaning that although the tool found few links, those it did find were correct (no false positives). This high precision can be attributed to the conservative approach in the LLM prompting as described earlier. The low recall and accuracy in Iteration 1 highlighted the need to capture more links (reduce false negatives). By Iteration 2, after improving the prompt to ensure no requirements were skipped, recall jumped to 67.9% and accuracy to 73.4%. Further enhancements in Iteration 3 (such as better handling of partial matches and refining evidence extraction) yielded about 73.6% recall. Finally, Iteration 4 introduced a confidence scoring mechanism and additional knowledge graph constraints to catch missing links; the tool then achieved 96.6% recall and 96.8% accuracy, essentially meeting the target of $> 90\%$ on both. Precision remained 100% throughout all iterations, meaning the system did not produce any incorrect links in our test dataset. The F_1 score, which balances precision and recall, improved dramatically from 29.3% in Iteration 1 to 98.3% in Iteration 4, indicating a well-balanced and robust performance by the end.

In absolute terms, for the final iteration, out of 64 total requirements in the test contract, the tool correctly linked 57 requirements with relevant evidence found in the PMP (True Positives) and correctly identified that 3 requirements had no evidence in that document (True Negatives, which in this context means those requirements were indeed not addressed in the PMP and likely require evidence from other documents or were out of scope). There were 2 False Negatives, i.e., requirements for which the tool failed to find the existing evidence in the PMP. Notably, there were 0 False Positives in any iteration, so the precision is 1.0 (the tool never claimed an evidence link where there was none). By comparing with manual verification, we found that most of the false negatives in early iterations were due to the LLM not recognizing evidence phrased very differently from the requirement wording. After ontology enhancements and additional prompt context, only 2 requirements remained unlinked (false negatives) in the final iteration. Those cases were ones where the evidence was implicit or scattered in the document, indicating a limit to the LLM's ability to infer compliance without explicit statements (a topic for future improvement). Beyond the binary performance metrics, the tool provided qualitative insights. For example, as mentioned, it identified inconsistencies in the contractor document's chapter numbering while extracting evidence. In one case, the LLM correctly pointed to a section titled "Risk management"

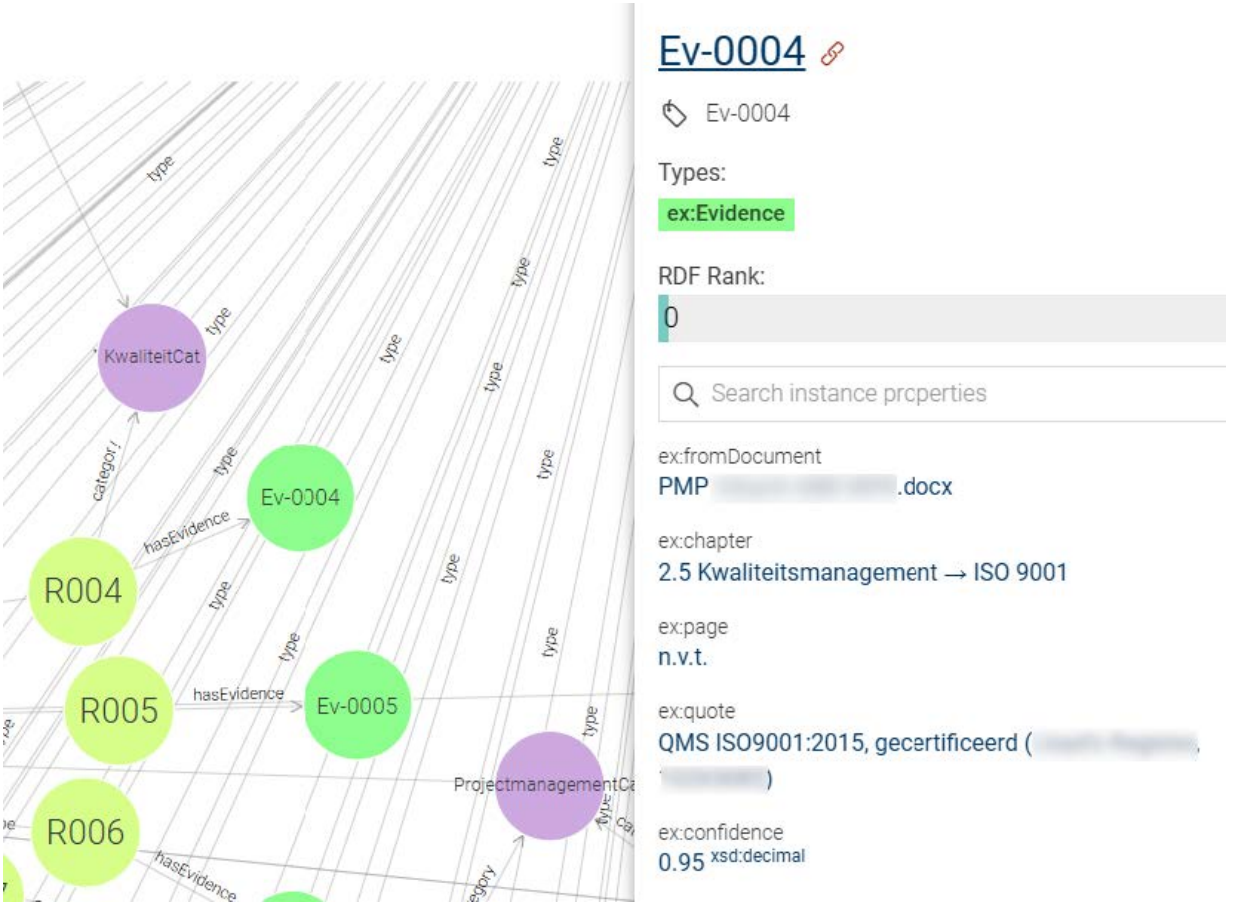

Figure 2: Knowledge Graph Representation

as evidence for a requirement on risk coordination, but flagged it under chapter 4 whereas the contractor's table of contents had it under chapter 3. This led to discovering a documentation error by the contractor. Such findings suggest the AI tool not only checks compliance but can also help improve document quality and consistency. We also evaluated the usability and acceptance of the tool via the focus group and SUS questionnaire. The average SUS score given by the five participants was **78.5**. According to standard SUS interpretations (Lewis, 2018; Sauro, 2018), this score falls in the 80th percentile, corresponding to a rating above "good" (approximately a "B+" on a grading scale). An SUS above 68 is generally considered above average; thus, our result indicates that users found the prototype reasonably easy to use. They particularly appreciated the ability to click a requirement and immediately see the evidence text, which one participant noted "saves a lot of time compared to flipping through PDFs manually." Some participants were initially skeptical about AI "reading" their documents, but after seeing the accuracy of results, they expressed increased trust. The focus group discussion revealed that users valued the knowledge graph's transparency — it reassured them that the AI wasn't making arbitrary guesses but actually linking to specific document sections. However, the participants also pointed out areas for improvement. In a few instances, the evidence text returned by the tool was quite lengthy; users suggested highlighting the exact sentences that matter. They also desired a clearer indication of confidence for each link (even though the system internally had confidence scores, the front-end only showed the link or no link). This feedback aligns with our own observation that a confidence threshold could be used to only show high-confidence links by default, with lower-confidence suggestions flagged for human review. Overall, the results demonstrate that the AI-assisted traceability tool can dramatically improve the traceability process: it achieved near-perfect precision and very high recall in linking requirements to evidence in a complex real document, and it did so in a matter of minutes (the end-to-end runtime for analyzing 64 requirements against a 150-page PMP was under 10 minutes on an LLM API, which is negligible compared to days of manual work). The high usability score further suggests that with a bit more refinement, practitioners would be willing to adopt such a tool in their workflow.

Discussion

The successful demonstration of the prototype confirms that leveraging LLMs for requirement traceability in construction is not only feasible but highly effective under the tested conditions. In this section, we reflect on the impli-

Table 1: Design iterations of the AI-assisted requirement verification tool.

Iter.	Implemented change	Design focus
1	Baseline pipeline combining LLM-based requirement extraction, evidence identification, and knowledge graph storage of requirement–evidence links.	Establish end-to-end feasibility of automated verification workflow.
2	Revised prompt structure to enforce complete requirement coverage and systematic section-wise evidence scanning.	Improve completeness of requirement handling and structured evidence search.
3	Refined evidence prompts to require explicit textual quoting and provenance references; improved document chunking strategy.	Strengthen grounding of links and standardize evidence extraction format.
4	Integrated additional knowledge graph validation constraints and final prompt refinements for handling implicit references and edge cases.	Increase structural robustness and consistency of requirement–evidence mapping.

Table 2: Traceability link classification performance per iteration (case study evaluation)

Metric	Iteration 1	Iteration 2	Iteration 3	Iteration 4
Accuracy	0.172	0.734	0.781	0.968
Precision	1.000	1.000	1.000	1.000
Recall	0.172	0.679	0.736	0.966
F_1-score	0.293	0.809	0.848	0.983

cations of these findings, discuss the contribution of this work in context, and outline limitations and future work.

Implications and contributions

The research provides evidence that an AI-assisted approach can significantly reduce the manual effort required for verifying process compliance in construction projects. By automatically generating traceability links, the tool addresses a pain point for contractors, who typically must allocate considerable time to compile compliance matrices for each requirement. The near-100% precision means that users can trust the links that are present, focusing their attention on verifying missing links (false negatives) rather than double-checking every provided link for correctness. In practice, this flips the verification process from a manual search for evidence to an AI-assisted review of suggested evidence, potentially saving time and catching errors that humans might overlook due to fatigue or oversight. One of the experts in our focus group mentioned that the tool "would allow junior engineers to do in hours what used to take an experienced engineer days," hinting at productivity gains and knowledge transfer benefits. From a scientific perspective, this work contributes a novel integration of technologies: it combines an advanced natural language understanding model (Open AI GPT-5) with semantic web techniques (RASE markup, RDF knowledge graph, SHACL constraints) to achieve a level of performance that neither approach could easily attain alone. Pure LLM-based solutions might achieve good recall but suffer from hallucinations, while pure rule-based/ontology solutions struggle with the ambiguity of natural language. Our hybrid approach demonstrates a synergistic effect: the knowledge graph and constraints guide the LLM and provide structure, while the LLM provides the flexible understanding needed to interpret diverse requirement and evidence texts. This approach is generalizable beyond the specific case; it could be applied to other domains where requirements (or regulations) need to be traced to evidence (e.g., safety certification, quality assurance in manufacturing, or even legal compliance in finance). Thus, a broader contribution is showing how zero-shot LLM capabilities can be harnessed in a controlled, explainable way for traceability tasks. Furthermore, this research adds to the Design Science knowledge base by illustrating the application of DSRM in the construction IT context. We followed a structured iterative design-evaluate cycle and have documented the evolution of the artifact. The improvement across iterations (Table 2) serves as a case example of how setting concrete objectives (like recall > 90%) and continuously

evaluating against them leads to a more effective artifact. It also underscores the importance of evaluation at multiple levels: our evaluation was not just technical (metrics) but also involved end-user feedback, which is crucial for any AI tool to be practically viable. The high SUS score in the final evaluation is as important a result as the high F_1-score; both technical performance and user acceptance must align for successful adoption.

Limitations

Despite the encouraging results, there are several limitations to acknowledge. First, the evaluation was conducted on a single case project (albeit a fairly large and representative one). While the results show the tool can work extremely well on that case, projects can vary. Different contract structures, requirement phrasing styles (especially if not in English, whereas our LLM was primarily English-trained), or evidence document types might pose new challenges. For instance, some projects might have requirements scattered across multiple documents or require linking not just one contractor report but a chain of documents (like design drawings or test reports). Our current prototype handles one requirements document and one evidence document; scaling to multiple heterogeneous sources will require further development. Second, the reliance on a third-party LLM (OpenAI's GPT 5) introduces practical issues such as cost and data privacy. Running GPT-5 on large documents can be expensive, though we tried to optimize prompts to stay within reasonable token limits. More critically, sending potentially sensitive project documents to an external API can be problematic for companies concerned with confidentiality. This limitation could be mitigated by on-premise LLM solutions or fine-tuned smaller models in the future. There is ongoing research to distill or adapt large models for specific tasks which could be explored to reduce dependency on external APIs. Another limitation is that, while precision was perfect in our tests, we cannot guarantee it will always remain so as we generalize. We tuned the system to be conservative to avoid false positives; this worked for the case data, but a very differently structured document might confuse the LLM to produce an incorrect link. If a false positive (hallucination) does occur, it could mislead users into thinking a requirement is satisfied when it is not, which is a serious risk. Therefore, deploying this in a real project would require thorough validation and perhaps maintaining a human in the loop who at least spot-checks the evidence for each requirement. Additionally, our method of splitting the evidence document by sections and sequentially querying the LLM might miss evidence that is, say, a combination of two sections or implied across the document. More sophisticated retrieval (like using vector embeddings to fetch the top relevant passages for a requirement) could enhance the evidence search phase. Finally, regarding the evaluation method: our ground truth traceability links were established via manual review by the researchers (and double-checked with the help of the domain experts). There is some degree of subjectivity in determining what counts as "evidence" for a requirement, especially for process-oriented requirements that might not have a binary satisfied/not satisfied state. We treated the contractor's own verification statements in the PMP as the evidence of compliance. It is possible that in some cases the contractor's documentation might claim compliance where an external auditor might disagree. In our metrics, we assumed the contractor's documentation combined with our judgment is the truth. A more rigorous validation in the future could involve independent auditors verifying the links as well.

Future work

Building on the prototype's success and the limitations identified, several avenues for future work are evident. One important next step is to generalize and test the tool on additional projects. We plan to apply the approach to other case studies, possibly in different domains (for example, rail or highway projects, or even outside construction such as aerospace systems engineering) to evaluate how well the LLM handles different writing styles and terminologies. This could be complemented by fine-tuning the LLM on a corpus of requirement-evidence pairs (if such data can be accumulated) to see if a fine-tuned model could achieve similar results more efficiently. Another future improvement is enhancing the explainability of the AI decisions. Integrating techniques from explainable AI (XAI) could allow the system to provide a justification for each trace link, beyond just the raw text. For example, the tool could highlight which keywords or phrases in the requirement matched with the evidence, or even output a natural language justification like "Requirement X is satisfied in section Y of the PMP where it states '...' which corresponds to the required process." Such features would further increase user trust and understanding of the AI's reasoning. Introducing a confidence threshold for suggestions is also worth exploring. We observed that by iteration 4, the few missed links could potentially be discovered by allowing the AI to be more "creative" (in iteration 4 it might have still erred on the side of caution). If we allow a slightly lower precision in exchange for 100% recall, we could then flag the uncertain links for human review. A hybrid approach could be: the tool marks some links as "high confidence" (auto-verified) and others as "low confidence – needs human check." This way, no potential evidence is missed, and the human verifier's effort is focused only on the questionable cases. From a technical standpoint, integrating a vector-based retrieval step could improve evidence discovery. Instead of or in addition to scanning document sections sequentially, we can use embeddings to find the most semantically similar passages to each requirement and present those to the LLM. This retrieval augmented generation approach (Hey et al., 2025) could help when evidence is not explicitly a near copy of requirement wording. Finally, expanding the knowledge graph to capture more context could be valuable. Currently, our KG links requirements to evidence found in one document. In

reality, evidence of compliance could span multiple documents (e.g., a test report plus a certification). The ontology could be extended to represent complex verification chains (for instance, a requirement is satisfied by a procedure which is evidenced by a test, which is documented in a report). This aligns with the broader vision of Model-Based Systems Engineering (MBSE) where every requirement can be traced to model elements, test cases, and results. Our work is a step in that direction by automatically populating a knowledge base; future work might integrate with MBSE tools or requirement management databases to pull in more types of trace links.

Conclusion

This research demonstrates a practical AI-assisted solution to requirement traceability in construction projects. By combining the strengths of LLMs in understanding unstructured text with the rigor of knowledge graphs for information organization and validation, we achieved a tool that can automate a large portion of the traceability process with high accuracy and user acceptance. The Design Science approach ensured the artifact was iteratively improved to meet the desired performance. The resulting prototype not only contributes a new method for managing requirements in construction but also provides a blueprint for tackling similar problems in other domains where requirements verification is crucial. As AI technologies continue to evolve, we expect such hybrid human-AI systems to become an integral part of the systems engineering toolkit, augmenting human capabilities in managing complexity and ensuring compliance in large-scale projects.

ENABLING CROSS-STUDY COMPARISON: A FRAMEWORK FOR AUTOMATED BIM-QA EVALUATION

Sylvain Hellin[1,2], Stefan Fuchs[1,2], Stavros Nousias[1,2], André Borrmann[1,2]
[1]Chair of Computing in Civil and Building Engineering, Technical University of Munich, Germany

Abstract

Driven by LLM advances, Question Answering (QA) systems for Building Information Models (BIM) have proliferated, yet no standardized methods exist for cross-study comparison. We present an automated evaluation pipeline employing LLM judges to assess BIM-QA answers across five quality criteria and validate it through inter-rater agreement analysis with two domain experts and two LLM judges on 74 IFC-Bench question-answer pairs. LLM judges achieve high inter-rater reliability (Krippendorff's α = 0.70–1.00), exceeding human experts (α = 0.32–0.57), and show good agreement with expert consensus (α = 0.48–0.85), positioning the pipeline as a suitable solution for automated, reproducible BIM-QA benchmarking.

Introduction

Building Information Models (BIMs) store comprehensive building data, yet accessing this information requires specialized software and domain expertise. This creates a barrier for many project stakeholders, such as facility managers, owners, or contractors, who need timely access to building information but lack the technical skills to navigate complex BIM software. Natural language Question Answering (QA) systems offer a promising solution by enabling stakeholders to query building models using natural language (Zheng and Fischer, 2023; Hellin et al., 2025). As these systems transition from research prototypes toward practical deployment, a critical question arises: how can we systematically evaluate their answer quality?

Traditional exact-match metrics fail when answers vary in phrasing, and automated metrics like BLEU and ROUGE correlate poorly with human preference when multiple valid responses exist (Liu et al., 2023). This limitation reveals a deeper challenge: the BIM-QA field currently lacks standardized evaluation methodology. Research groups typically develop custom benchmarks and evaluate on non-shared datasets, making cross-study comparison difficult and hindering cumulative scientific progress.

While IFC-Bench provides a shared benchmark dataset (Hellin et al., 2025), a consistent evaluation methodology remains missing. A validated, reproducible evaluation method would enable meaningful performance comparison across systems and research groups. For non-deterministic LLM-based systems, such standardized evaluation is essential before practitioners can trust them for professional use.

This paper addresses this gap by introducing an automated LLM-based evaluation pipeline for BIM-QA systems. The pipeline implements a multi-dimensional evaluation framework comprising a four-category question taxonomy and five binary quality criteria (Hellin et al., 2026), detailed in the Evaluation Framework section. While multi-dimensional evaluation offers richer assessment than binary accuracy, its practical utility depends on reliable and automated application across evaluators. Specifically, this validation targets inter-rater *reliability*: whether different evaluators reach the same judgments when assessing the same answers against the same ground truth. Assessing evaluation *validity* for novel questions without established ground truth remains a separate, open direction. To validate the pipeline and the underlying evaluation framework, we investigate the following research questions:

- **RQ1:** What discriminative power and redundancy do the evaluation criteria exhibit across BIM-QA systems of varying quality?
- **RQ2:** How reliably can the proposed framework be applied across different evaluators?
- **RQ3:** How well do LLM judges approximate human expert evaluation?

The experimental results yield three key findings:

- *Criteria differ in discriminative power and redundancy (RQ1).* *Transparency* and *Completeness* best differentiate BIM-QA systems (56–57 percentage points (pp) cross-system range). *Relevance* shows ceiling effects (38pp range) and high correlation with *Completeness* (ρ = 0.76–0.81), suggesting potential consolidation to four criteria.
- *LLM judges achieve higher inter-rater reliability than human experts (RQ2).* Percentage agreement exceeds 77% across all evaluator combinations and criteria. However, chance-corrected reliability (α) reveals a clear split: LLM-LLM agreement is high (α = 0.70–1.00), while human-human agreement remains lower (α = 0.32–0.57).
- *Automated evaluation enables standardized cross-study comparison (RQ3).* Post-hoc consensus analysis confirms that LLMs align with calibrated expert judgment better than uncalibrated experts agreed with each other. This alignment holds across two model families (GLM-

4.7 and Gemini), positioning LLM-as-judge as a practical solution to the field's fragmentation problem.

Related work

BIM question answering systems

The evolution from BIM Natural Language Query (NLQ) systems to generative BIM-QA systems has transformed evaluation requirements. Traditional BIM-NLQ systems translate natural language into structured queries (e.g., BIMQL, SPARQL), enabling evaluation through query execution correctness: the generated query either matches the expected query or it does not (Yin et al., 2023; Guo et al., 2020). In this paradigm, evaluation remains tractable: correct queries produce correct results.

Recent BIM-QA systems go beyond query translation, responding in natural language directly and introducing evaluation challenges absent in query translation approaches. Prior work presented an LLM-based agentic workflow achieving 79.8% accuracy on IFC-Bench, but acknowledged that binary accuracy fails to capture nuanced answer quality: a system might provide correct values without disclosing calculation methods, leaving engineers unable to verify results (Hellin et al., 2025). This transition from query generation to answer generation requires different evaluation approaches, as binary accuracy cannot capture the nuanced quality dimensions that practitioners need. Multi-dimensional frameworks address this gap by decomposing answer quality into distinct, measurable criteria, motivating their application to BIM-QA.

Multi-dimensional QA evaluation

Beyond BIM, the inadequacy of traditional metrics for evaluating generative QA has driven the development of multi-dimensional frameworks. When evaluating long-form QA answers, domain experts consistently prioritize factuality and completeness (Xu et al., 2023). Traditional reference-based metrics such as BLEU and ROUGE, which rely on surface-level lexical overlap between generated and reference answers, fail to capture these semantic quality dimensions (Liu et al., 2023). The RAGAS framework (Es et al., 2024) operationalized evaluation through faithfulness (grounding in retrieved context), answer relevance, and context precision, while other work distinguished *correctness* from *faithfulness* (Adlakha et al., 2024). Notably, these frameworks lack explicit transparency criteria, specifically disclosure of methods and sources, identified as essential for high-stakes technical decisions where practitioners must verify results (Kell et al., 2024). Despite these advances, no validated and automated evaluation method currently exists for BIM-QA systems or AEC-related QA systems in general.

LLM-as-judge for evaluation

Applying multi-dimensional frameworks at scale faces a practical constraint: human expert evaluation is time-consuming and resource-intensive. The LLM-as-judge paradigm offers a potential solution by enabling consistent, automated evaluation at scale. Zheng et al. (2023) demonstrated that GPT-4 achieves over 80% agreement with human preferences on MT-Bench, a multi-turn chatbot evaluation benchmark, while the G-Eval framework (Liu et al., 2023) incorporated chain-of-thought reasoning for improved alignment with human judgments.

However, systematic biases may limit reliability. Studies have identified position bias, verbosity bias, and self-enhancement bias (Zheng et al., 2023), while other work demonstrated that swapping response order can flip evaluation outcomes, revealing sensitivity to presentation rather than content quality (Wang et al., 2023).

Critically, LLM-as-judge has not been systematically tested for reliability in technical domains like BIM-QA, where answers require verification against structured building data. Its applicability to such domain-specific evaluation remains an open question.

Inter-rater agreement for evaluation validation

Validating evaluation frameworks requires quantifying agreement between evaluators. Krippendorff's α is recommended for computational linguistics tasks: unlike Cohen's κ, it handles missing data and multiple raters without assuming rater-specific marginal distributions (Artstein and Poesio, 2008). Following established guidelines, $\alpha > 0.8$ indicates good reliability and $0.67 < \alpha < 0.8$ allows tentative conclusions (Krippendorff, 2004). Since α can be misleadingly low with imbalanced class distributions, percentage agreement provides a complementary view of rater concordance.

These four research threads converge on three unexplored questions: what evaluation criteria should be selected for granular multi-dimensional evaluation of BIM-QA systems, how reliably can different judges apply these criteria, and to what extent can LLM-as-judge replicate human expert judgments?

Evaluation framework

The evaluation framework comprises two components, both introduced in a prior study (Hellin et al., 2026). First, questions are categorized by data retrieval complexity; then answers are assessed using category-informed criteria. The question's category influences how the *Faithfulness* criterion is assessed, as detailed in the criteria definitions. We briefly describe both components below.

Question taxonomy

Most QA taxonomies categorize questions by syntactic structure or reasoning complexity (Rogers et al., 2021). This approach works well for text-based corpora (e.g., documents or web pages) where answers are stated explicitly, but BIM models contain heterogeneous information: some values are stored as explicit properties, others must be computed through aggregation or geometric operations, and some questions address data not present in the model at all. Prior work in BIM compliance checking proposed categorizing rules by data retrieval complexity (Solihin

and Eastman, 2015). Building on this, Hellin et al. (2026) adapted this classification to BIM-QA, defining four categories based on data retrieval complexity:

Category 1 (Direct Retrieval): Queries answerable through direct access to explicitly stored BIM properties without computation. *Example:* ''What is the fire rating of door D-101?'' The value is stored as an explicit property.

Category 2 (Aggregation): Queries requiring simple, deterministic operations (counting, summing, averaging) on accessible data. *Example:* ''How many windows are on the second floor?'' This requires filtering and counting, not stored directly.

Category 3 (Geometric/Spatial): Queries requiring complex computation beyond simple aggregation, where multiple valid approaches (and potentially multiple valid answers) may exist. *Example:* ''What is the gross floor area?'' This requires complex geometric computation, and different standards (ISO 9836, BOMA) may yield different valid results.

Category 4 (Incomplete Information): Queries addressing information unavailable in the BIM model, potentially answerable through explicit assumptions. *Example:* ''What is the energy consumption of the building?'' This cannot be answered deterministically and requires assumptions about occupancy, climate, and systems not modeled to provide a reasonable estimation.

Note on Category 4: This category diverges from (Solihin and Eastman, 2015)'s original Category 4 (complex simulations requiring external software). In BIM compliance checking, a BIM model containing all necessary information is considered a prerequisite, without which the process is meaningless. In contrast, for BIM-QA, users do not know in advance whether the information is available in the BIM model. Even if not definitive, an estimation or partial answer with properly disclosed assumptions may still be valuable.

Since the category depends on information accessibility, the same question might be categorized differently depending on the model being queried. For example, a floor area question could be Category 1 if the value is stored as a space property, or Category 3 if it must be computed geometrically.

This taxonomy informs how evaluation criteria, particularly *Faithfulness*, are applied, as described below.

Evaluation criteria

Answer quality is evaluated using binary judgments (Yes or No) across five criteria defined in Hellin et al. (2026). Binary judgments facilitate clear decision boundaries and reliable inter-rater agreement measurement. The N/A option applies when a criterion cannot meaningfully be assessed, either because the system abstained or because the question type does not require that criterion:

Criterion 0 (Abstention): Whether the system provided an answer or declined. If abstained, Criteria 1–4 are marked N/A since no content exists to evaluate. This criterion captures the coverage-reliability tradeoff: systems that appropriately abstain on uncertain queries avoid errors at the cost of reduced coverage, while systems that never abstain may overconfidently provide unreliable answers.

Criterion 1 (Faithfulness): Whether all claims are grounded in acceptable sources for the question's category. Acceptable grounding depends on question type:

- **Category 1:** BIM model data only: values must be directly retrieved from explicit properties
- **Category 2:** BIM model data plus deterministic computations (counting, summing, averaging)
- **Category 3:** BIM data plus complex geometric computations derived from model
- **Category 4:** BIM data plus computations plus *explicitly stated* assumptions

This category-dependent approach maintains alignment with RAG evaluation literature for Categories 1–2, while extending acceptable grounding to accommodate geometric derivations (Category 3) and incomplete information handling (Category 4). N/A only if system abstained.

Criterion 2 (Completeness): Whether the answer includes all relevant facts. N/A if the question expects only a single value with no ancillary information (e.g., ''What is the building height?''). This criterion is equivalent to recall for questions asking about a list of specific facts or items, but has a broader application.

Criterion 3 (Transparency): Whether the answer explicitly identifies sources or methods. Users must be able to verify information sources for the system to be useful in practice (Kell et al., 2024). *Example:* For ''What is the gross floor area?'', a transparent answer would state ''The gross floor area is 2,450 m², calculated by summing the areas of all IfcSpace entities with PredefinedType='FLOOR'.'' An opaque answer stating only ''2,450 m²'' would fail this criterion. This criterion is also essential for faithfulness assessment in Categories 3 and 4, since the system must explicitly reveal what assumptions were made. Transparency further enables post-hoc verification: users can trace reported values back to their source in the BIM model and confirm intermediate reasoning, complementing answer-level assessment. N/A only if system abstained.

Criterion 4 (Relevance): Whether the answer directly addresses the question asked. *Example of irrelevance:* For ''What is the fire rating of door D-101?'', an answer describing the door's dimensions, material, and manufacturer without mentioning fire rating would fail this criterion: the information provided, while accurate, does not address what was asked. N/A only if system abstained.

Validation methodology

We conducted inter-rater reliability analysis with LLM judges alongside human experts, an approach that enables simultaneous assessment of framework reliability and automated evaluation feasibility.

Dataset and evaluated system

We used 74 question-answer pairs from IFC-Bench (Hellin et al., 2025). Questions were distributed across four categories: Category 1 (13), Category 2 (39), Category 3 (5), and Category 4 (17).

The evaluated BIM-QA system is an LLM-based agentic workflow that processes natural language queries against IFC-encoded building models (Hellin et al., 2025). The system (1) receives a natural language question and the path to a BIM model, (2) dynamically generates and executes Python code to query the BIM model, (3) iteratively refines queries based on intermediate results, and (4) synthesizes a final response in natural language.

Evaluators

Human Evaluators: Two BIM domain experts, both with academic backgrounds in the AEC domain and over five years of practical experience with BIM workflows, independently evaluated all 74 responses. Both followed documented evaluation guidelines.

LLM Judges: To assess whether LLM-as-judge findings generalize across models, we employed two LLM judges from different providers:

- GLM-4.7, an open-weight ~400B-parameter model by Zhipu AI and successor to GLM-4.5 (GLM-4.5 Team et al., 2025), accessed via the Zhipu AI platform (z.ai)
- Gemini 3 Pro[1], accessed via Google AI Studio API

Both LLMs received identical structured prompts containing: (1) the question, question category, ground truth answer, and system-generated answer; (2) criterion definitions with category-dependent *Faithfulness* rules specifying acceptable grounding sources; (3) output format requiring Yes, No or N/A ratings with mandatory justification. The justification field is intended as a human-inspectable audit trail of the judge's decision rather than as a chain-of-thought elicitation mechanism. The *Faithfulness* criterion is operationalized with category-specific numerical accuracy rules: for Categories 1–2 (deterministic retrieval and aggregation), numerical values must match the ground truth within 2% for continuous measurements and exactly for discrete counts; for Categories 3–4, where multiple valid approaches may exist, the focus shifts to whether the methodology is explicitly disclosed and values are plausible. Full evaluation prompts, scripts, and rating data are available in the project repository (see below).

Evaluation Inputs: Both human and LLM judges received identical inputs for each question: the question text, question category, ground truth answer, and system-generated answer, along with criterion definitions and evaluation guidelines. This design isolates evaluation consistency from verification capability: all evaluators assessed system answers against the same reference standard. Ground truth answers were validated against the BIM models prior to the study to ensure dataset reliability. Evaluation prompts, scripts, and rating data are available at `https://github.com/sylvainHellin/ec3-2026-hellin-fuchs-nousias-borrmann`.

Human Evaluation Protocol: Both human evaluators worked independently and were blind to each other's ratings throughout the study. Evaluators reviewed criterion definitions and evaluation guidelines before beginning but did not complete a formal calibration session. This absence was intentional: in practice, different research groups cannot calibrate with each other before evaluating BIM-QA systems, so the framework must be self-contained enough to produce consistent results without joint training. Evaluators had access to BIM models for reference if needed, though evaluation primarily involved comparing system answers against provided ground truth. Human evaluators averaged approximately three minutes per question-answer pair.

Statistical methods

We measure inter-rater agreement using Krippendorff's α, which handles the N/A responses that arise when criteria do not apply to certain question types. We report both α and percentage agreement, as high percentage agreement can occur with low α when class distributions are highly imbalanced (ceiling effects).

Correlation between criteria is measured using Spearman's ρ to identify redundancy and independence patterns.

Consensus evaluation

After completing the blind evaluation, both human evaluators jointly reviewed all 20 questions where their ratings disagreed on at least one criterion. For each disagreement, they discussed their reasoning against the evaluation guidelines and independently decided whether to revise their original rating. This process resolved 18 of 20 disagreements. The two remaining disagreements, Q316 (whether omitting a window name makes an answer incomplete) and Q472 (how to classify a response where the system provided partial data but stated it could not answer, a ''soft abstention'' case), reflect genuine definitional boundaries not fully specified by the current guidelines. The consolidated expert opinion serves as a calibrated human baseline for assessing LLM surrogate suitability, while all original blind evaluation metrics remain unchanged.

Cross-system discriminative analysis

In addition to the answers from the agentic QA system described above, which were evaluated by both human and LLM judges, we generated two additional answer sets using different QA systems. These additional answers were evaluated by GLM-4.7 only. Comparing criterion scores across these three BIM-QA systems reveals which criteria best differentiate systems of varying capability.

- **Agentic QA**: The LLM-based agentic workflow from prior work (Hellin et al., 2025) using GLM-4.7, which dynamically explores BIM models via Python

[1] `https://deepmind.google/technologies/gemini/pro/`

code execution.

- **Static Baseline**: Same LLM with static context: a fixed summary of model elements provided without dynamic exploration capability.
- **Lightweight Agentic**: Same agentic architecture using Gemini 2.5 Flash Lite, a smaller model.

For each criterion, we computed the cross-system range (maximum minus minimum ''Yes'' rate) as a measure of discriminative power.

Results

Cross-system discriminative power

Table 1 presents criterion scores across three systems. *Transparency* (57pp range), *Completeness* (56pp), and *Faithfulness* (50pp) best discriminate between systems; *Abstention* (41pp) and *Relevance* (38pp) show weakest discrimination.

Table 1: Criterion scores (% Yes) across BIM-QA systems

Criterion	Agentic	Static	Light	Range
Abstention†	15%	52%	56%	41pp
Faithfulness	72%	28%	22%	50pp
Completeness	73%	17%	24%	56pp
Transparency	75%	31%	18%	57pp
Relevance	76%	42%	38%	38pp

†*For Abstention, lower is better (fewer abstentions = more answers attempted).*

Figure 1 shows the full rating distributions across systems, revealing that the agentic system's advantage holds across all criteria.

Correlation analysis

Correlation analysis reveals that *Completeness* and *Relevance* are highly correlated for both LLM judges (GLM: ρ = 0.81, Gemini: ρ = 0.76) and moderately correlated for human evaluators (H1: ρ = 0.40, H2: ρ = 0.65). This suggests potential criterion redundancy: a complete answer is almost always relevant. *Faithfulness* shows the lowest median correlations with other criteria (ρ = 0.26–0.65 across raters), though with considerable variability between evaluators, suggesting it captures a largely distinct quality dimension.

Both LLM judges exhibit stronger inter-criteria correlations than human evaluators, with positive ratings on one criterion predicting positive ratings on others. Full inter-criteria correlation matrices for each evaluator are available in the project repository.

Inter-rater agreement

Krippendorff's α ranges from 0.51 to 0.76 across criteria for the four-rater analysis (both human experts and both LLM judges), indicating moderate to substantial agreement (Figure 2, top). LLM-LLM agreement (α = 0.70–1.00) consistently exceeds human-human agreement (α = 0.32–0.57), with perfect agreement on *Abstention* and *Relevance*.

Since α can be misleadingly low when class distributions are highly imbalanced, we complement it with raw percentage agreement (Figure 2, bottom). Percentage agreement across all four evaluators exceeds 77% for all criteria, with *Abstention* (94.6%) and *Transparency* (93.2%) achieving highest concordance. LLM-LLM agreement reaches 100% for *Abstention* and *Relevance*. The combination of high percentage agreement with moderate α values reflects ceiling effects: when most responses receive positive ratings, expected chance agreement is high, limiting α's discriminative power.

Surrogate validation

The post-hoc consensus process (see Consensus Evaluation) yielded near-perfect human agreement (α = 0.88–1.00), confirming that the original blind disagreements were interpretation-driven rather than reflecting fundamental framework deficiencies. With this calibrated baseline established, we assess LLM surrogate suitability by comparing consensus-LLM agreement against original human-human agreement.

Both LLM judges align with expert consensus at α = 0.48–0.85, though their per-criterion profiles differ: GLM shows stronger *Faithfulness* alignment (H_{cons}-LLM_1: *Abstention* 0.85, *Faithfulness* 0.69, *Completeness* 0.48, *Transparency* 0.63, *Relevance* 0.78), while Gemini aligns better on *Transparency* (H_{cons}-LLM_2: *Abstention* 0.85, *Faithfulness* 0.48, *Completeness* 0.56, *Transparency* 0.73, *Relevance* 0.78). Both exceed the original uncalibrated human-human agreement (α = 0.32–0.57) for every criterion, as visible in Figure 2 (rightmost columns, top; rightmost bars, bottom).

This pattern supports the surrogate argument: LLMs not only agree with each other, but align with calibrated expert consensus at levels exceeding uncalibrated human-human agreement. For practical benchmarking, where individual calibration across research groups is infeasible, LLM judges offer a more reliable approximation of expert evaluation.

Discussion

Our results reveal a notable pattern: LLM judges achieve higher reliability than human experts, and generally align with each individual human at levels comparable to or exceeding human-human agreement.

The four-rater agreement (α = 0.51–0.76) falls within the ''tentative conclusions'' range, below the $\alpha > 0.8$ threshold for ''good reliability'' (Krippendorff, 2004). Our results therefore provide preliminary evidence rather than full validation. A full validation would require larger samples, particularly for Category 3 (n=5), and consistently higher agreement. The findings nonetheless establish a foundation: the framework produces measurable inter-rater agreement, and category-dependent patterns offer actionable guidance.

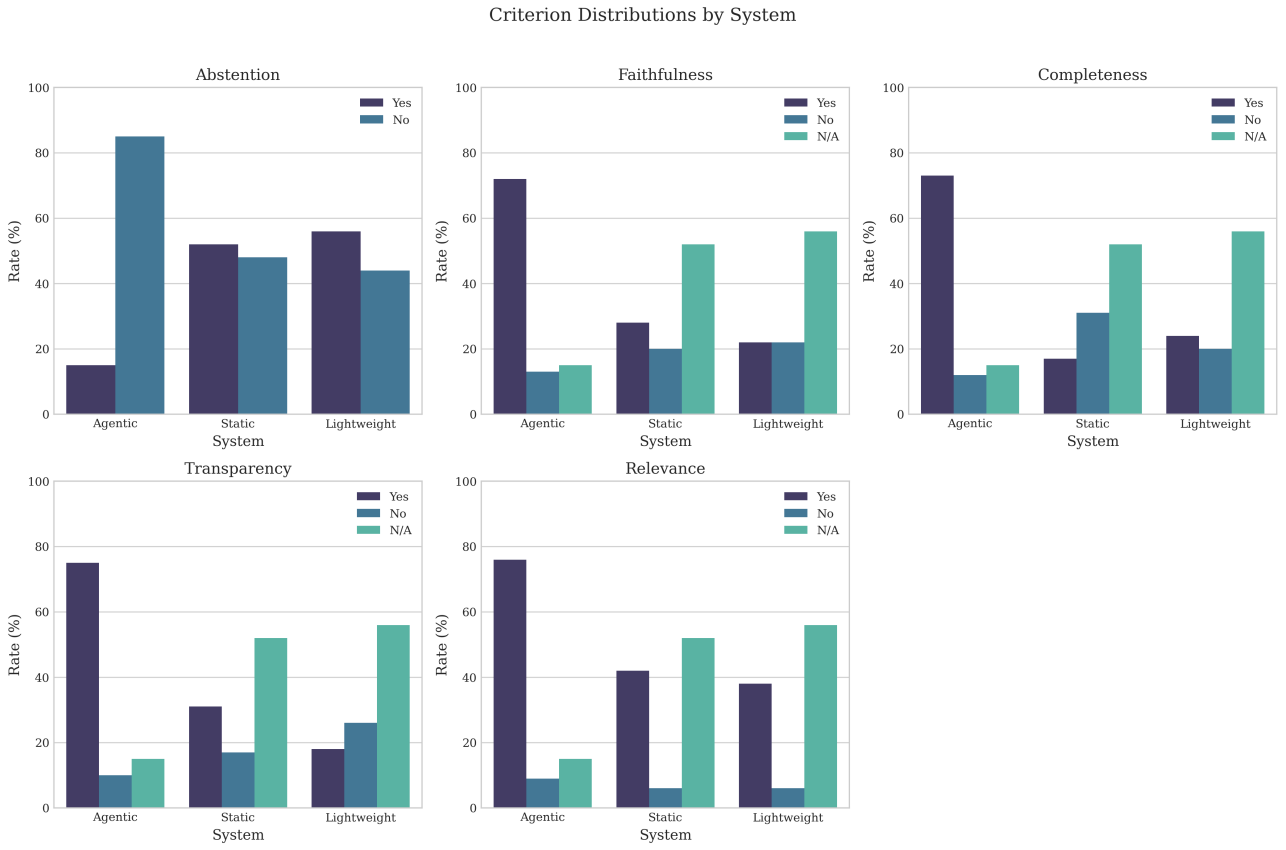

Figure 1: Criterion rating distributions across three BIM-QA systems. The agentic system achieves highest positive rates across all criteria. Higher abstention rates in Static and Lightweight systems produce corresponding N/A rates for other criteria.

Understanding evaluator differences

Why do LLM judges achieve such high reliability (α = 0.70–1.00) while human experts show lower agreement (α = 0.32–0.57)? We hypothesize three contributing factors: (1) *Criterion application consistency*: LLMs apply criteria exactly as specified, while human evaluators may interpret criteria through tacit domain expectations not captured in written guidelines; (2) *Engagement and attention*: evaluating 74 pairs against detailed criteria is repetitive work where human attention may waver, while LLMs process each instance uniformly; (3) *Criterion interpretation*: for *Completeness*, evaluators differed on whether supplementary context was required; for *Faithfulness*, they applied different verification strategies. The absence of a formal calibration session likely amplified these effects. While the criteria themselves, or the briefing provided to evaluators, may carry some inherent ambiguity, this is unlikely to be the whole story: as the post-hoc consensus analysis confirms, brief interpretive alignment is sufficient for the same raters to reach near-perfect agreement on the same criteria.

For example, Human 1's *Faithfulness* ratings exhibited higher correlation with LLM judges (α = 0.73 for H1-GLM vs. α = 0.42 for H1-H2), suggesting systematic differences in evaluation approach. Consider Question 153: ''What is the total length of exterior walls?'' The system answered ''877.47 meters,'' citing its methodology (summing the Length property for walls where IsExternal=True); the ground truth was 267.45 meters. Human 1 rated *Faithfulness* as No, recognizing the numerical discrepancy. Human 2 rated Yes, focusing on whether the methodology was grounded in BIM data. Both LLM judges also rated Yes. This illustrates a fundamental interpretation difference: does *Faithfulness* assess factual correctness, or grounded methodology? The higher LLM reliability on *Faithfulness* may reflect more uniform application of the category-specific numerical accuracy rules (see Validation Methodology).

Practical implications for BIM-QA evaluation

Our results provide preliminary evidence for LLM-as-judge suitability in domain-specific technical evaluation, extending prior findings from general-domain tasks (Zheng et al., 2023). The high LLM-LLM agreement (α = 1.00 for *Abstention* and *Relevance*, 0.89 for *Transparency*, 0.77 for *Completeness*) suggests that automated evaluation offers strong reproducibility for most criteria, with *Faithfulness* (α = 0.70), the most semantically nuanced criterion, showing the lowest but still acceptable reliability.

Two complementary findings position LLM-as-judge as a practical solution for BIM-QA evaluation. First, LLMs achieve high inter-rater reliability across model families. Second, LLMs align with calibrated expert consensus better than uncalibrated humans agreed with each other. To-

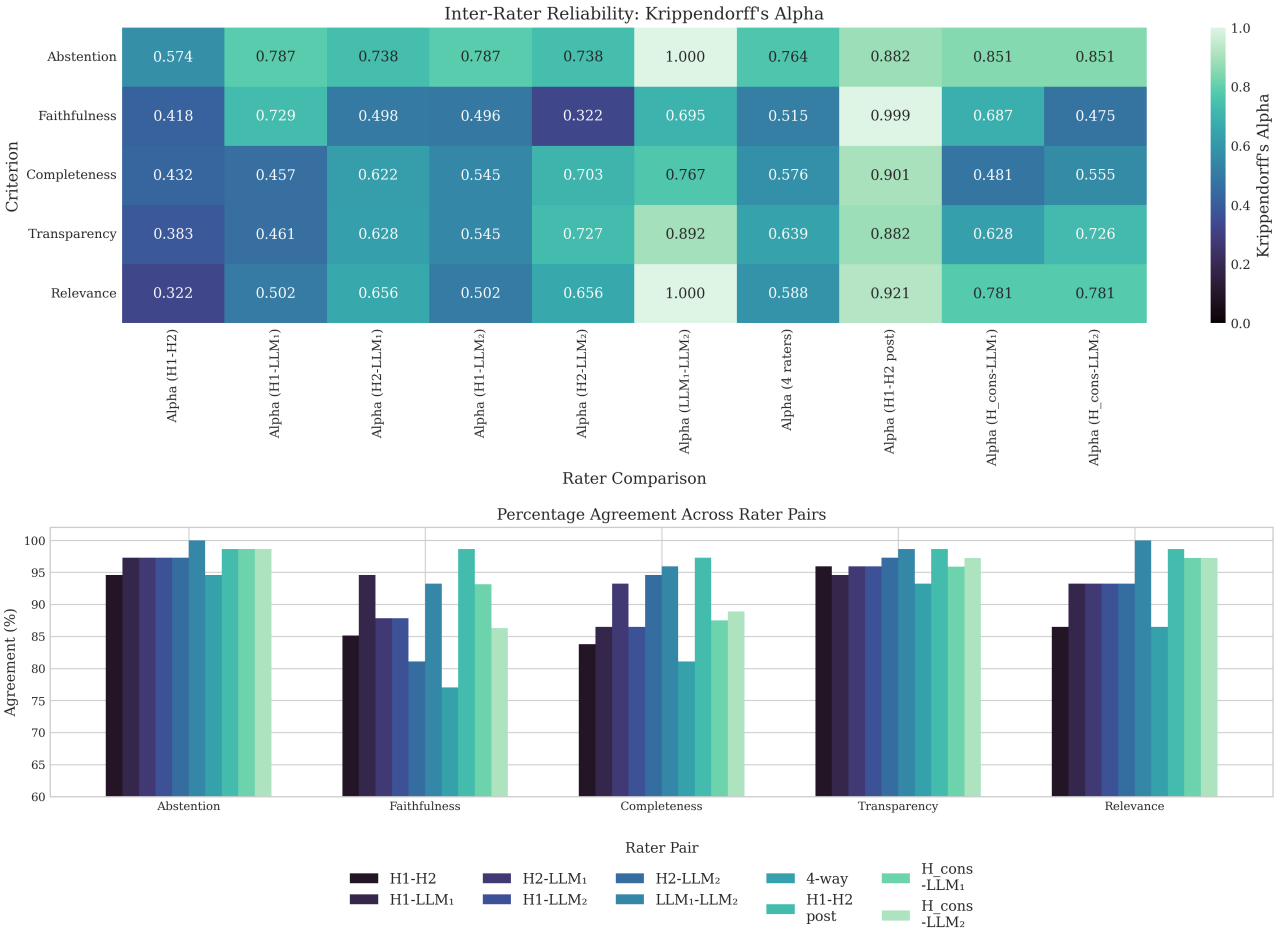

Figure 2: Inter-rater agreement analysis. ***Top:*** *Krippendorff's α heatmap showing agreement between rater pairs (H1, H2: human experts; LLM_1: GLM-4.7; LLM_2: Gemini 3 Pro) across criteria. Higher values (darker) indicate stronger agreement. Human-LLM agreement generally equals or exceeds human-human agreement. Rightmost columns show post-hoc consensus results (see Surrogate Validation).* ***Bottom:*** *Percentage agreement across rater pairs by criterion. LLM-LLM agreement consistently exceeds or matches human-human agreement, with perfect agreement on Abstention and Relevance. Rightmost bars show post-hoc consensus results.*

gether, these findings address the fragmentation problem: different research groups can compare BIM-QA systems using automated evaluation that not only produces reproducible results, but approximates the judgment of calibrated domain experts.

The correlation analysis also suggests framework simplification: given *Relevance*'s high correlation with *Completeness* (ρ = 0.76–0.81), ceiling effects (100% LLM-LLM agreement), and weak discriminative power (38pp range), we recommend consolidating *Relevance* with *Completeness* in future iterations, reducing the framework from five criteria to four.

Limitations and framework refinements

Several limitations constrain interpretation. First, both LLM judges are frontier models; findings may not generalize to smaller models. Second, all questions target IFC-based building models, limiting generalization to other BIM formats or structured-data domains. We hypothesize that LLM judges may benefit from IFC's well-documented presence in pretraining data; generalization to proprietary schemas remains to be tested. Third, the absence of calibration was intentional (to test framework self-sufficiency); the post-hoc consensus analysis revealed two definitional gaps (soft abstention handling, completeness boundaries) that enhanced guidelines should address. Fourth, with only two human evaluators, we cannot estimate population-level variance in human agreement. A replication study with balanced category sampling, the four retained criteria following *Relevance* consolidation, and a larger calibrated rater pool is needed to move from preliminary evidence to full validation. Fifth, while three systems were evaluated for discriminative analysis, inter-rater analysis used only one system's outputs. The agreement claim concerns the evaluation protocol rather than any specific system, and should hold across BIM-QA systems given consistent criteria operationalization and equal information access. Sixth, both human evaluators are co-authors of the study, which may introduce interpretation bias despite independent evaluation protocols and blinding to each other's ratings. Finally, all judges evaluated the system's reported answer against the ground truth rather than independently re-deriving it from the BIM model; intermediate reasoning verification is a property of the

system under test (supported by *Transparency* at the user level) and lies outside the protocol's scope. The study therefore assessed evaluation *reliability* (agreement across raters given the same ground truth) rather than evaluation *validity* (correctness of judgments for novel questions without ground truth); the latter remains an important direction for future work.

Conclusions

This paper introduced an automated LLM-based evaluation pipeline for BIM-QA systems and validated the underlying multi-dimensional evaluation framework through inter-rater agreement analysis with two human experts and two LLM judges. The validation reveals two complementary findings. First, LLM judges achieve high inter-rater reliability (α = 0.70–1.00), exceeding uncalibrated human agreement (α = 0.32–0.57) across all criteria. Second, a post-hoc consensus analysis demonstrates that LLMs align with calibrated expert consensus (α = 0.48–0.85) at levels exceeding the original uncalibrated human-human agreement, confirming that LLMs approximate expert judgment, not merely agree with each other. Together, these findings position LLM-as-judge as a suitable surrogate for scalable, reproducible BIM-QA benchmarking, addressing the field's fragmentation problem.

Cross-system analysis confirms discriminative validity, while correlation and ceiling effects in *Relevance* suggest consolidation with *Completeness*. Two disagreements that survived consensus discussion highlight definitional boundaries (soft abstention handling and completeness thresholds) that future guideline refinements should address.

COMPARISON OF SEGMENTATION MODELS FOR POTHOLE DETECTION USING UAV IMAGERY

Varshney Muskan[1], Singh Aryan Raj[1], Garg Sahil[2]
[1,2]Department of Civil Engineering, Indian Institute of Technology Delhi (IIT Delhi), New Delhi, India

Abstract

Potholes are a significant cause of vehicle damage and road safety accidents. Existing inspection practices rely on manual surveys using inspection vehicles or vehicle-mounted cameras, which are time-consuming, non-scalable, and often provide incomplete visibility. This paper presents a comparative study of instance-segmentation-based deep learning models for pothole detection using UAV imagery, enabling wider and more consistent coverage. A custom dataset was developed and augmented using geometric transformations. YOLOv8 and transformer-based RF-DETR models were evaluated using precision, recall, and mAP@50. The best model achieved mAP@50 of 66.3%, highlighting challenges in detecting shallow potholes under limited training data.

Introduction

Potholes are a common form of pavement distress that develops due to repeated traffic loading, environmental exposure, and material fatigue, and they pose long-term risks to road safety, vehicle integrity, and transportation efficiency (Ibragimov et al. 2022). Even shallow potholes can progressively worsen over time, contributing to increased vehicle operating costs and a higher likelihood of traffic accidents when maintenance interventions are delayed (Ali et al. 2023).

Effective monitoring of road surface conditions is therefore essential for sustainable transportation infrastructure management. Conventional inspection practices typically rely on manual surveys conducted using inspection vehicles or visual assessments performed by trained personnel (Anand et al. 2025). Although widely used, such approaches are labor-intensive, subjective, and difficult to scale across extensive road networks. In addition, vehicle-mounted inspection systems often provide limited visibility of the road surface due to restricted viewing angles, occlusions, and perspective distortion, which can hinder reliable detection of subtle or spatially distributed defects (Yu et al. 2024).

Advances in computer vision and deep learning have enabled automated approaches for pavement distress detection using image and video data, offering more objective and repeatable alternatives to manual inspection (Safyari et al. 2024). Convolutional neural networks have demonstrated strong capability in learning discriminative visual features for pothole detection, significantly outperforming traditional image processing methods under diverse imaging conditions (Jakubec et al. 2023). Object detection frameworks such as YOLO have been widely explored due to their computational efficiency and suitability for large-scale deployment, while instance segmentation techniques provide pixel-level delineation of defect boundaries that supports more detailed geometric characterization (Li et al. 2024).

Despite methodological progress, most pothole detection studies continue to rely on ground-based or vehicle-mounted imaging platforms, where consistent surface coverage is difficult to achieve (Chen et al. 2024). Unmanned aerial vehicles (UAVs) offer a complementary sensing perspective by enabling wide-area, top-down observation of road surfaces with reduced occlusion and more uniform imaging geometry. Recent work has demonstrated the effectiveness of UAV imagery for pavement crack detection and surface distress assessment, highlighting its growing relevance for scalable road condition monitoring applications (Ellenberg et al. 2015).

In parallel with advances in sensing platforms, transformer-based vision models have emerged as an alternative to conventional convolutional architectures. By leveraging self-attention mechanisms, these models can capture long-range contextual relationships and improve generalization in visually complex scenes (Carion et al. 2020). Recent developments in lightweight and deformable transformer variants have further improved convergence behavior and performance under limited training data conditions (Zhu et al. 2020). However, the application of transformer-based instance segmentation models to pothole detection using UAV imagery remains insufficiently explored in existing literature. Recent studies have further shown that improved YOLOv8-based architectures are particularly effective for small object detection in UAV aerial imagery, making them suitable for detecting subtle pavement defects from aerial perspectives (Ni et al. 2024).

Addressing this gap requires systematic evaluation of segmentation-based approaches that can accurately localize potholes while accounting for the challenges associated with aerial imagery, subtle surface defects,

and limited annotated data. Such analysis is necessary to better understand model behavior and to support the development of reliable, scalable road surface monitoring systems.

Dataset and experimental setup

Data collection and annotation

A total of 196 road surface images were collected using a quad-copter unmanned aerial vehicle (UAV) equipped with an RGB camera. The UAV was operated to capture views of pavement surfaces, enabling wide-area coverage and consistent imaging geometry. The data acquisition strategy was designed to capture realistic road surface conditions under varying illumination levels, surface textures, and environmental influences. As a result, the dataset includes visual challenges such as shadows, debris, worn asphalt regions, uneven lighting, and surface irregularities that commonly affect road condition assessment.

All images were manually annotated using polygon-level masks to precisely delineate pothole regions. The annotation process was performed using the Roboflow Annotate tool, enabling accurate boundary-level labeling required for instance segmentation tasks. Shallow potholes with weak visual contrast posed particular challenges during annotation due to gradual depth transitions, shadows, and surface stains, leading to unavoidable annotation uncertainty. Despite these challenges, polygon-based annotations were preferred over bounding boxes, as they provide a more precise spatial representation of pothole boundaries and better support pixel-level segmentation, geometric analysis, and potential severity estimation in future extensions of this work.

Data augmentation

To address dataset scarcity and improve model generalization, the original dataset was expanded from 196 to 475 images using targeted geometric data augmentation techniques. The augmentation strategy focused on preserving the structural characteristics of potholes while introducing controlled variability in spatial orientation. The applied augmentations included horizontal flipping, small-angle rotations within a range of ±10°, and shear transformations limited to ±10°.

To prevent unrealistic geometric distortions and maintain annotation fidelity, no more than two augmentation operations were applied to any single image during training. This constraint ensured that the augmented samples remained representative of real-world aerial road scenes while avoiding excessive deformation of pothole boundaries.

The selected augmentation techniques were intended to enhance robustness to variations in UAV viewpoint, flight orientation, and minor perspective changes commonly encountered during aerial image acquisition. By increasing the effective diversity of the training data, the augmentation process contributed to improved detection and segmentation performance under diverse visual and geometric conditions.

Data augmentation was performed exclusively on the training set after dataset splitting, ensuring that the validation and test sets remained unaltered. This approach prevents data leakage and supports an unbiased evaluation of model performance

Models and training strategy

This study evaluates seven instance segmentation model configurations, comprising convolutional neural network–based and transformer-based architectures, to examine the influence of data augmentation, weight initialization, and model design on pothole detection from aerial imagery. All experiments were conducted under a consistent training environment to ensure comparability across configurations.

Four convolutional neural network–based configurations were developed using the YOLOv8 instance segmentation framework. The first configuration corresponds to a baseline YOLOv8 model trained without any data augmentation. A second YOLOv8 configuration incorporated additional training samples while maintaining the same augmentation-free setting. The third YOLOv8 configuration applied horizontal flipping as a single geometric augmentation to increase viewpoint invariance. The fourth YOLOv8 configuration employed a combination of horizontal flipping with mild shear and rotation transformations, enabling greater robustness to camera orientation and road alignment variations.

Three transformer-based configurations were implemented using the RF-DETR instance segmentation framework. All RF-DETR models were initialized using large-scale pretrained weights. The first RF-DETR configuration applied horizontal flipping combined with small-angle rotation. The second RF-DETR configuration used horizontal flipping together with shear and rotation transformations. The third RF-DETR configuration employed horizontal flipping with normal rotation only. These augmentation strategies were selected to balance increased data diversity with preservation of realistic road geometry.

Across all configurations, no more than two geometric augmentations were applied to any individual image during training in order to avoid unrealistic distortions of pothole boundaries. This constraint ensured that augmented samples remained representative of real-world aerial road scenes.

All models were trained within the Roboflow cloud-based training environment using available optimization settings and GPU acceleration. Maintaining a unified training platform and consistent preprocessing pipeline ensured that observed performance differences could be attributed to model architecture and augmentation strategy rather than implementation variability.

This structured experimental setup enables a controlled comparison between convolutional and transformer-based instance segmentation models, as well as an

assessment of the role of specific geometric augmentations in aerial pothole detection. Quantitative performance outcomes are presented separately in the Results section.

Training setup

The final dataset comprised 475 images, including both original and augmented samples. The original dataset was partitioned into training, validation, and test subsets using an approximate 70:20:10 split to ensure reliable performance evaluation and to mitigate overfitting. The training subset was used for model learning, while the validation and test sets were reserved for hyperparameter tuning and final performance assessment, respectively.

Two input resolutions, 640 × 640 and 432 × 432, were systematically explored during the training process. Both YOLOv8 and RF-DETR models were trained using each of these resolutions. It was observed that YOLOv8 converged most effectively at an input resolution of 640 × 640, whereas RF-DETR achieved the most stable and optimal convergence at 432 × 432. Consequently, these resolutions were adopted for the final experiments (640×640 for YOLOv8, 432×432 for RF-DETR). Model weights were initialized using pretrained checkpoints instead of random weights, enabling effective transfer learning and faster convergence, particularly under limited data availability.

Table 1: Summary of training configurations and hyperparameters

Model Name	Input Resolution	Augmentation Strategy	Weight Initialization
Road Hazards 2	640 × 640	None	Public Checkpoints (MS COCO)
Road Hazards 3	640 × 640	Horizontal Flip	Road Hazards 2
Road Hazards 6	640 × 640	Horizontal Flip	Public Checkpoints (MS COCO)
Road Hazards 7	640 × 640	Horizontal Flip + Shear Rotation ±10° horizontal, vertical	Road Hazards 6
Road Hazards 10	432 × 432	Horizontal Flip + Rotation ±10°	Objects365 Pretrained
Road Hazards 12	432 × 432	Horizontal Flip+ Shear Rotation ±10° horizontal, vertical	Objects365 Pretrained
Road Hazards 13	432 × 432	Horizontal Flip+ Rotation ±10°	Objects365 Pretrained

In addition to the configurations summarized in Table 1, RF-DETR models were trained using a batch size of 16, 100 epochs, a learning rate of 1×10^{-4}, and the AdamW optimizer. For YOLOv8, training was performed using the available hyperparameter settings provided by the Roboflow platform. These settings were not manually modified and were kept consistent across experiments to ensure fair comparison.

Evaluation metrics and loss functions

Model performance was evaluated using standard instance segmentation metrics commonly adopted in object detection and segmentation tasks. Mean Average Precision at an Intersection over Union threshold of 0.50 (mAP@50) was used as the primary evaluation metric, as it provides a balanced measure of detection accuracy under moderate localization constraints. In addition, precision and recall were reported to analyze false-positive and false-negative behavior, which is particularly important in safety-critical applications such as road condition monitoring.

During training, multiple loss components were continuously monitored to assess learning dynamics and segmentation quality. This included a Dice loss to evaluate the quality and overlap of predicted segmentation masks, classification loss to measure label prediction accuracy, and bounding box localization loss to quantify spatial regression performance. The evolution of both loss values and evaluation metrics across training epochs was analyzed to assess convergence behavior, detect potential overfitting, and guide model selection.

Results and discussion

The quantitative performance of all trained models is summarized in Table 1.

Table 2: Performance comparison of pothole detection models

Model Name	Type	mAP@50	Precision	Recall
Road Hazards 2	YOLOv8 (Baseline)	45.9%	74.1%	40.0%
Road Hazards 3	YOLOv8 (Extra data)	48.0%	56.5%	45.5%
Road Hazards 6	YOLOv8 (Augmented)	59.6%	74.8%	54.5%
Road Hazards 7	YOLOv8 (Double Aug)	56.0%	59.9%	60.5%
Road Hazards 10	RF-DETR (Transformer)	66.3%	87.5%	55.0%
Road Hazards 12	RF-DETR (Transformer)	65.9%	75.0%	59.0%
Road Hazards 13	RF-DETR (Transformer)	65.6%	78.0%	60.0%

The experimental results demonstrate the progressive improvement in pothole detection and segmentation performance achieved through model architecture

selection and data augmentation strategies. Comparative evaluation across convolutional and transformer-based models highlights both the benefits and limitations of current instance segmentation approaches when applied to aerial road surface imagery.

The initial YOLOv8 baseline models exhibited limited generalization capability. Early configurations achieved mAP@50 values in the range of approximately 46–48%, indicating difficulty in distinguishing shallow potholes from visually similar background artifacts such as shadows, stains, and surface irregularities. Precision was moderate, while recall remained comparatively low, reflecting a tendency to miss subtle, low-contrast pothole instances. These observations suggest that purely convolutional architectures struggle to capture sufficient contextual information when pothole boundaries are weak or ambiguous.

With the introduction of targeted data augmentation and incremental dataset expansion, YOLOv8 performance improved noticeably. Augmented variants achieved mAP@50 values in the range of approximately 56–60%, accompanied by an increase in recall to around 60%. This improvement highlights the importance of data diversity in enhancing robustness to variations in viewpoint, surface texture, and local appearance. Nevertheless, despite these gains, the convolutional models continued to face challenges in accurately delineating pothole boundaries under low-contrast conditions, indicating an architectural limitation rather than a data-only constraint.

The transformer-based RF-DETR models delivered the strongest overall performance across all evaluated metrics. The best-performing configuration achieved a mAP@50 of 66.3%, with precision reaching up to 87.5% and recall stabilizing in the range of 55–60%. Other RF-DETR variants produced comparable results, with mAP@50 values consistently above 65%. The transition from YOLOv8 to RF-DETR resulted in the largest single performance improvement, underscoring the effectiveness of global self-attention mechanisms and strong pretrained representations for capturing long-range contextual relationships in aerial imagery.

Figure 1 illustrates the training dynamics and loss behavior of the best-performing RF-DETR model. The mAP@50 curve stabilizes within the range of approximately 0.63–0.67 during the first 8–10 epochs, indicating rapid convergence driven by effective transfer learning. Minor oscillations observed after convergence suggest sensitivity to limited training data rather than training instability or overfitting. Dice loss remains relatively high and fluctuating, reflecting the inherent difficulty of producing consistent segmentation masks for shallow potholes with weak or gradual visual boundaries. Classification loss and bounding box localization loss remain generally stable, with occasional spikes attributable to small object sizes and annotation uncertainty.

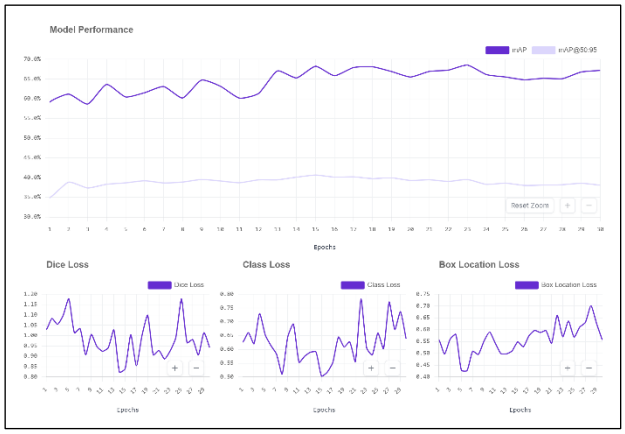

Figure 1: Performance and loss metrics of model Road Hazards 13

Qualitative evaluation further supports the quantitative findings. As illustrated in Figure 2, both YOLOv8 and RF-DETR models successfully detect potholes that are well illuminated and exhibit clear texture contrast relative to the surrounding road surface. Correct detections with high confidence scores demonstrate the capability of the models under favorable visual conditions. However, false positives are commonly triggered by dark stains, shadows, and worn surface patches that visually resemble pothole depressions. Missed detections primarily occur for extremely shallow potholes characterized by gradual depth transitions and weak contrast, particularly near road edges where surface wear blends into surrounding textures.

Figure 2: Single image showing all 3 cases: 1. Correct predictions (88%, 74%), 2. False positives (48%), and 3. False Negatives (below 88% mask)

Compared to YOLOv8, RF-DETR models exhibit a noticeable reduction in shadow-induced false positives and generate more spatially coherent segmentation masks, even in visually cluttered scenes. This behavior confirms the advantage of transformer-based architectures in leveraging broader contextual information, enabling more effective differentiation between true pothole regions and visually similar non-pothole artifacts.

Overall, the results indicate that while transformer-based instance segmentation models provide clear performance advantages over convolutional baselines, detection accuracy remains constrained by dataset scale, annotation ambiguity, and the subtle visual nature of shallow potholes. These findings emphasize that further improvements will likely require larger and more diverse

datasets, enhanced annotation strategies, and the incorporation of complementary geometric or contextual cues beyond RGB imagery alone.

Limitations

Despite the encouraging results obtained in this study, several limitations must be acknowledged. First, the dataset size remains relatively small, consisting of 196 original images, which restricts the diversity of visual scenarios available during training. Although geometric augmentation was employed to partially alleviate this constraint, the limited number of unique real-world samples may still impact generalization to unseen road conditions.

Second, all annotations were produced by a single annotator, introducing unavoidable subjectivity in boundary delineation, particularly for shallow potholes with weak visual contrast. Ambiguous transitions between damaged and undamaged road surfaces make precise annotation challenging and can lead to inconsistencies that affect pixel-level evaluation metrics.

Third, the applied data augmentation strategy was limited to basic geometric transformations. More complex augmentations that simulate real-world imaging conditions, such as motion blur, glare, weather effects, and illumination variation, were not incorporated. The absence of such augmentations may reduce robustness under highly variable environmental conditions commonly encountered in long-term field deployments.

Conclusion

This work presented the development of a custom instance-segmentation dataset for pothole detection and a systematic evaluation of deep learning models trained under realistic data constraints using aerial imagery. A total of 196 original road surface images were manually annotated and expanded through targeted geometric augmentation. Multiple model configurations were trained and evaluated within a unified cloud-based training environment to ensure consistent experimentation and reproducibility.

Baseline convolutional models based on YOLOv8 achieved mAP@50 values in the range of approximately 45–60% as dataset size and augmentation strategies were progressively improved. While these results demonstrate the feasibility of CNN-based approaches for pothole detection, they also revealed limitations in generalization, particularly when detecting shallow potholes with weak visual contrast and ambiguous boundaries. Transitioning to the transformer-based RF-DETR architecture resulted in the strongest overall performance, achieving mAP@50 values of approximately 65–66% and peak precision of up to 87.5%. These improvements confirm the advantage of strong pretraining and global attention mechanisms when operating under limited data availability and visually complex backgrounds.

The primary performance bottlenecks identified in this study were the limited scale of the annotated dataset and unavoidable annotation uncertainty associated with shallow, low-contrast pavement defects. Despite these constraints, the trained models exhibited stable convergence behavior and reliable qualitative performance, particularly in reducing shadow-induced false positives that commonly affect appearance-based detection methods. Such robustness is critical for practical deployment, where minimizing false alarms directly impacts the efficiency of inspection and maintenance workflows.

Overall, this study establishes a viable prototype for aerial pothole detection using instance segmentation and demonstrates the effectiveness of transformer-based architectures for challenging real-world road surface monitoring scenarios. Beyond detection, the generated segmentation masks provide a strong technical foundation for future extensions such as area-based pothole severity estimation, temporal damage progression analysis, and maintenance prioritization. With further dataset expansion, improved annotation strategies, and the integration of complementary geometric or sensing cues, the proposed approach has strong potential to support scalable and data-driven road infrastructure monitoring systems.

Future work

Future work will focus on improving robustness and scalability of the proposed pothole detection system. Expanding the dataset to include more diverse imaging conditions and adopting multi-annotator consensus labeling are expected to enhance segmentation reliability for shallow and ambiguous defects.

Beyond detection, integrating segmentation masks with geometric mapping and depth estimation techniques will enable physically meaningful severity metrics, supporting maintenance prioritization. Model optimization for efficient edge deployment and further improvements through transformer scaling and semi-supervised learning remain promising directions.

SEEING IN THE DARK: LOW-LIGHT IMAGE ENHANCEMENT FOR MODULAR CONSTRUCTION

Yuanyang Qi, Jie Hong, Tingtian Li, and Xiao Li
CI^3 Lab, Department of Civil Engineering, The University of Hong Kong, HK SAR, China

Abstract

Modular construction uses off-site modules for on-site assembly; computer vision supports progress monitoring, inspection, and assembly. These tasks may occur in poorly lit spaces, where low light degrades image quality, while prior work has not addressed low-light enhancement for this setting. We propose RetinexRefiner, a two-stage framework that first performs illumination-based enhancement and then refines the result to suppress residual artefacts such as colour cast and noise. Trained end-to-end, it achieves improved visibility on night construction images, reaching 28.07 dB PSNR and 0.83 SSIM, and is applicable to construction sites and similar dim environments.

Introduction

Modular construction transforms the industry by fabricating volumetric units off-site and assembling them on-site (Ferdous et al., 2019; Zheng et al., 2020), with benefits in quality control, productivity, and safety (Tsz Wai et al., 2023). The on-site phase centres on module handling: monitoring progress (e.g. verifying module statuses) and ensuring safety (e.g. detecting proximity between modules and other objects) (Zheng et al., 2020; Ekanayake et al., 2021). Computer vision supports these activities through progress monitoring, inspection, and assembly (Zheng et al., 2020; Fang et al., 2020; Ekanayake et al., 2021; Qi et al., 2025). The accuracy of such vision tasks depends on image quality (Liu et al., 2023; Li et al., 2021). In practice, the work may take place in poorly lit indoor spaces, shaded areas, or at night (Chauhan and Seppänen, 2023; Ekanayake et al., 2021), where low light degrades images and can cause automated checks to miss defects or misestimate progress (Chauhan and Seppänen, 2023; Ekanayake et al., 2021; Li et al., 2021). Reliable imaging in such conditions is therefore important both for safety (e.g. detecting obstacles and workers) and for progress verification (e.g. documenting module placement and assembly state); improving low-light image quality can directly support these vision-based tasks. Prior work on modular construction has focused on module detection and progress monitoring under normal lighting, and most existing vision systems for construction assume well-lit scenes rather than dim or nocturnal conditions (Zheng et al., 2020; Fang et al., 2020; Ekanayake et al., 2021; Qi et al., 2025); low-light image enhancement for this setting has not been addressed. It is thus critical to explore low-light enhancement methods that can improve visibility for monitoring, inspection, and assembly in modular construction.

Low-light image enhancement aims to improve visibility and restore corruptions (noise, artefacts, colour distortion) hidden in the dark or introduced when brightening underexposed photos. Histogram equalisation and gamma correction directly amplify low visibility but barely consider illumination, often causing noise and colour distortion. Retinex-based methods (Land, 1977) decompose an image into reflectance and illumination; LIME (Guo et al., 2016) refines illumination with structure priors but assumes corruption-free inputs, leading to amplified noise in real low-light scenes. DUAL (Zhang et al., 2019a) performs dual illumination estimation for exposure correction. Deep learning methods have advanced the field (Li et al., 2021). RetinexNet (Wei et al., 2018) introduces a deep Retinex decomposition network and the LOL dataset; KinD (Zhang et al., 2019b) decouples illumination and reflectance for degradation removal. Both require multi-stage training. RUAS (Liu et al., 2021) combines Retinex unrolling with neural architecture search for a lightweight enhancement network. RetinexFormer (Cai et al., 2023) proposes a one-stage Transformer with illumination-guided attention blocks (IGAB) that outperform prior Retinex-based CNNs on multiple benchmarks. Other lines of work include zero-reference and physical-prior methods (Guo et al., 2020; Wang et al., 2024), diffusion-based and dual-branch pipelines (Feng et al., 2024), codebook retrieval and flow-based enhancement (Zhou et al., 2024; Wang et al., 2022), zero-shot neural implicit enhancement (Chobola et al., 2024), and learning-based pipelines for raw or extreme dark imaging (Chen et al., 2018; Jiang et al., 2025); recent work also explores new colour spaces for low-light enhancement (Yan et al., 2025). For construction and monitoring, we focus on Retinex-based paired learning so that we have an explicit illumination map and a clear reference (ground truth) for evaluation. Retinex-based methods follow the imaging relation that observed intensity is the product of reflectance and illumination; they offer interpretable decomposition, explicit illumination maps, and a natural fit for paired supervised learning. We build on RetinexFormer because it achieves strong performance

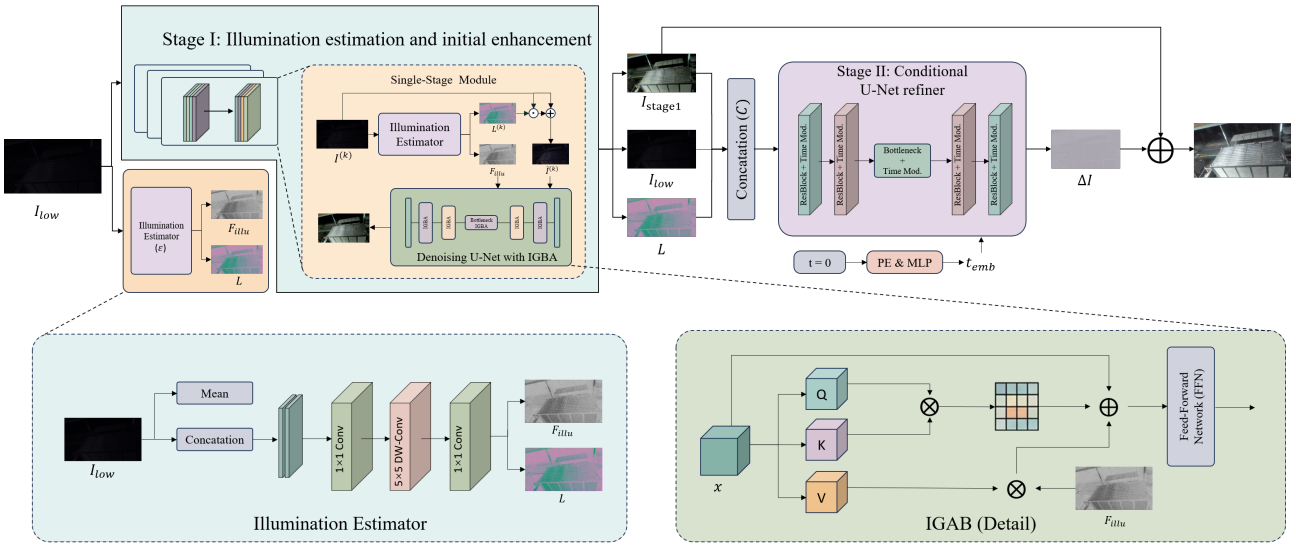

Figure 1: RetinexRefiner two-stage pipeline. Low-light input I_{low} is fed to Stage I (illumination estimation and initial enhancement), which outputs an illumination map L and an initial enhanced image I_{stage1}. Stage II (conditional U-Net refiner) takes $[I_{\text{low}}; I_{\text{stage1}}; L]$ and predicts a residual; the final output is $I_{\text{final}} = I_{\text{stage1}} + \text{Refiner}(\cdot)$. Both stages are trained end-to-end.

among Retinex-based methods and provides an explicit illumination map, which we use to condition the refiner. However, like other one-stage methods, it can leave residual artefacts in very dark regions, such as colour cast, noise, and under- or over-correction.

To address this, we propose RetinexRefiner, a two-stage pipeline that extends RetinexFormer with a refinement stage to correct such artefacts. The pipeline is trained end-to-end on paired normal-light and low-light construction images. Our main contributions can be summarised as follows:

- We address low-light image enhancement for modular construction, where on-site monitoring and assembly may occur in poorly lit or indoor conditions and prior work has not focused on this setting.
- We propose RetinexRefiner, a two-stage pipeline: stage one performs Retinex-based illumination estimation and initial enhancement; stage two uses a conditional U-Net refiner on the low-light image, stage-one output and illumination map to correct residual colour cast and noise, with both stages trained end-to-end on paired images.
- Quantitative and qualitative experiments on night construction images show improved visibility and competitive PSNR/SSIM, outperforming the stage-one baseline and comparison methods.

The paper is organised as follows. Section 2 presents the methodology (two-stage pipeline, Retinex formulation, stage I and stage II). Section 3 describes the experiments, results and ablations. Section 4 discusses limitations; Section 5 concludes and outlines future work.

Methodology

Pipeline overview

Figure 1 summarises the RetinexRefiner pipeline. Given a low-light image I_{low}, the first stage estimates illumination and yields an illumination map L and an initial enhanced image I_{stage1}. The second stage takes I_{low}, I_{stage1}, and L as input and predicts a residual. The final output is

$$I_{\text{final}} = I_{\text{stage1}} + \text{Refiner}(\cdot), \tag{1}$$

where I_{low} is the low-light input image, I_{stage1} is the stage-one enhanced image, L is the illumination map from stage one, I_{final} is the final enhanced output, and $\text{Refiner}(\cdot)$ denotes the conditional U-Net applied to the concatenation $[I_{\text{low}}; I_{\text{stage1}}; L]$. Both stages are differentiable and trained end-to-end.

Retinex-inspired formulation

We follow the Retinex assumption: an image is the element-wise product of reflectance and illumination,

$$I = R \odot L, \qquad R, L \in \mathbb{R}^{3\times H\times W}, \tag{2}$$

where I is the observed image, R is the reflectance, L is the illumination, $\odot$ denotes element-wise multiplication, and H, W are the image height and width. Stage one yields $I_{\text{stage1}} = \mathscr{F}_{\text{RF}}(I_{\text{low}})$ and $L = \mathscr{E}(I_{\text{low}})$. Stage two predicts a residual and adds it:

$$\begin{aligned} \Delta I &= \mathscr{R}([I_{\text{low}}; I_{\text{stage1}}; L], t = 0), \\ I_{\text{final}} &= I_{\text{stage1}} + \Delta I. \end{aligned} \tag{3}$$

where $[\cdot;\cdot;\cdot]$ denotes channel concatenation, $\mathscr{R}$ is the conditional U-Net refiner, ΔI is the predicted residual, t is the time step (fixed at 0 in our setup), and I_{final}, I_{stage1} are the final and stage-one enhanced images. The first stage performs illumination estimation and initial enhancement;

we extend the pipeline with the refiner for the second stage.

Stage I: Illumination estimation and initial enhancement

Stage one follows the one-stage Retinex-based framework of Cai et al. (2023), with three single-stage modules in sequence. At the k-th stage ($k = 1,2,3$), the illumination estimator forms $X_{\text{in}} = [I^{(k)}; \text{mean}_c(I^{(k)})]$ and outputs F_{illu} and $L^{(k)}$:

$$\begin{aligned} F_{\text{illu}}, L^{(k)} &= \mathscr{E}_{\text{stage}}(X_{\text{in}}) \\ &= \phi_2 \circ \phi_{\text{dw}} \circ \phi_1(X_{\text{in}}), \end{aligned} \tag{4}$$

where X_{in} is the concatenation $[I^{(k)}; \text{mean}_c(I^{(k)})]$ with mean_c the channel-wise mean, $I^{(k)}$ is the image at the k-th sub-stage ($I^{(1)} = I_{\text{low}}$), F_{illu} is the illumination feature, $L^{(k)}$ is the light-up map, $\mathscr{E}_{\text{stage}}$ is the illumination estimator, and ϕ_1, ϕ_{dw}, ϕ_2 are 1×1 conv, depth-wise conv, and 1×1 conv respectively. The input is modulated and fed to the denoising U-Net with IGAB:

$$\tilde{I}^{(k)} = I^{(k)} \odot L^{(k)} + I^{(k)}, \quad I^{(k+1)} = \mathscr{D}(\tilde{I}^{(k)}, F_{\text{illu}}) + \tilde{I}^{(k)}, \tag{5}$$

where $\tilde{I}^{(k)}$ is the lit-up image, $I^{(k+1)}$ is the output of the k-th sub-stage, and $\mathscr{D}$ is the denoising U-Net with illumination-guided attention blocks (IGAB). Each IGAB uses

$$\mathbf{A} = \text{softmax}(\mathbf{K}^\top \mathbf{Q} / \sqrt{d}), \quad \text{Attn} = \mathbf{A}(\mathbf{V} \odot F_{\text{illu}}), \tag{6}$$

and

$$\begin{aligned} \text{IGAB}(x, F_{\text{illu}}) &= W_O \text{Attn} + \text{PE}(F_{\text{illu}}) + \text{FFN}(x), \\ \text{FFN}(x) &= W_2 \, \text{GELU}(\text{DWConv}(W_1 x)), \end{aligned} \tag{7}$$

where $\mathbf{A}$ is the attention weight matrix, Attn is the attention output, $\mathbf{Q}$, $\mathbf{K}$, $\mathbf{V}$ are the query, key, and value from the input feature x, x is the input feature to the block, d is the head dimension, W_O, W_1, W_2 are learnable projection matrices, PE is positional encoding, FFN is the feed-forward network, GELU is the Gaussian Error Linear Unit activation, DWConv is depth-wise convolution, and $\odot$ is element-wise multiplication. Thus

$$\begin{aligned} I^{(1)} &= \mathscr{F}_1(I_{\text{low}}), \\ I^{(2)} &= \mathscr{F}_2(I^{(1)}), \\ I_{\text{stage1}} = I^{(4)} &= \mathscr{F}_3(I^{(2)}). \end{aligned} \tag{8}$$

where $\mathscr{F}_k$ denotes the k-th single-stage module ($k = 1,2,3$), and $I^{(4)}$ denotes the output after the third sub-stage (i.e. I_{stage1}). We train stage one jointly with stage two.

Stage II: Conditional U-Net refiner

Stage two takes the condition $C = [I_{\text{low}}; I_{\text{stage1}}; L] \in \mathbb{R}^{9 \times H \times W}$ and fixed $t = 0$. The time embedding is sinusoidal:

$$\mathbf{t}_{\text{emb}} = \text{MLP}(\text{PE}(t)), \tag{9}$$

where t is the time step (fixed at 0), PE is sinusoidal positional encoding, MLP is a multilayer perceptron, and $\mathbf{t}_{\text{emb}}$ is the time embedding vector. Each residual block is modulated by $\mathbf{t}_{\text{emb}}$:

$$\begin{aligned} h &= \sigma(\text{Conv}_1(x) + \text{proj}(\mathbf{t}_{\text{emb}})), \\ \text{ResBlock}(x, \mathbf{t}_{\text{emb}}) &= \sigma(\text{Conv}_2(h)) + \text{skip}(x), \end{aligned} \tag{10}$$

where x is the input to the block, h is the intermediate feature after the first conv and modulation, σ is the SiLU activation, Conv_1, Conv_2 are convolutional layers, proj projects $\mathbf{t}_{\text{emb}}$ to the feature dimension, and $\text{skip}(x)$ is the identity shortcut. The U-Net computes $x_0 = \text{Conv}_{3\times3}(C)$, then encoder ResBlocks with pooling, bottleneck, decoder ResBlocks with skip connections, and

$$\Delta I = \text{Conv}_{3\times3}(u_2), \qquad I_{\text{final}} = I_{\text{stage1}} + \Delta I, \tag{11}$$

where x_0 is the initial feature map from the 3×3 convolution on C, $C = [I_{\text{low}}; I_{\text{stage1}}; L]$ is the 9-channel condition, ΔI is the predicted residual, and u_2 is the decoder feature after the second upsampling block. This single-step refinement improves detail and reduces artefacts. Stage one already handles most of the illumination correction and denoising; the remaining errors are often local and residual (e.g. colour cast, residual noise in dark regions). The refiner, conditioned on I_{low}, I_{stage1}, and L, corrects these with a lightweight U-Net rather than enlarging the first-stage model. Both stages are trained end-to-end on paired normal/low-light images; the training objective and data generation are described in the Experiments section. Algorithm 1 summarises the inference procedure.

Experiments

Datasets

We use a paired dataset: normal-light images (reference, from a construction or site image set) and synthetically darkened low-light images. In line with common practice in supervised low-light enhancement when large-scale real low-light/normal-light pairs are scarce (Wei et al., 2018), we synthesise the low-light side from normal-light references rather than using night-time captures. Low-light images are generated with the darkening curve $y = b \cdot (a \cdot x)^\gamma$, where x is the normal-light pixel value, y is the darkened value, a, b, γ are coefficients sampled per channel (e.g. $a \in [0.38, 0.52]$, $b \in [0.22, 0.38]$, $\gamma \in [1.6, 2.0]$). Because coefficients are randomised per image and channel, some synthetic low-light inputs are intentionally very dark, covering challenging under-exposure. Optionally we add signal-dependent noise variance $\sigma_s^2 \propto L$ (with L the local illumination) and signal-independent noise variance σ_c^2, yielding $z = \text{clip}(y + n_s + n_c)$, where z is the final low-light value, and n_s, n_c are zero-mean Gaussian noise. We refer to the reference set as the normal dataset and the darkened set as the night dataset; the dataset comprises 200 image pairs. We randomly split these pairs into 160 pairs for training and 40 pairs for held-out testing (ratio 4:1). Geometric augmentation (flips, rotation) and crops of 128×128 are used during training.

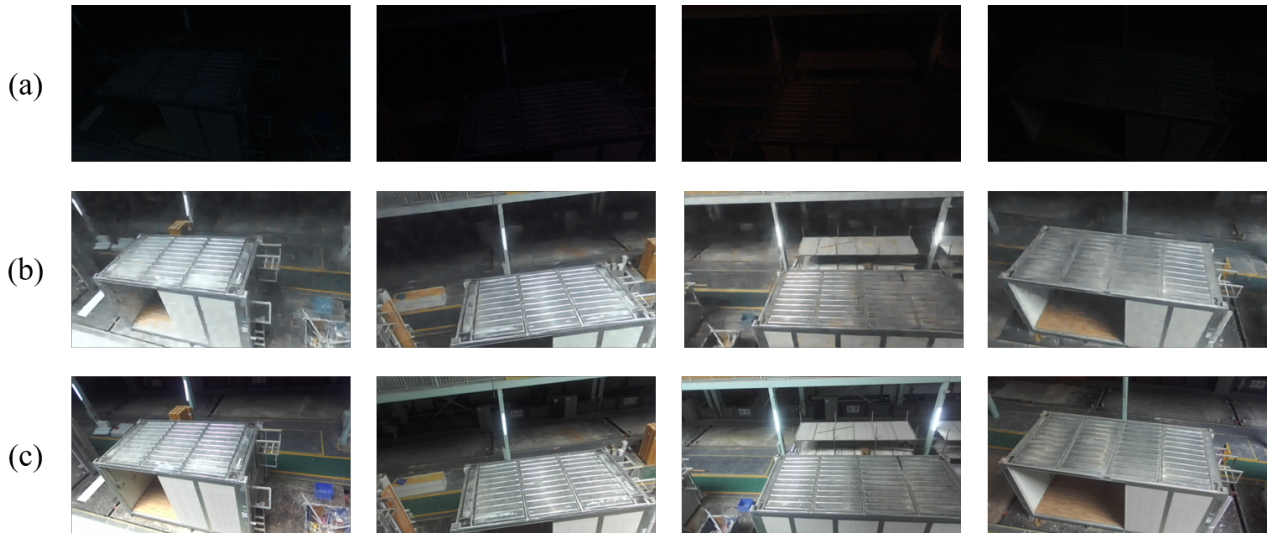

Figure 2: Multiple examples: (a) low-light input, (b) RetinexRefiner output, (c) ground truth. Each column is one sample from the construction dataset.

Implementations

We implement RetinexRefiner in PyTorch. Stage one (illumination estimation and initial enhancement) uses the RetinexFormer backbone (Cai et al., 2023) unchanged; stage two is a conditional U-Net that takes the 9-channel concatenation $[I_{\text{low}}; I_{\text{stage1}}; L]$ and predicts a residual. The refiner has an encoder-decoder structure with skip connections: it downsamples twice (average pooling), processes the bottleneck, then upsamples with bilinear interpolation and concatenates skip features before predicting the residual. The residual blocks are modulated by a sinusoidal time embedding (we fix $t = 0$ at inference). Both stages are trained end-to-end. The training objective is L1 loss between the output and the ground-truth normal-light image; we do not use a separate loss on stage one. We train for 60,000 iterations with Adam (learning rate 1×10^{-4}, betas 0.9 and 0.999), cosine-annealing restart (three periods of 5000 iterations, minimum learning rates 10^{-4} and 10^{-5}), batch size 4, and mixup (beta 1.2) with optional identity mapping. Gradient clipping is applied. Training and model settings are summarised in Table 1.

Table 1: Training and model settings for RetinexRefiner: number of iterations, batch size, crop size, optimizer (Adam with learning rate 1×10^{-4}), and loss (L1 to ground-truth normal-light image).

Setting	Value
Iterations	60k
Batch size	4
Patch size	128×128
Optimiser	Adam (1×10^{-4})
Loss	L1

Evaluation metrics

We use peak signal-to-noise ratio (PSNR, in dB) and structural similarity (SSIM) as evaluation metrics. PSNR measures the ratio between the maximum possible signal and the reconstruction error; higher is better. SSIM captures luminance, contrast, and structure similarity between the enhanced image and the reference; it lies in $[0, 1]$ and higher is better. The normal-light images serve as the reference (ground truth) for both metrics. These are standard full-reference metrics for paired low-light enhancement when references are available.

Quantitative results

We compare with traditional Retinex-based and deep learning methods: LIME (Guo et al., 2016), DUAL (Zhang et al., 2019a), RetinexNet (Wei et al., 2018), KinD (Zhang et al., 2019b), and RetinexFormer (Cai et al., 2023) (stage one only). Table 2 reports PSNR and SSIM on the held-out test set of the construction night dataset. LIME and DUAL, as unsupervised methods that do not optimise for reference matching, yield the lowest scores (PSNR $\approx$ 9.15 dB, SSIM $\approx$ 0.05). Among learning-based methods, RetinexNet reaches 21.50 dB PSNR and 0.69 SSIM; KinD attains 18.16 dB PSNR with higher SSIM (0.82). RetinexFormer (stage one) reaches 27.47 dB and 0.82 SSIM. RetinexFormer is already a strong baseline; further gains are often incremental when stacking a second stage. RetinexRefiner improves over this baseline to 28.07 dB PSNR and 0.83 SSIM (about +0.6 dB and +0.007 SSIM), showing that the conditional U-Net refiner still adds consistent gain. The refiner corrects residual colour cast, noise, and detail loss that remain after stage one. Stage one alone can leave artefacts in very dark regions; the refiner, conditioned on I_{low}, I_{stage1}, and L, both preserves well-enhanced regions and fixes under-corrected ones with modest extra parameters and one extra forward pass.

Algorithm 1 RetinexRefiner inference. Stage I (illumination estimation and initial enhancement) computes the illumination map and runs three sub-stages to obtain I_{stage1}; Stage II builds the 9-channel condition, runs the refiner U-Net, and adds the residual to obtain I_{final}.

Require: Low-light image $I_{\text{low}} \in \mathbb{R}^{3\times H\times W}$
Ensure: Enhanced image $I_{\text{final}} \in \mathbb{R}^{3\times H\times W}$

Stage I: Illumination estimation and initial enhancement
$F_{\text{illu}}, L \leftarrow \mathscr{E}(I_{\text{low}})$ ▷ Illumination map and features
$I^{(1)} \leftarrow \mathscr{F}_1(I_{\text{low}})$ ▷ First sub-stage
$I^{(2)} \leftarrow \mathscr{F}_2(I^{(1)})$ ▷ Second stage (IGAB with F_{illu})
$I_{\text{stage1}} \leftarrow \mathscr{F}_3(I^{(2)})$ ▷ Third stage; initial enhanced image
Stage II: Conditional U-Net refinement
$C \leftarrow [I_{\text{low}}; I_{\text{stage1}}; L]$ ▷ 9-channel condition
$\mathbf{t}_{\text{emb}} \leftarrow \text{MLP}(\text{PE}(t=0))$ ▷ Sinusoidal time embedding
$x_0 \leftarrow \text{Conv}_{3\times3}(C)$ ▷ Initial feature map
Encode: $x_0 \to x_1 \to x_2$ with ResBlocks + pooling, save skip features
Bottleneck: process x_2 with ResBlocks modulated by $\mathbf{t}_{\text{emb}}$ ▷ $h = \sigma(\text{Conv}_1(x) + \text{proj}(\mathbf{t}_{\text{emb}}))$, out $= \sigma(\text{Conv}_2(h)) + \text{skip}(x)$
Decode: upsample, concatenate skips, ResBlocks; obtain u_2 ▷ decoder feature after second upsampling
$\Delta I \leftarrow \text{Conv}_{3\times3}(u_2)$; $I_{\text{final}} \leftarrow I_{\text{stage1}} + \Delta I$ ▷ output equation
return I_{final}

Qualitative results

Figure 2 shows multiple examples from the construction dataset: each column is one sample, with (a) low-light input, (b) RetinexRefiner output, and (c) ground truth (normal-light references are real photographs; low-light inputs are synthetic). The enhanced results recover visibility and detail and are close to the reference. Figure 3 compares methods on the same low-light scene: the top row gives the input and results of LIME, DUAL, and KinD; the bottom row gives the ground truth and results of RetinexNet, RetinexFormer, and the proposed RetinexRefiner. LIME and DUAL exhibit strong colour cast; KinD and RetinexNet improve brightness but remain hazier or less faithful to the reference. The proposed RetinexRefiner is closest to the ground truth in brightness, colour, and detail. In construction and site imagery, text, equipment, and structural details become more visible for monitoring and inspection. These comparisons complement the PSNR/SSIM tables by illustrating perceptual differences that are not fully reflected by those scores alone.

Ablation study

We conduct ablations on the test set of the construction night dataset (Table 3). Training with darkening only yields 16.33 dB PSNR and 0.20 SSIM; adding noise during data synthesis raises performance to 28.07 dB and 0.83 SSIM, showing that noise augmentation improves robustness to real low-light conditions. For the refiner inputs, the full condition $[I_{\text{low}}; I_{\text{stage1}}; L]$ reaches 28.07 dB and 0.83 SSIM. Omitting the illumination map L gives 27.92 dB and 0.83 SSIM; omitting I_{low} gives 27.92 dB and 0.82 SSIM. Both variants are slightly worse than the full model, indicating that L helps the refiner correct residual artefacts and that I_{low} provides useful low-light context. These results validate the design of the conditional refiner.

Table 2: Quantitative comparison (PSNR / SSIM) on the test set of the construction night dataset.

Method	PSNR (dB)	SSIM
LIME (Guo et al., 2016)	9.1515	0.0499
DUAL (Zhang et al., 2019a)	9.1495	0.0522
KinD (Zhang et al., 2019b)	18.1600	0.8158
RetinexNet (Wei et al., 2018)	21.5028	0.6931
RetinexFormer (stage one) (Cai et al., 2023)	27.4707	0.8201
RetinexRefiner (ours)	**28.0747**	**0.8265**

Table 3: Ablation study (test set) on the construction night dataset.

Variant	PSNR (dB)	SSIM
Darkening only	16.3250	0.2033
Darkening + noise	**28.0747**	**0.8265**
Refiner w/o L	27.9220	0.8271
Refiner w/o I_{low}	27.9226	0.8239
Full $[I_{\text{low}}; I_{\text{stage1}}; L]$	**28.0747**	**0.8265**

Discussion

RetinexRefiner contributes to low-light enhancement for construction and built-environment imagery in two ways. First, in terms of application, prior low-light work has not targeted construction or modular assembly; we focus on night construction and similar dim environments for monitoring, inspection, assembly and related vision tasks, where RetinexRefiner can improve visibility over the compared methods. Second, RetinexRefiner provides a two-stage low-light pipeline for construction and built-environment imagery. The main novelty is a lightweight conditional refiner after a Retinex-based backbone: unlike LIME (Guo et al., 2016) and DUAL (Zhang et al., 2019a), we use end-to-end trained stages on paired images; unlike RetinexNet (Wei et al., 2018) and KinD (Zhang et al., 2019b), we train both stages jointly with a single refiner; relative to RetinexFormer (Cai et al., 2023) as stage one, the refiner conditioned on I_{low}, I_{stage1}, and L fixes residual colour cast and noise in dark regions. We position this as a practical refinement module for construction-site imagery under the paired protocol used in this study.

While this study proposes a practical design with measur-

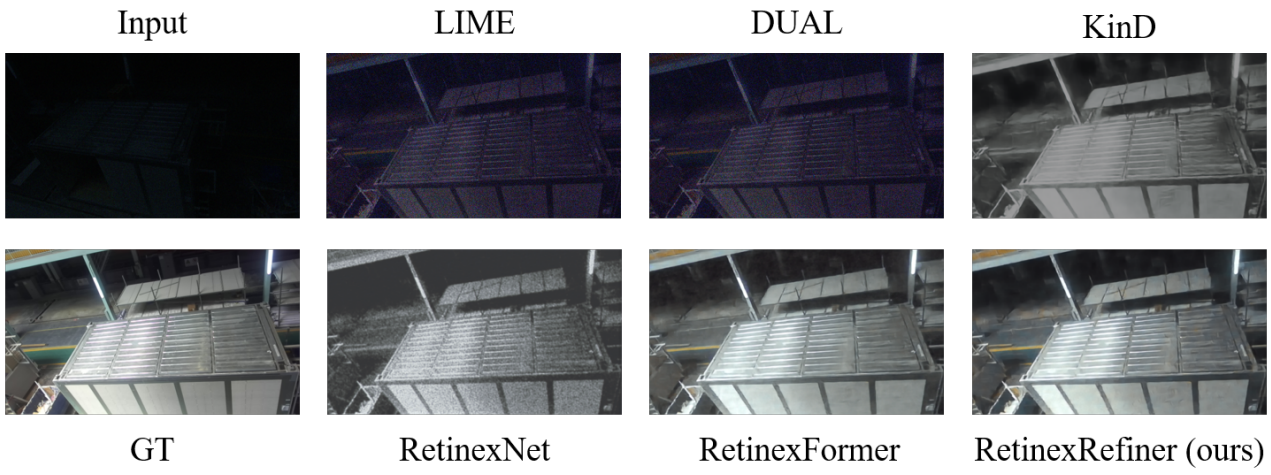

Figure 3: Comparison of methods on one low-light image (construction scene). The low-light input (top left) is a synthetic degradation of the ground-truth normal-light image (bottom left). Top row: input, LIME, DUAL, KinD. Bottom row: ground truth, RetinexNet, RetinexFormer, and the proposed RetinexRefiner.

able gains, it has the following limitations. First, the low-light image in each training/test pair is synthetically generated (darkening and optional noise) from a real normal-light construction or site photograph used as the reference; we do not use pixel-aligned real night-time field captures of the same scene paired with normal-light ground truth. The setup is therefore supervised on synthetic low-light with real references, not unpaired real night-time enhancement. Real camera response and sensor noise may differ from our synthetic low-light branch, so performance may degrade under domain shift; future work includes collecting real paired field imagery where feasible and exploring unpaired enhancement methods. Second, we report only full-reference metrics (PSNR and SSIM); they may not fully reflect perceptual issues such as colour shifts, haloing, or over-smoothing. We do not report no-reference image quality metrics or subjective user studies in this work; these are important directions for future evaluation. Third, the impact of low-light enhancement on downstream tasks such as object detection or semantic segmentation has not been measured—future work will validate this impact. Fourth, we currently compare Retinex-style and classical baselines under a paired protocol; broader cross-family comparisons will be addressed in future work.

Conclusion

In conclusion, we have presented RetinexRefiner, a two-stage Retinex-based method for low-light image enhancement in construction and built-environment contexts. Unlike multi-stage methods that train stages separately or one-stage methods that leave residual artefacts, our pipeline reuses RetinexFormer for illumination estimation and initial enhancement, then applies a lightweight conditional U-Net refiner conditioned on the low-light image, the stage-one output, and the illumination map to predict a residual that improves detail and reduces colour cast and noise; the two stages are trained end-to-end on paired images. Experiments on the construction night dataset show that RetinexRefiner reaches 28.07 dB PSNR and 0.83 SSIM, outperforming the stage-one baseline and comparison methods (LIME, RetinexNet, KinD, RetinexFormer), demonstrating its effectiveness for low-light imagery relevant to modular construction and similar dim environments. The approach is broadly applicable to construction sites, indoor sites, and other scenarios where reliable imaging in the dark is needed.

Future work will focus on: (1) exploring unpaired low-light enhancement methods and using real paired data from construction or field imagery to improve robustness under domain shift; (2) validating the impact of enhancement on downstream tasks such as object detection and semantic segmentation, and reporting task-level metrics (e.g. detection accuracy on enhanced images); (3) incorporating no-reference image quality metrics and subjective user studies to assess perceptual quality beyond PSNR and SSIM.

FROM GENERAL SPACE PLANNER TO LEARNING-BASED GENERATION: A SYSTEMATIC MAPPING OF REPRESENTATION, OBJECTIVES, AND CONTROL

Suhyung Jang[1,2] and André Borrmann[1,2]
[1]Georg Nemetschek Institute, Technical University of Munich, Munich, Germany
[1]Chair of Computing in Civil and Building Engineering, School of Design and Engineering, Technical University of Munich, Munich, Germany

Abstract

Recent advances in learning-based artificial intelligence (AI) show that shared representations (e.g., pixelized images and tokenized corpora) enable multitask foundation model training, whereas digital building layout representations have diverged. Grounded in Eastman's General Space Planner, this study systematically maps 59 studies over a half-century (1971–2025) to trace how building layout representations evolved with expanding objectives and emerging control mechanisms. Publications surged in the final half-decade (52.5%), with representations shifting from simplified to free-formed representations as control mechanisms and objectives diversify. The trends suggest a bottleneck, as consistent transfer of learning-based building layout generation is difficult without a shared representation.

Introduction

Automated building layout planning has been studied for more than five decades, beginning with early computational approaches in the 1960s and evolving through successive waves of constraint-based reasoning (Liggett, 2000), optimization, and, more recently, pattern-based generation (Weber et al., 2022). Despite such sustained effort, automatically generated building layouts have often been limited to single-floor rectilinear primitives. Although recent image-generation approaches have expanded the variety of generated forms, they still face difficulties integrating with current computer-aided design (CAD) or building information modeling (BIM) workflows (Jang et al., 2025b).

A building layout is not merely a set of space boundaries. Spaces, together with adjacency, connectivity, containment, and other relations must be considered. In addition, layout representations should reflect the hierarchy of building components (e.g., levels, rooms, and building elements). These requirements become more pronounced as layout planning shifts from conforming to connectivity and planned proportions conditions to satisfying multiple and sometimes competing design objectives such as code compliance, target cost, environmental performance, and user preferences.

Digital building layout representation, therefore, must represent geometry and topology simultaneously and often must combine multiple encodings to do so (Jang et al., 2025a). As a result, the field has progressed through diverse and sometimes incompatible choices of representation, alongside diversified objective formulations, emerging representations and control techniques. This has made it difficult to establish a stable representational basis for comparing methods or transferring models across building layout tasks. By contrast, in vision and language, shared representations provide stable minimal units for composition spaces, allowing learning-based artificial intelligence (AI) models to learn common structures and generalize across datasets and downstream tasks (LeCun et al., 2015).

For raster images, inputs are consistently defined by a two-dimensional pixel grid with channel values, and for text, contemporary transformer pipelines convert language to token sequences whose semantics are embedded into latent spaces to model context. These shared conventions have been central to multitask learning and foundation models. Building layout representations, however, have diverged over time as objectives and control mechanisms expanded, leaving unclear which representational components are minimally required for transferable learning-based generation across diverse objectives and contexts.

To address this issue, this paper analyzes the automated building layout planning studies conducted over the last half-century to clarify how building layouts have been represented, what has been optimized, and how layout generation has been controlled. To make longitudinal comparisons possible, we use Charles Eastman's General Space Planner (GSP) as a foundational reference (Eastman, 1973), and reorganize its core elements into a three-part analytical framework consisting of representation, objective, and control for decade-by-decade trend mapping (Figure 1).

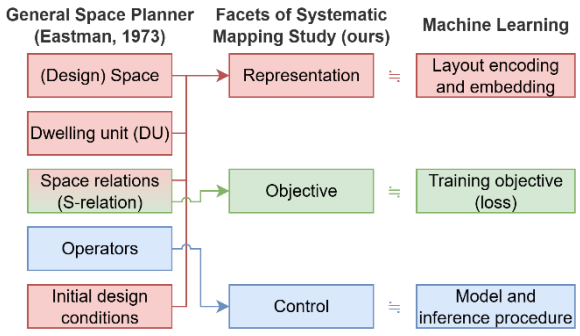

Figure 1: Three analytical facets of the systematic mapping study

Representation captures how layouts are encoded in terms of spatial units, boundaries, and relational structures. Objectives capture what requirements are targeted and how they are formalized through metrics, constraints, or performance criteria. Control captures how planning proceeds through mechanisms used to generate, modify,

and converge on candidate layouts, including search, optimization, constraint solving, learning-based procedures, or interactive refinement. In generalized learning-based building layout generation, these three facets correspond to the representational space in which layouts are encoded, the objective function that defines desirable solutions, and the procedural mechanism through which candidate layouts are generated and refined. This framing is designed to provide a common analytical basis for comparing classical and recent learning-based approaches within a single coding scheme. The goal of this study is to systematically identify persistent elements as central features in building layout planning over multiple decades, as well as to elucidate emerging requirements and methodological advancements associated with the increasing complexity of building layout planning. The analysis is directed toward establishing prerequisites for learning-based AI models that support transferable and extensible general space planning.

The remainder of this paper is organized as follows. The second section describes the systematic mapping study protocol and coding procedure. The third, fourth, and fifth sections present decade-by-decade analyses of trends in representation, objectives, and control. The sixth section discusses current challenges and future prospects, and the seventh section concludes the paper.

Research method

Systematic mapping studies aim to structure a research area by classifying and counting contributions across a predefined scheme, providing an overview of what has been studied and where the literature has appeared. We adopted the updated systematic mapping study guidelines (Petersen et al., 2015), and followed a protocol consisting of planning, conducting, and reporting activities.

Study identification

Space layout planning has co-evolved with broader layout optimization research in manufacturing and industrial engineering, which makes keyword-only retrieval prone to substantial noise. To keep the map focused on building layout planning, a discipline-scoped sampling strategy was adopted for study identification. This study first identified studies from representative journals in the field by discipline. Journal names were collected from Scimago Journal Rankings (SJR), gathering all journals under the "Engineering" subject area, specifically "Building and Construction," and "Architecture" subject categories. Then we developed a Python code using pybliometrics.scopus, a library that supports application programming interface (API)-based searching, to collect the papers from the Scopus database within the relevant disciplines. We queried Scopus using title-level layout terms, namely "space planning," "space layout," "building layout," "architectural layout," "room layout," "space plan," "room plan," "floor plan," and "floorplan," combined with building-related filters in titles, abstracts, and keywords (e.g., "building," "architectural," "dwelling unit," "room," and "housing"). In total, 212 records were retrieved within the target time window (1970-2025).

Study selection was conducted in two stages through title and abstract screening, followed by a full-text screening. We excluded (1) review papers, (2) design theory papers without layout generation, (3) layout analysis papers without automated planning/generation, and (4) studies focusing on urban or site-scale layouts. This screening resulted in 35 included articles.

To improve coverage of earlier and transitional work, we additionally identified candidate studies from two prior secondary sources covering the search window, with one source targeting studies before 2000 (Liggett, 2000) and another targeting studies between 2000 and 2025 (Xu et al., 2025). After removing duplicates and records that could not be retrieved in full text, 17 additional articles were included. Additionally, seven conference papers from the computer vision and machine learning domain were included after snowballing. In total, 59 records were included in the final map.

We then organized the 59 included studies by decade for analysis. The final corpus contains 3 studies from the 1970s, 2 from the 1980s, 6 from the 1990s, 5 from the 2000s, 12 from the 2010s, and 31 from 2020–2025, meaning that publications from the most recent five years account for 52.54% of the screened corpus.

Data extraction and classification

For systematic mapping, we constructed a facet-based classification scheme grounded in GSP's core concepts and aligned the facets with learning-based AI components to support cross-paradigm comparison.

GSP defines a layout planning problem using the following concepts: Space, Dwelling Unit (DU), Space Relations (S-relations), Operators, and an initial design condition. In GSP, S-relations specify constraints to be satisfied, and operators specify how DUs are manipulated within Space. However, across fifty years of research, the role of "relations" has expanded: relations are used in two ways: (1) to encode relational structure (e.g., adjacency / connectivity graphs) and (2) to define what must be satisfied or optimized (e.g., requirements, objectives, performance criteria). To avoid conflating these roles, we separate relation information into two coding targets: relational encoding under *representation*, and relation-derived requirements under *objectives*.

The classification is organized into three primary facets: *representation*, *objective*, and *control*:

- *Representation* captures how the design space, units, and relations are encoded. Because building layouts are often represented using mixed forms (e.g., rectangular vector boundaries together with adjacency graphs), we record (R1) the primary representation and (R2) one or more supporting representations. We also map the representation dimension (R3), where 2.5D augments planar layouts with limited height information (e.g., extrusion or vertical elements for simulation) and 3D models spaces as full volumetric entities.

- *Objective* captures what requirements the method targets and how they are formalized. We record (O1) objective structure (e.g., constraint satisfaction, single-objective, multi-objective, non-optimization generation, learned objective) and (O2) one or more objective metric families (e.g., connectivity, cost, preferences, performance).
- *Control* captures how candidate layouts are generated, modified, and converged. We record (C1) the primary control mechanism, (C2) supporting mechanisms used for enforcement or refinement, and (C3) the interaction mode.

Table 1: Sub-facets and categories of the three analytical facets of systematic mapping study.

Facet	Sub-facet	Categories
Representation (R)	Primary representation (R1)	R1∈{Vector (Rectangle), Vector (Coordinate), Graph, Grid, Voxel, Image}
	Supporting representation (R2)	R2⊆{Vector (Rectangle), Vector (Coordinate), Graph, Grid, Voxel, Image}
	Dimension (R3)	R3∈{2D, 2.5D, 3D}
Objectives (O)	Structure (O1)	O1∈{Constraint-satisfaction, Single-objective, Multi-objective, Learned-objective, Non-objective-oriented}
	Metric (O2)	O2⊆{Adjacency/Connectivity, Area/Size, Circulation/Travel, Distance/Proximity, Orientation/View, Thermal/Energy, Lighting/Daylight, Code/Regulation, Cost, Structural/Engineering performance, Preference/User, Constructability}
Control (C)	Primary mechanism (C1)	C1∈{Operation-based, Case-based, Parameter-based, Learned-based (single-stage), Learned-based (multi-stage)}
	Supporting mechanism (C2)	C2⊆{Operation-based, Case-based, Parameter-based, Learned-based (single-stage), Learned-based (multi-stage)}
	Interactive control (C3)	C3∈{Automatic generation, Interactive generation}

The classification scheme was developed iteratively through an initial category draft based on domain knowledge and subsequent refinement by consolidating and renaming categories based on patterns observed in the collected studies (Table 1).

Representation (R)

Representation describes how a building layout is encoded as a computational object, including the spatial primitives (e.g., rooms, boundaries, cells) and the relational structures used to express adjacency, connectivity, and hierarchy when applicable. Because layout planning requires both geometric reasoning (shape, size, coordinates) and topological reasoning (relations and constraints), many studies rely on heterogeneous representational stacks rather than a single universal format. Consistent with early space-planning work that combined relational encodings with explicit geometric units (Eastman, 1973; Grason, 1971; Pfefferkorn, 1972), we map representation at three levels: (1) a primary representation (R1) that serves as the main modeling unit for generation or optimization, (2) a supporting representation (R2) used to encode constraints, semantics, or downstream structures, and (3) the representation dimension (R3), which captures whether the layout is modeled in 2D, 2.5D, or 3D. Here, planar layout generation with extrusion but without explicit vertical relations is classified as 2.5D, while methods that represent vertical relations are classified as 3D.

Primary representation (R1)

Figure 2 summarizes a shift from early emphasis on coarse digital layout encodings toward higher geometric freedom via grid- and image-based formats.

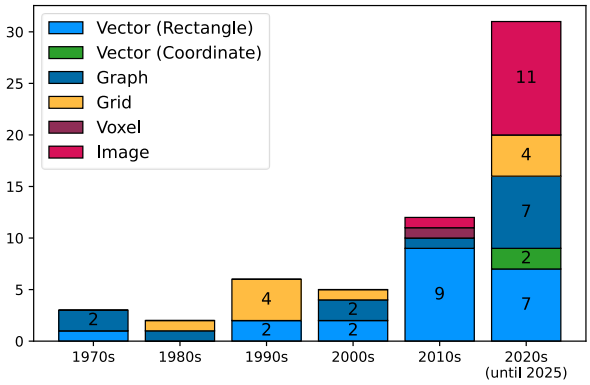

Figure 2: Period-wise distribution of primary representation formats (R1).

In the 1970–80s (n=5), graph dominates (60.0%), with vector-rectangle and grid each at 20.0%, reflecting topology-oriented formulations with simple geometric instantiation (Roth et al., 1982). Grid-based representation marks an early move toward freer boundary expression (Liggett and Mitchell, 1981). In the 1990s (n=6), grid-based representations become the majority primary representation (66.7%). Several studies in this period proposed operator-based grid methods that expand space boundaries to satisfy constraints and produce an initial draft, which is then refined by a human designer toward a less constrained layout (Jo and Gero, 1995). In the 2000s (n=5), primary encodings split between graph and vector-rectangle (40.0% each), with grid at 20.0%, indicating coexistence of topological representation and explicit geometric units. The 2010s (n=12) are dominated by vector-rectangle (75.0%) while image and voxel begin to appear (8.3% each), reflecting diversification through both 2D and 3D encodings (Dino, 2016; Hua, 2016; Marson and Musse, 2010). In the 2020s (until 2025; n=31), image becomes the largest primary category (35.5%), with graph still substantial (22.6%). Overall, the trend indicates increasing reliance on representations that support flexible boundaries and forms, while graph persists as a stable carrier of topological representation.

Supporting representation (R2)

Figure 3 reports supporting representations used alongside R1. Since use of R2 is optional, the total number reflects coded occurrences rather than the number of papers per period. In the 1970–80s (n=4), vector-rectangle dominates (75.0%) with graph at 25.0%, consistent with setups where topological reasoning is primary but explicit rectangular geometry is used to instantiate spatial units. In later work, an explicit separation between topology and geometry is made more systematic; for example, Medjdoub and Yannou (2000) generate a graph describing topological configuration first and then place rectangular space units to realize geometry. In the 2010s (11 coded occurrences), graph becomes the dominant supporting representation (81.8%), with vector-coordinate and vector-rectangle each at 9.1%, suggesting more frequent use of graph as a feasibility/semantic scaffold around diverse primary encodings. In the 2020s (until 2025; n=29), graph remains the most frequent supporting representation (51.7%), followed by image (24.1%) and vector-rectangle (20.7%), with grid at 3.4%. This aligns with recent pipelines that combine image generation with explicit relational structure; for instance, Zheng and Petzold (2023) show graph-guided generation of topology-reflected layout images by using the graph together with image representations. Across periods, even as boundary representation becomes freer (grid/image/vector-coordinate), graph-based support remains central for preserving or recovering adjacency relations and enforcing topological constraints.

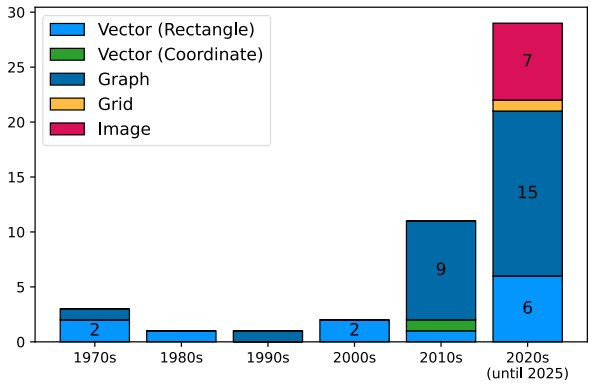

Figure 3: Period-wise distribution of supporting representation formats (R2).

Representation dimension (R3)

Figure 4 indicates that most studies remain focused on 2D representation, with limited adoption of 2.5D or 3D layout generation. In the 1970–80s (n=5), 1990s (n=6), and 2000s (n=5), all coded cases are 2D (100%). In the 2010s (n=12), 2D remains the majority (75.0%), while 2.5D appears (16.7%) and explicit 3D appears in a small minority (8.3%). The only 3D case uses voxel-based representation (Dino, 2016). In the 2020s (until 2025; n=31), 2D remains dominant (90.3%) with 2.5D at 9.7%. Most 2.5D cases arise when planar layouts are extruded or augmented with vertical elements (e.g., walls/windows) to support downstream simulation goals. For example, Rodrigues et al. (2014) extruded generated floor plans to form an energy-performance simulation loop for automated layout generation. Overall, fully automated 3D building layout generation remains underexplored, even though many studies note vertical variation in real buildings as a key limitation and future direction.

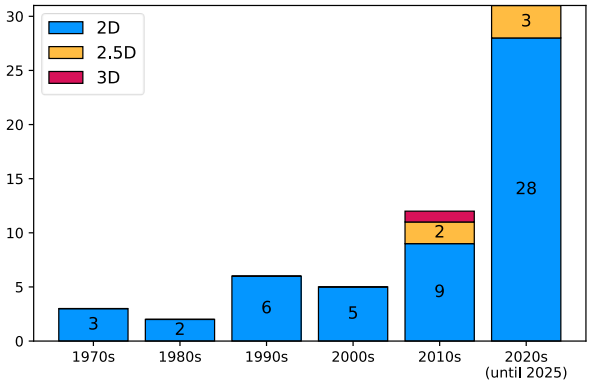

Figure 4: Period-wise distribution of representation dimension (R3).

Objectives (O)

Objectives capture what layout planning methods attempt to achieve and how requirements are formalized into computational targets. To remain compatible across rule-based optimization and learning-based pipelines, we separate objectives into objective structure (O1), which describes the formal type of target, and objective metrics (O2), which describe the substantive design criteria being operationalized.

Objective structure (O1)

Figure 5 shows a transition from constraint-satisfaction-based generation to multi-criteria optimization and, more recently, learned loss formulations. In the 1970–80s (n=5), objective structure is dominated by constraint satisfaction (80.0%), with the remainder framed as single-objective optimization (20.0%), reflecting early feasibility and rule-compliance formulations. From the 1990s (n=6), multi-objective optimization becomes dominant (66.7%), while constraint satisfaction remains substantial (33.3%), consistent with the broader use of evolutionary and annealing-style optimization for competing criteria.

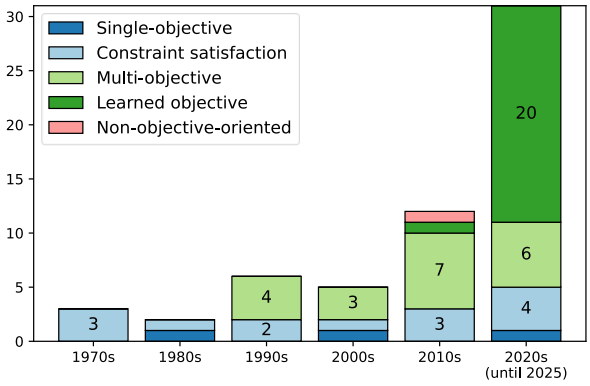

Figure 5: Period-wise distribution of objective structure (O1).

In the 2000s (n=5), multi-objective remains the majority (60.0%), with constraint satisfaction and single objective

each at 20.0%. In the 2010s (n=12), multi-objective continues to lead (58.3%), while constraint satisfaction accounts for 25.0%, and both learned objective (i.e., loss minimization) and non-optimization generation appear (8.3% each), indicating early entry of learning-based formulations. In the 2020s (until 2025; n=31), learned objective (loss minimization) becomes dominant (64.5%), while multi-objective persists (19.4%) and constraint satisfaction remains present (12.9%), with single objective at 3.2%. Overall, as learning-based AI becomes increasingly central to automated building layout generation, objective attainment shifts toward learning optimized patterns from accumulated data, which in turn elevates the importance of representations that can robustly encode and map design-relevant structure (e.g., geometry and topology) into machine-comprehensive formats.

Objective metric (O2)

Figure 6 indicates continuity in core building layout factors and divergence in the objective metrics over time. Across all periods, adjacency/connectivity and area/size are the most persistent and frequently utilized objectives, indicating that they are minimal requirements for functional building layout planning.

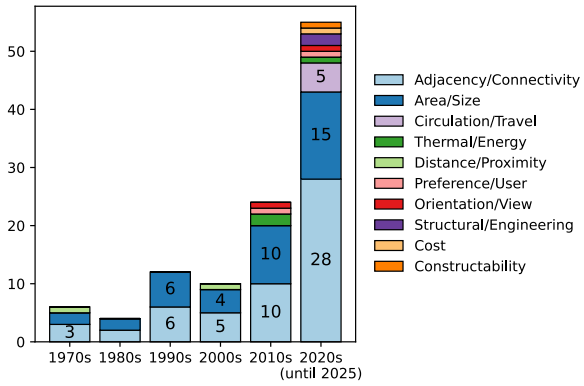

Figure 6: Period-wise distribution of objective metric categories (O2).

In early periods, between 1970s to the 2000s, are mainly concentrated on adjacency/connectivity, area/size, and distance/proximity conformance. Through the 2010s, additional categories appear, including thermal/energy, preference/user, and orientation/view. Between 2020-2025, the coded metric families expand further, adding circulation/travel, structural/engineering, cost, and constructability. These expanding objective scopes are represented by several examples. Rodrigues et al. (2014) exemplifies thermal- and energy-driven optimization by generating plan layouts under topological constraints and searching for alternatives that improve simulated thermal/energy performance. Likewise, Almashaqbeh and El-Rayes (2021) is representative of work optimizing cost and constructability, particularly in modular layout contexts. This diversification of more implementation-specific objectives reflects increasing interest beyond adjacency and area constraints satisfaction.

Control (C)

Control captures how building layout generation proceeds (i.e., the mechanisms used to explore, modify, and converge on candidate solutions) in each study. This facet includes classical strategies such as operator-based search and optimization (e.g., rule-based geometric operations followed by evaluation), case-based reuse (e.g., cased-based reasoning), parameter-based exploration of a defined design space (e.g., parametric modeling and design parameter exploration), and recent learning-based generation (e.g., generative adversarial networks, diffusion models, and transformer models). We code control into primary control mechanism (C1), supporting mechanism (C2), and interaction type (C3).

Primary control mechanism (C1)

Figure 7 shows a transition from operation-centric generation to learned generation in the 2020s, while non-learned mechanisms remain present. In the 1970–80s (n=5), primary control is entirely operation-based (100.0%). In the 1990s (n=6), operation-based control remains dominant (83.3%), with case-based approaches appearing at 16.7%. In the 2000s (n=5), operation-based and parameter-based control each account for 40.0%, with case-based at 20.0%, indicating diversification of classical control strategies. In the 2010s (n=13), operation-based control returns to a strong majority (69.2%), with parameter-based at 15.4%, and learned multi-stage and case-based each at 7.7%. In the 2020s (until 2025; n=31), learned single-stage becomes the largest category (41.9%), followed by learned multi-stage (32.2%), while operation-based (n=5) and parameter-based (n=3) remain at 16.1% and 9.7%. This split suggests that multi-stage learned pipelines may represent a modern reconfiguration of earlier operation-centric control, where learning provides the initial synthesis and operation-style steps reappear as gradual refinement to enforce feasibility and relational consistency.

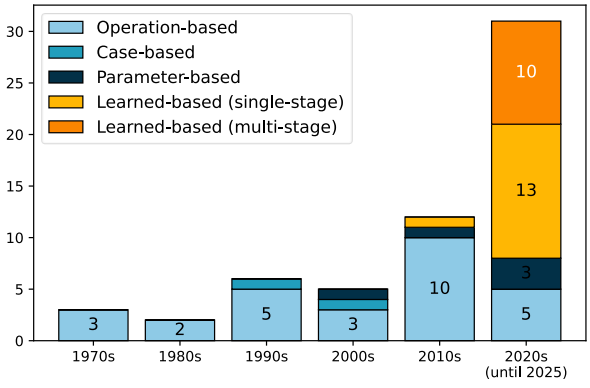

Figure 7: Period-wise distribution of primary control mechanisms (C1).

Supporting control mechanism (C2)

Figure 8 depicts that the use of C2 is sparsely reported across the mapped studies, so interpretation is restricted to cases where a supporting mechanism is explicitly described. In the 1990s, the observed supporting mechanisms are entirely parameter-based (3 occurrences).

In the 2000s, operation-based supporting control appears only once (1 occurrence). In the 2010s, parameter-based supporting control is more common (3 occurrences) while operation-based refinement again appears only in an isolated instance (1 occurrence). In the 2020s (until 2025 in this coding), the observed supporting mechanisms are parameter-based (2 occurrences), with no operation-based supporting refinement recorded.

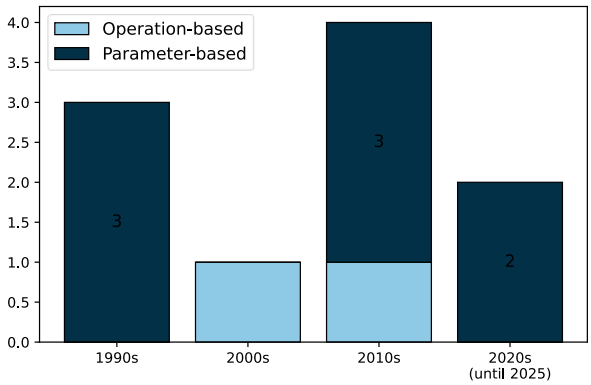

Figure 8: Period-wise distribution of supporting control mechanisms (C2).

Taken together, C2 functions as a robustness layer that stabilizes outcomes on top of the primary control mechanism. Parameter-based supporting control is consistent with restricting or re-parameterizing the design space to reduce sensitivity and guide convergence, whereas operation-based supporting control aligns with hybrid workflows where predefined operators are applied as cleanup or feasibility enforcement after an initial non-operator step. This pattern is consistent with pipelines where a layout is first proposed by a higher-level procedure and then adjusted through operators until constraints and geometric realizability are satisfied. For example, Rosenman (Rosenman, 2000) describes an evolutionary approach in which candidate plans are iteratively transformed and then modified with operators until constraints are met. Merrell et al. (2010) similarly illustrate a learned-to-operator pattern, where a probabilistic model supports program/adjacency generation and axis-aligned split/trim operators instantiate and refine rectangular layout, using supporting steps to ensure feasibility and geometric realization.

Interactive control (C3)

Across the field, interaction is typically limited to setting initial requirements (e.g., constraints, program, adjacency) while generation proceeds automatically, and interactive refinement remains comparatively underrepresented as a core research setting (Figure 9). Recent work begins to incorporate explicit interactive control modes: Shekhawat et al. (2021) propose a system where a user edits an adjacency graph via a graphical user interface (GUI) and the system generates a grid-based plan satisfying the edited relations; Zeng et al. (2024) similarly assume a designer-provided connectivity/adjacency graph and generate a plan layout conditioned on that structure. These examples indicate a shift toward interactive injection of topology or constraints in the 2020s, but the dominant workflow remains fully automated generation.

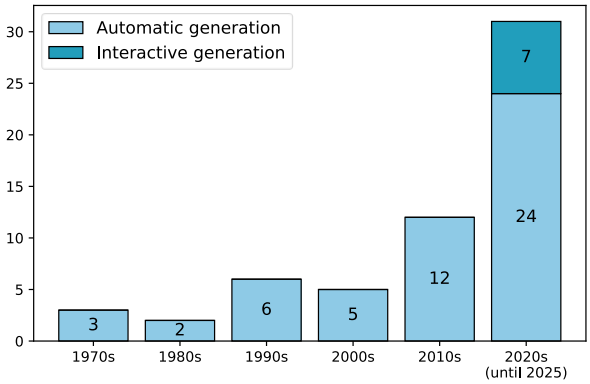

Figure 9: Period-wise distribution of interactive control types (C3).

Discussion

Over the last half-century, representation choices in building layout planning have diversified alongside increasing objective complexity and more sophisticated control mechanisms. At the same time, several primitives remain consistently central, most notably spatial proportions and adjacency relationships. The most recent half-decade marks a quantitative and qualitative inflection driven by learning-based AI. The rise of image-based primary representations and loss-minimization objectives, and learning-based control have become more prominent, increasing geometric freedom while further elevating the importance of representation and inductive bias in model learning.

Yet the trends observed in this study suggest that the field is moving toward divergence rather than convergence, unlike the trajectory that enabled foundation models in the natural language and vision domains. The confusion matrix in Figure 10 highlights this diverging landscape of representations, with the primary representation on the y-axis and the secondary representation on the x-axis. Early work in the 1970s primarily combined graph-based topology with rectangular vector units. In the 1980s–1990s, grid-based representations became more prominent, offering a robust design space that can express diverse shapes while preserving relative spatial relations. From the 2000s into the 2010s, hybridization became more systematic to represent richer context: rectangular primitives often remain the main modeling unit, while graphs increasingly serve as supporting scaffolds to maintain topological consistency.

In the 2020s, representation combinations diversify sharply around image-oriented generation, with graphs and vectors frequently retained as supporting encodings, and occasional pipelines that invert the direction by using images to support graph-based procedures. Overall, literature increasingly pursues higher geometric freedom while continuing to preserve explicit topological structure. This divergence may become more consequential as the field expands beyond predominantly two-dimensional layouts. As the R3 (Dimension) analysis indicates, most studies still operate in 2D, with only limited attention to

2.5D and 3D. However, real buildings are often multi-floor, and vertical spatial relationships must be accounted for, including inter-floor circulation, stacked adjacencies, and the continuity of cores and shafts. This may partly explain why 3D studies remain limited: compared with 2D layouts, 3D settings make it harder to define shared spatial units, build reusable datasets, and evaluate results under common criteria. One possible direction is to combine graph-based topology with more flexible geometric decoders, so that explicit relations can be preserved without overly constraining 3D form.

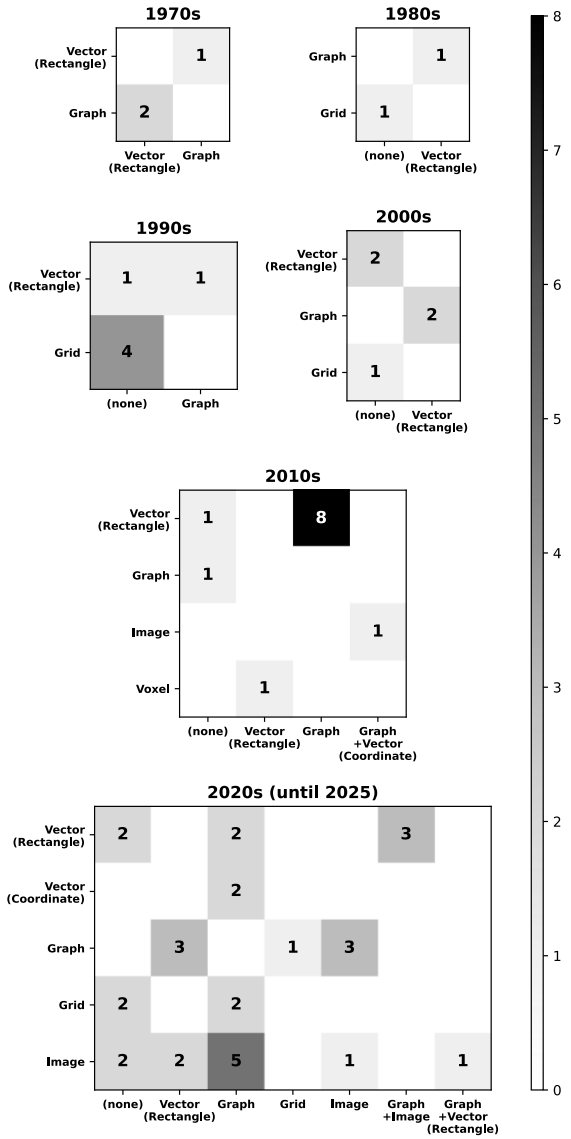

Figure 10: Combination of representation methods across periods.

If this divergence continues, the field may accumulate separate representational tracks for 2D, 2.5D, and 3D, each with different assumptions about basic units and primary relations. That would make comparison, reuse, and cumulative development more difficult. It would also weaken the conditions for domain-specific foundation model training, which usually benefits from a shared representation with stable primitives. A more convergent direction could support dataset sharing, common evaluation, and pretraining across layout tasks and dimensional settings. For practice, this means that multi-floor layout systems need representations that support not only generation, but also inspection and revision. For future benchmarks, evaluation should move beyond single-floor generation and include vertical connectivity, cross-floor consistency, and topology-preserving edits. With the expected shift toward three-dimensional building layout generation, the next stage of the field will depend in part on how this balance between geometric freedom and explicit structure is resolved.

Conclusions

This paper presented a systematic mapping study of automated building layout planning over more than five decades (1971 to 2025). Using Eastman's General Space Planner as a stable conceptual reference, we coded 59 studies along three facets: representation, objectives, and control, to enable decade-by-decade comparison across both classical and learning-based paradigms. The resulting map provides a longitudinal account of what has remained stable in layout planning, what has diversified, and where bottlenecks arise as learning-based methods become dominant.

Several findings are consistent across the full-time window. Adjacency or connectivity and area or size persist as the most central objectives, suggesting that relational coherence and proportional allocation remain minimal requirements across paradigms. As objective sets expand beyond feasibility toward broader criteria such as performance, cost, and constructability, representation and control choices co-evolve, with studies increasingly adopting richer representational stacks and more complex control strategies.

The map also indicates a recent inflection in the last half-decade, which accounts for more than half of the corpus. Learning-based generation becomes a dominant driver, coinciding with the rise of image-based primary representations and learned loss minimization. While these shifts support greater geometric freedom, they do not eliminate the need for explicit structure: graph-based encodings remain central, often as supporting representations for preserving or recovering topology and enabling feasibility and constraint enforcement. Overall, the field is trending toward representational divergence rather than convergence, unlike domains that benefited from shared conventions for foundation-model training. This divergence becomes more consequential under dimensional expansion, since most studies remain 2D despite the multi-floor nature of real buildings and the need to represent vertical relations. Continued fragmentation across 2D, 2.5D, and 3D will further raise the cost of reuse and comparison, whereas full convergence may improve comparability but risks impractical complexity when attempting to preserve both geometric freedom and explicit topology within a single formalism.

Rather than prescribing a single universal representation for building layouts, this study highlights a recurring

pattern in the literature. The pattern shows that geometric freedom is increasingly pursued through flexible encodings, while explicit topological structure is repeatedly retained. Looking ahead, especially toward three-dimensional and multi-floor layout generation, clearer reporting of representational stacks and their mappings, together with evaluation procedures that remain valid across representational and dimensional regimes, will be important for cumulative progress.

A NEURO-SYMBOLIC AI PIPELINE FOR GENERATING SHACL-BASED DIGITAL BUILDING REGULATIONS

Alex Donkers and Ekaterina Petrova
Eindhoven University of Technology, Eindhoven, The Netherlands

Abstract

Automated compliance checking requires the transformation of natural language building regulations into machine-interpretable code. Current Large Language Model (LLM) approaches for generating digital rules often suffer from hallucinations and structural inconsistencies. This paper proposes a neuro-symbolic AI pipeline that grounds LLM reasoning in symbolic logic and domain ontologies to generate SHACL shapes. Evaluation against Dutch construction regulations demonstrates that the pipeline successfully generates functional SHACL shapes for relational, mathematical, and conditional constraints. This work contributes a scalable framework for translating complex legislative code into executable, interoperable digital rule sets for the AECO industry.

Introduction

Digital transformation of the Architecture, Engineering, Construction, and Operations (AECO) industry is increasingly dependent on digitization of building regulations. Traditionally, regulations are authored as natural language documents, which are inherently ambiguous and require manual interpretation by experts. Not only is this process time-consuming and prone to human error, it also limits innovations in BIM-based design workflows. To bridge the gap between human-readable regulations and machine-interpretable code, the research community has explored various ways of digitizing building regulations. One of the emerging ideas is the use of the Shapes Constraint Language (SHACL) to validate Linked Building Data (Nuyts et al., 2024).

However, manual creation of SHACL shapes is a highly specialized task that requires deep knowledge of both semantic web technologies and the specific domain of the regulations, such as fire safety. Recent advancements in Natural Language Processing (NLP), specifically Large Language Models (LLMs), offer a potential solution for automating this process. These LLMs introduce risks when applied to the regulatory domain, including generating terms that do not match with the target ontology, and the appearance of structural inconsistencies in the digital rule representation. Such challenges prevent digital rules from being operationally executable and negatively affect the human trust in these rules.

To overcome these issues, this paper proposes a neuro-symbolic AI pipeline to generate SHACL-based digital building regulations. The aim is to find how symbolic logic representations, such as ontologies and SHACL templates, can be used to enhance reasoning of the LLM. After exploring related work in Section 2, Section 3 explains this neuro-symbolic AI approach in more detail. The approach is tested with Dutch construction regulations in Section 4, after which Section 5 and 6 discuss and conclude this work.

Related work

Digital building codes

Digitization of building codes is a long-standing research topic, and systems to assist in (automated) compliance checking (ACC) have been around for over 50 years (Amor and Dimyadi, 2021). A shared understanding of requirements for such digital building codes is presented by Noardo et al. (2022). These include that normative text should be interpretable by humans and machines, and that we should aim for interoperability through shared dictionaries. Early ideas on the use of Artificial Intelligence (AI) to assist ACC exist since roughly 1990 (Niwa, 1989). Much work in digitization of rules was driven by developments in Building Information Modeling (BIM). In recent years, developments in Natural Language Processing and Large Language Models drove research in rule digitization (Fuchs, 2021).

Ontologies for digital building codes

Ontologies can be used to enhance the interoperability of digital building regulations. As described by Amor and Dimyadi (2021), compliance checking happens on the intersection of building information and normative knowledge, and therefore ontologies representing both sides of the intersection are needed. The research community has increasingly adopted the Linked Building Data (LBD) concept, and the W3C LBD community group presented ontologies that can represent topological building information (Building Topology Ontology, BOT, by Rasmussen et al. (2021)), building elements (Built Element Ontology, BEO, by Ramonell Cazador (2026)), properties (Ontology for Property Management, by Rasmussen et al. (2018)), and geometry (Ontology for Managing Geometry, OMG, Wagner et al. (2019)). Next to these general building ontologies, a wide variety of domain ontologies exists that enable modeling specific domain knowledge. Ontologies representing (AECO-specific) normative knowledge are

more scarce (Werbrouck et al., 2026).

NLP and the generation of digital building codes

The transformation of natural language regulations into machine-interpretable formats has progressed from manual rule interpretation to computer-aided interpretation. A clear example is the semantic tagging of rules with the RASE (Requirement, Applicability, Selection, Exception) method, that moves from manual tagging to human-in-the-loop LLM-based tagging (Al-Turki et al., 2024). The transition is driven by using NLP and domain ontologies to map regulatory terms to semantic concepts, frequently targeting IFC-based compliance (Zhang and El-Gohary, 2016). Subsequent efforts expanded these NLP techniques to extract spatial terms for reasoning (Li et al., 2016) and used models like BERT to transform fire safety regulations into SPARQL queries via semantic labeling and keyword matching (Zheng et al., 2022). Recent research in rule interpretation highly focused on the application of LLMs. Fuchs et al. (2024) applied ChatGPT to transform natural language to LegalRuleML, while Chiappini et al. used ChatGPT to convert text to SPARQL. Currently, the field is moving toward neuro-symbolic AI, which combines neural AI approaches with formal symbolic logic. While early work relied on structured spreadsheets (Costa et al., 2024), current work uses ontologies to improve the reasoning of LLMs (Donkers and Petrova, 2025).

Methodology

System architecture

Figure 1 shows the system architecture for the SHACL converter. It contains a column with input data (the regulatory statement, a domain ontology, W3C LBD ontologies, and SHACL shape instructions), a middle block that prepares input for the LLM (represented by the colored arrows), and the last column with the LLM functionalities. The following subsections discuss the internals of each block in detail.

Linguistic pre-processing

The process begins with the extraction of features from a regulatory statement. The spaCy NLP framework is used to identify noun chunks, which are base phrases with a noun as their head. These noun chunks are later used by the LLM to correctly map terms in the regulations to terms in the ontology. Using noun chunks instead of single tokens in the sentence overcomes incorrect mapping of nouns to terms in the ontology. For example, "A portable fire extinguisher" has universal part-of-speech (POS) tags `DET-ADJ-NOUN-NOUN`, however, "fire" and "extinguisher" should not be mapped to ontology terms in isolation, as "fire" is a compound modifier of "extinguisher". Individual tokens are also extracted, where specific POS tags are excluded to not clutter the ontology term selection. The `nl_core_news_lg` model is used, given that this paper converts Dutch regulations.

Ontologies

To prevent the LLM from hallucinating terms, domain ontologies are used that contain classes that should be used by the LLM. This paper makes use of the Fire-BIM Building Ontology, which is an extensive collection of terms related to the fire safety domain. To enable bridging from these terms to the domain of building information modeling, a subset of the W3C Linked Building Data ontologies (Building Topology Ontology (BOT), Built Element Ontology (BEO), Ontology for Property Management (OPM), Ontology for Geometry Management (OMG)) is used in this work. Listing 1 shows how these ontologies could be linked to make linked building data statements about fire compartments and the spaces they contain.

```
inst:FireCompartment_1 a fbo:FireCompartment ;
    bot:hasZone inst:Space_1, inst:Space_2 ;
    omg:hasGeometry inst:Geometry_1 .
inst:Space_1 a fbo:Space .
inst:Space_2 a fbo:Space .
```

Listing 1: RDF snippet of linking a fire compartment to the spaces it contains

Optimizing ontology representation for LLMs - Encoding rdfs:label and rdfs:comment into vectors - Cosine similarity to measure the distance between the noun chunks and the embedded ontology terms - Selection: n=30

One of the major limitations of LLMs is the amount of tokens that can be used in the prompt, as larger token numbers are more costly and tend to worsen the LLM results. Token counts of the used ontologies (retrieved programmatically using the `google-genai` SDK's native `count_tokens` method to ensure alignment with the model's tokenizer) are presented in Table 1. Striking are the high token counts of BOT (caused by long rdfs:comments in multiple languages) and FBO and BEO (caused by an extensive amount of classes).

Table 1: Ontology token count in Gemini's tokenizer

Ontology	Tokens
fbo.ttl	96.384
bot.ttl	32.042
opm.ttl	4.207
omg.ttl	4.024
beo.ttl	51.900
Total	**188.557**

To limit the high token counts, two methods are applied. For ontologies with `rdfs:comments` in multiple languages, all terms are queried using `FILTER(LANG(?comment)='nl'))` to only select the Dutch comments. For ontologies with a large number of classes and properties, a cosine similarity algorithm is ran between the terms and noun chunks selected during the linguistic pre-processing, and the `rdfs:labels` and

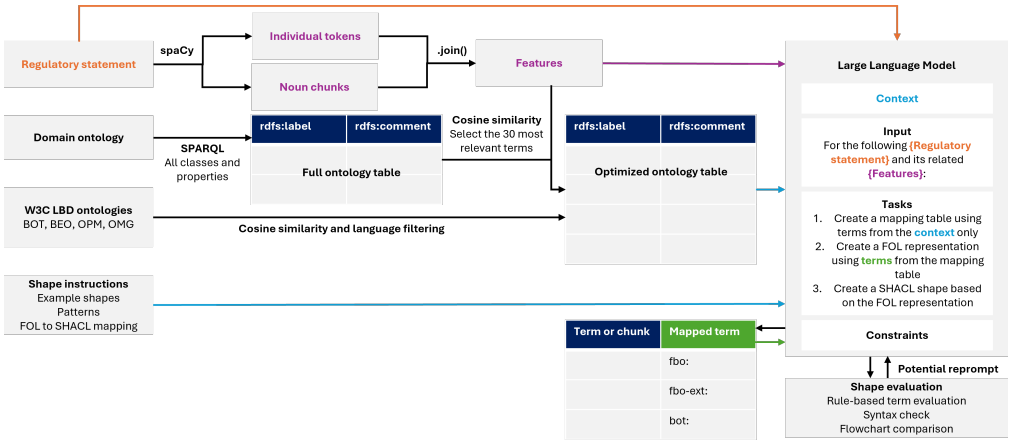

Figure 1: A neuro-symbolic pipeline for generating SHACL shapes

`rdfs:comments` of all terms in the ontology. First, both the regulatory terms and the ontology terms are embedded using the `sentence-transformers/all-mpnet-base-v2` model with Mean Pooling. Then, `sklearn.metrics.pairwise.cosine_similarity` is used to compute the cosine similarity of each entity in the regulatory terms list with each term from the ontologies. For each regulatory term, the top 10 terms are selected, after which these terms are combined and filtered for duplicates. "10" is a rather arbitrary number, that should be evaluated case-by-case, depending on the complexity of regulations and the ontology.

Digital representations of regulations

While SHACL has shown to be able to digitally represent regulations (Donkers and Petrova, 2024), it is a constraint language, not a logic language. Laws are naturally structured as logical implications, where:

$$\forall x(\text{Antecedent}(x) \rightarrow \text{Consequent}(x))$$

First-Order Logic mapping This work aims to preserve this natural structure of the laws (isomorphic modeling) using First-Order Logic (FOL) mapping. Some benefits are that 1) human experts are able to verify the mapping, 2) FOL is implementation agnostic and could be used to generate digital building codes in other formats, and 3) FOL explicitly splits the antecedent and the consequent. The latter if of great importance, as LLMs tend to mix these up when generating SHACL in a zero-shot prompting architecture. The FOL antecedent and consequent can be mapped to other rule markup languages, such as SHACL (`sh:SPARQLTarget` and `sh:PropertyShape`), RASE (Applicability/Selection and Requirement/Exception), IDS (Applicability and Requirements), SWRL (Rule body and Rule head), N3, (LHS and RHS).

There is room for discussion on how to model exceptions in FOL, as one could either model an exception as a negation $(A \wedge \neg E) \rightarrow R$ (making it part of the antecedent) or as a disjunction to the requirement $A \rightarrow (R \vee E)$ (making it part of the consequent). In this paper, we assume exceptions to be modeled using the latter method, as this relates best to how exceptions are written in Dutch regulations, and thus how a rule interpreter should interpret the rule.

SHACL Patterns While FOL serves as an intermediate representation to ensure logical isomorphism with the legal text, SHACL enables making the digital rule operationable. SHACL shapes can be used to validate Linked Building Data graphs for compliance with regulations, and provide means to generate a validation report once the data graph violates the rules dictated in the shapes graph.

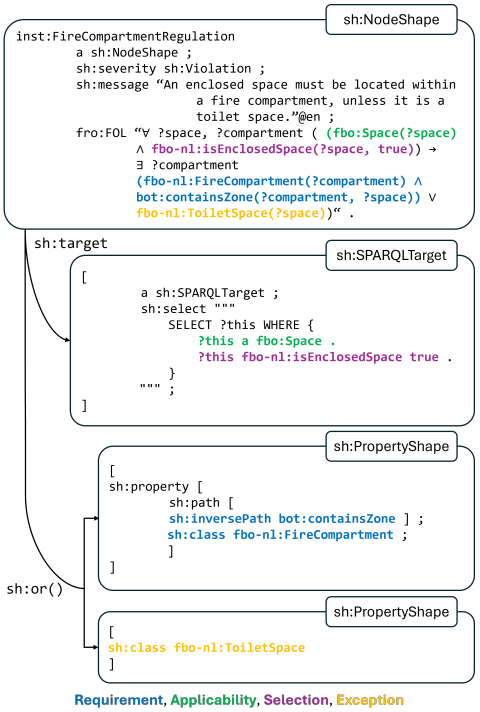

Figure 2: FOL & SHACL representation of a regulation with RASE tags

Figure 2 shows how a text-based regulation can be repersented in FOL, and how that FOL would logically convert to a SHACL shape, where the antecedent is represented in a `sh:SPARQLTarget` and the consequent in

sh:PropertyShapes. The figure also shows how this shape would map to RASE.

While SHACL is a W3C standard, it has a lot of structural ambiguity, meaning rules can be represented using different SHACL representations. These representations do cause SHACL validation engines to behave differently, e.g. by changing how exceptions are modeled, or by different use of logical operaters. An LLM without guidance typically hallucinates a hybrid syntax, making it difficult to evaluate the generated SHACL shape and to predict its constraint behavior. To guide the LLM in generating predictable shapes, a set of standardized SHACL shapes and patterns are prepared. These templates serve to constrain the LLMs output to specific modeling idioms, such as property constraints, inverse relationships, cardinality constraints, topological containment, and logical operators when modeling multiple requirements. This eliminates the structural inconsistencies that occur in zero-shot SHACL generation.

Large language model prompt strategy

A Large Language Model (gemini-2.5-flash) was used via Google's genai Python library. The study applies a structured prompting strategy following In-Context Learning and Constrained Decoding principles. The LLM is provided with explicit Inductive Bias through predefined SHACL templates, minimizing the structural inconsistency of the SHACL generation. Model configurations include temperature=0.0 and max_output_tokens=2048. The prompt contains of 1) Semantic context, 2) Input data, 3) Tasks, 4) Constraints, 5) SHACL generation rules. Those individual items are discussed in the following paragraphs. Listing 2 shows the prompt that was used in Python.

```
You are a Specialist in Semantic Web and Building Regulations.

### SEMANTIC CONTEXT
- Domain ontology: {fbo_str}
- Building ontologies: {w3c_str}
- SHACL templates: {shacl_templates}

### INPUT DATA
Regulatory Text: {regulatory_text}
Extracted Features: {', '.join(features)}

### TASKS
1. MAPPING TABLE: Link statement concepts to context URIs.
2. FIRST-ORDER LOGIC (FOL): Formalize the requirement logic.
3. SHACL SHAPE: Generate a Turtle-formatted constraint shape.

### CONSTRAINTS
- Only use URIs from the provided context.
- If you cannot map a term to the terms from the ontologies in the context, create a new term in the fbo-ext: namespace
- For properties, check directionality. bot:containsZone means that X contains Y, not Y contains X. bot:containsElement means that X contains Y, not Y contains X.
- Output the SHACL shape within code blocks.
- Classes always start with Uppercase, properties lowercase.
- In the FOL representation, preferably use the terms from the mapping table with correct prefixes.

### SHACL generation
- the →'' of the FOL logically splits the FOL into 'applicability' (left of →'') and 'requirements' (right of →''). 'applicability' should be modeled as sh:SPARQLtarget.
- The Rule that needs to be checked (REQUIREMENT) is always part of the consequent, and thus right of the →'', and thus should be in the property node in SHACL.
```

Listing 2: The LLM prompt in Python

Context injection The first part of the prompt involves semantic priming, where the LLM is provided with a domain ontology, a set of building-related W3C LBD ontologies, and SHACL templates. The ontologies are loaded as string-based representations instead of the original Turtle files, based on the optimization method in Section 'Optimizing ontology representation for LLMs'. This significantly reduces the token count of ontologies, e.g. this method optimizes the BOT tokens from 32042 to 2107.

After injecting the semantic context, the input data for the LLM in inserted, being the regulatory text as a string, and a list with features. This feature list is a combination of the noun chunks and the individual tokens selected by the NLP algorithm.

Multi-stage prompting The context is followed by a set of tasks following a multi-stage prompting method, to enable managing the high cognitive load associated with mapping context logic to SHACL. The tasks use a Chain-of-Thought reasoning to decouple the generation of a mapping table, the generation of an FOL representation, and the generation of a SHACL shape. By first mapping features to terms from the ontology in a mapping table, the prompt aims to reduce the number of hallucinated terms. The generation of FOL is then using the mapping table, reusing the mapped terms from the multiple ontologies. The FOL is then converted to a SHACL shape, using the constraints and templates loaded in the prompt. The mapping table, the FOL, and the SHACL shape are all returned by the LLM, enabling human validation.

Evaluation

The generated SHACL shapes are finally evaluated using automated and human-in-the-loop methods. A RegEx-based Python function evaluates the existance of certain syntactical elements in the SHACL shape, such as sh:SPARQLTarget and sh:NodeShape. It also evaluates the existence of the domain ontology prefixes. Secondly, a set of human-in-the-loop evaluation methods were developed. First, human experts can select a list of terms that should be in the returned SHACL shape. A RegEx search looks for the term, allowing for prefixed and unprefixed terms. If not available, the LLM is reprompted, with the previously generated SHACL shape and an error message stating that the term is missing. Secondly, a rule-based method to convert SHACL shapes to the Mermaid

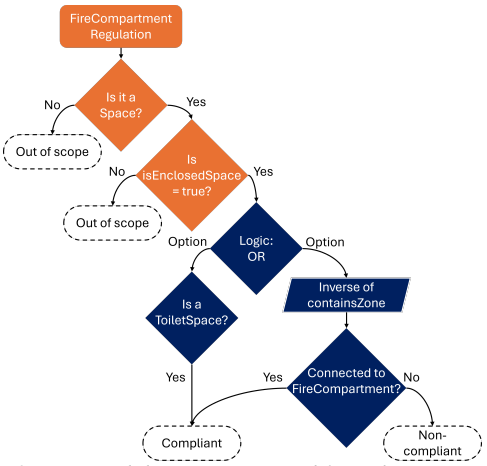

Figure 3: Mermaid diagram generated from the SHACL shape in Figure 2

diagramming language is developed, which enables presenting the SHACL shape as a human-readable flowchart. As Mermaid is code-based, it is possible to include the URIs of terms in the decision tree, making it interactive. This way, a human expert can click on the diagram to open definitions of terms. The antecedent and consequent are colored orange and blue, respectively, to visually help the expert. Finally, two data graphs are modeled for each SHACL shape; one deliberately violating the shape, and one that should pass the check. Since the shapes make use of `sh:SPARQLTarget`, which is a SHACL Advanced Feature, not all SHACL validators are able to run these shapes. The Python-based `pySHACL` engine supports SHACL Advanced Features, which is why an evaluation script is built using this library.

Dataset description To evaluate the developed method, regulations from the Dutch construction law (*'Besluit bouwwerken leefomgeving'*) were converted to SHACL shapes. Steutel (2026) developed a method to convert Dutch fire safety regulations to SHACL. The same set of regulations is manually filtered for regulations that are described by the domain ontology, after which that subset is used in this work. The regulations are categorized using the same categories proposed by Nuyts et al. (2024) to get a sense of the strengths and weaknesses of this approach for each category.

Results

The converter is tested on articles or combinations of articles, as presented in 2. Categories are numbered as follows: 1. information availability, 2. value, 3. relational, 4. mathematical, 5. conditional.

All categories described by Nuyts et al. (2024) are tested and for each of the categories, the converter managed to generate a functional SHACL shape. To test category 1, an Information Requirements rule was modeled to check whether Abox building information was correctly modeled to be checked by rule 4.50(2d). Listing 3 shows the generated SHACL shape. The generator correctly distinguished the antecedent logic (placed in the `sh:SPARQLTarget` and the consequent logic (placed in the `sh:PropertyShape`). While `sh:SPARQLTarget` is not strictly necessary for this specific rule (`sh:target fbo-nl:TechnicalRoom` would suffice), the goal is to generate a set of SHACL shapes that has a stable structure across the set, and future shapes will likely need this modeling method.

Table 2: Article Mapping Results

Article	Category	Mapping	SHACL
4.50(1)	3	●	●
4.50(1)+(2a)	3, 5	●	●
4.50(1)+(2a)+(2b)+(2d)	2, 3, 5	●	●
4.50(1)+4.50(4)	3, 5	●	●
4.50(5)	3	●	●
4.50(1)+4.50(5)+4.50(8)	3, 5	●	○
4.51(2)	3, 4	●	●
4.50(2d) IR	1	●	●

```
fbo-nl:TechnicalRoomShape a sh:NodeShape ;
    sh:target [
        a sh:SPARQLTarget ;
        sh:select """
            SELECT ?this WHERE {
                ?this a fbo-nl:TechnicalRoom .
            }
        """ ;
    ] ;
    sh:property [
        sh:path fbo:hasUsableArea ;
        sh:message "A technical room must have a usable area."@en ;
        sh:minCount 1 ;
    ] .
```

Listing 3: An information requirement rule checking whether Abox building information is suitable for a compliance check

Almost all evaluated articles are categorized as category 3. relational. The SHACL shape generated from article 4.50(1) is shown in Listing 4. Noticable is the different URI representation of the `sh:NodeShape`, which is something that the LLM is not trained for. Listing 4 shows how the LLM correctly interpreted the inverse logic of `bot:containsZone`. The use of `sh:qualifiedValueShape` is somewhat redundant, but does influence the results of the compliance check.

```
<http://www.firebim.org/shapes/enclosed-space-in-fire-compartment> a sh:NodeShape ;
    sh:target [
        a sh:SPARQLTarget ;
        sh:select """"""
            SELECT ?enclosedSpace WHERE {
                ?enclosedSpace a bot:Space .
                ?enclosedSpace fbo-nl:isEnclosedSpace true .
            }
        """""" ;
    ] ;
    sh:property [
        sh:path [ sh:inversePath bot:containsZone ] ;
        sh:class fbo-nl:FireCompartment ;
        sh:qualifiedValueShape [
            a sh:NodeShape ;
            sh:targetClass fbo-nl:FireCompartment ;
```

```
        ] ;
        sh:message ""An enclosed space must be
     contained within a fire compartment."" ;
    ] ."
```

Listing 4: A generated SHACL shape for a relational regulation

Category 2 represents regulations with value checks. Listing 5 shows how the maximum usable area of a technical room and a minimum nominal power of combustion appliances in that technical room are modeled in SHACL by the converter. The units of these values are not yet modeled by the LLM; these are already given in the ontology and can be checked by a separate information requirements check. However, the converter could in the future be extended to include units, e.g. using an extra SHACL template.

```
[ a sh:NodeShape ;
    sh:class fbo-nl:TechnicalRoom ;
    sh:and (
        [ sh:property [ sh:path fbo:hasUsableArea ; sh
     :datatype xsd:decimal ; sh:maxInclusive "50"^^xsd:
     decimal ] ]
        [ sh:not ( [ a sh:NodeShape ;
            sh:property [ sh:path fbo-nl:
     hasCombustionAppliance ; sh:class fbo-nl:
     CombustionAppliance ;
                sh:node [ sh:property [ sh:path fbo-nl
     :hasNominalPower ; sh:datatype xsd:decimal ; sh:
     minInclusive "130"^^xsd:decimal ] ]
            ] ] )
        ]
    )
] .
```

Listing 5: A generated SHACL shape for a value check

Mathematical regulations (category 4) are represented by article 4.51(2). Listing 6 shows 2 of such mathematical functions. The first half of the listing presents a `sh:PropertyShape` that checks whether a fire compartment contains maximum four caravans or ancillary functions. The listing shows that the LLM modeled ancillary functions in the `fbo-ext:` namespace, following the instructions in Listing 2. This is an indication to the ontology engineer that the current domain ontology does not suffice in representing this regulation. The second part of the listing checks whether the total area of these caravans does not exceed 1000 m^2, for which it uses a `sh:SPARQLConstraint` that first queries the area of each individual caravan, then sums these areas, and finally checks whether these areas don't exceed 1000 m^2.

```
fbo-ext:
     FireCompartmentMaxWagonsAndAncillaryFunctionsShape
      a sh:NodeShape ;
  sh:targetClass fbo-nl:FireCompartment ;
  sh:property [
    sh:path bot:containsZone ;
    sh:qualifiedValueShape [
      a sh:NodeShape ;
      sh:or (
        [ sh:class fbo-nl:ResidentialFunctionCaravan ]
        [ sh:class fbo-ext:AncillaryFunction ]
      ) ;
    ] ;
    sh:qualifiedMaxCount 4 ;
    sh:message "Max 4 caravan or ancillary functions."
     @en ;
  ] ;

  sh:sparql [
    a sh:SPARQLConstraint ;
    sh:message "Total area must not exceed 1000 m2."
     @en ;
    sh:select """
      SELECT ?this (SUM(?area) AS ?totalArea)
      WHERE {
        ?this bot:containsZone ?zone .
        ?zone a ?zoneType ; fbo:hasUsableArea ?area .
        FILTER (?zoneType IN (fbo-nl:
     ResidentialFunctionCaravan,
          fbo-ext:AncillaryFunction))
      }
      GROUP BY ?this HAVING (SUM(?area) > 1000)
    """ ;
  ] .
```

Listing 6: A generated SHACL shape for mathematical regulations

Finally, conditional constraints (category 5) can be modeled using the logical operators in SHACL. Figure 2 shows how multiple conditions (in this case exceptions) are modeled by the LLM.

Article 4.50(1)+4.50(5)+4.50(8) did not correctly convert to SHACL. Listing 7 shows the input to the converter. While the mapping from features to terms in the ontology is correctly executed, the generated SHACL shape shows mistakes. A likely cause is the fact that the exception in statement 8 relates to the function of a building, whereas the requirements in statements 1 and 5 relate to a space. Although the LLM generated a syntactically correct SHACL shape, it assumed that `fbo-nl:LightIndustrialFunctionForCultivation` is a class that can be assigned to a space, while this is meant to be a function type of a building. It will therefore in practice not match with Abox building information.

```
1. An enclosed space is located in a fire compartment.
5. A non-enclosed functional area is located in a fire
     compartment.
8. The first and fifth statement do not apply to a
    light industrial function for the cultivation,
    growing, or storage of crops or comparable
    products, with a permanent fire load no greater
    than 150 MJ/m2, determined in accordance with NEN
    6090.
```

Listing 7: A translation of article 4.50(1)+4.50(5)+4.50(8) of the Dutch construction law

```
[ sh:and (
  [ sh:property [
    sh:path rdf:type ;
    sh:hasValue fbo-nl:
     LightIndustrialFunctionForCultivation ]
  ]
  [ sh:property [
    sh:path fbo-nl:hasPermanentFireLoad ;
    sh:maxInclusive 150 ]
  ]
) ]
```

Listing 8: The exception logic of 4.50(8)

Nested exceptions The converter is designed to specify complex exceptions as separate `sh:Nodeshapes`. Listing 5 shows how a complex exception (article 4.50(2d))to the regulation in Figure 2 is modeled by the converter. This rather atomic modeling principle allows a more flexible use of SHACL shapes, allowing end users to query and apply such complex exceptions separately (Donkers and Petrova, 2025), or allowing other SHACL shapes to reuse such exceptions.

Human-in-the-loop validation The generated Mermaid diagrams for each SHACL shape enable human-in-the-loop validation. We validated the generated SHACL shapes using these Mermaid diagrams. Although this method enables non-SHACL-experts to validate SHACL shapes, such methods should still be used with caution. For example, the incorrect use of light industrial functions for cultivation in Listing 8 did result in a syntactically correct SHACL shape, and thus formed a Mermaid diagram. While this Mermaid diagram is arguably easier to read than the SHACL shape, such minor errors are still hard to spot by the human eye.

Validating a data graph To test the functionality of the SHACL shapes in practical use cases, data graphs were created for each SHACL shape, and they were subsequently tested in a `pySHACL`-based script. Listing 9 shows the data graph that was modeled to violate the SHACL shape of article 4.51(2) (which is shown in Listing 6). It violates the rule twice: 1. the fire compartment contains too many caravans or ancillary functions, and 2. the total area of these functions is larger than 1000 m^2.

```
inst:InvalidCompartment a fbo-nl:FireCompartment ;
    bot:containsZone inst:C1, inst:C2, inst:C3, inst:
     C4, inst:A1 .
inst:C1 a fbo-nl:ResidentialFunctionCaravan ;
    fbo:hasUsableArea 250 .
inst:C2 a fbo-nl:ResidentialFunctionCaravan ;
    fbo:hasUsableArea 250 .
inst:C3 a fbo-nl:ResidentialFunctionCaravan ;
    fbo:hasUsableArea 250 .
inst:C4 a fbo-nl:ResidentialFunctionCaravan ;
    fbo:hasUsableArea 250 .
inst:A1 a fbo-ext:AncillaryFunction ;
    fbo:hasUsableArea 200 .
```

Listing 9: Data graph that violates article 4.51(2)

The validation report by pySHACL is printed in Listing 10, and correctly shows the two violations of Article 4.51(2).

```

```

Listing 10: Validation report generated by pySHACL

Discussion

The results demonstrate that grounding LLMs in domain-specific ontologies via a neuro-symbolic AI pipeline enables the generation of SHACL shapes out of natural language regulations. However, a few critical challenges remain unanswered.

The current injection of ontology terms uses a table with the `rdfs:label` and `rdfs:comment`. This loses part of the context of each term, e.g. how classes are associated to other classes, and with what properties. This knowledge is normally strongly represented in ontologies, and future work should answer whether injecting these relationships into the context of the LLM improves the results.

The converter takes individual regulatory statements, or manually inserted combinations of statements. It cannot deal with external sources or references to other articles unless they are explicitly included in the regulatory statement variable. Combining this neuro-symbolic pipeline with the regulation graph as presented by Donkers and Petrova (2025) would enable retrieving regulatory statements from a structured RDF database that helps navigating to the correct articles, tables, figures, and so forth.

While the token optimization method succesfully reduced the number of tokens of each ontology, the n=10 retrieval parameter for ontology terms could cause difficulties for complex regulations. More research is necessary to determine what ontology optimization strategy fits to different scenarios. The converter showed difficulties when converting regulations with a large number of requirements and exceptions, especially with multiple levels of nesting.

The choice of SHACL as a regulatory language poses difficulties in practice. Most SHACL validators traverse all parts of a `sh:and`-statement, even if the first statement fails, causing computational overhead. The nested SHACL approach also has difficulties with 'unknowns': SHACL is a binary that assumes that values that are not in the data graph do not exist. Especially in early design stages, some exceptions in the regulations might be unknown (e.g. whether a building has a sprinkler system), and SHACL shapes natively encounter difficulties with distinguishing between violations and data incompleteness. How to solve such practical challenges remains future research, and results of such research should then be reflected in this pipeline.

Conclusion

This paper presented a neuro-symbolic AI pipeline that leverages the strengths of Large Language Models grounded in symbolic logic and domain ontologies to automate the generation of SHACL-based digital building regulations. By using First-Order Logic as an intermediate representation and applying a structured prompting strategy with predefined SHACL templates, the approach significantly reduces the structural inconsistencies and hallucinations typically associated with zero-shot LLM outputs. The evaluation against Dutch construction regulations demonstrated that the pipeline can effectively handle various rule categories, including relational, mathematical, and conditional constraints, while providing human-interpretable validation via Mermaid diagrams.

However, the transition from individual regulatory state-

ments to a fully automated compliance ecosystem requires addressing several complexities. Future research will focus on integrating this pipeline with comprehensive regulation graphs. While the current method processes isolated articles, a graph-based approach would allow the system to navigate and resolve cross-references between different articles, annexes, and external guidelines. Furthermore, extending neuro-symbolic reasoning to interpret non-textual regulatory elements such as tables, formulas, and diagrams is essential for a holistic digitization process. By linking the generative power of LLMs with structured regulation databases, we can move toward a scalable framework capable of translating vast bodies of legislative code into executable, interoperable, and trustworthy digital rule sets for the AECO industry.

An LLM-Driven Agent-Based Framework for Cross-Regional Construction Policy Evaluation in the Greater Bay Area

Wentao Zhu, Xiao Li, Juan Wang, and Mingtian Xiong
The University of Hong Kong, Hong Kong SAR, China

Abstract

Cross-jurisdiction construction policies in the Guangdong–Hong Kong–Macao Greater Bay Area (GBA) aim to reduce institutional barriers and promote collaboration, yet their impacts are difficult to evaluate ex ante. This paper proposes an LLM-driven agent-based simulation framework integrating a stage-gated project lifecycle, heterogeneous stakeholder agents, and policy-parameterized institutional rules. Policy provisions are encoded into eligibility, cost–risk, and transition mechanisms, enabling traceable policy-to-outcome analysis. Validation is conducted through stylized-facts consistency, reproducing concentration growth and distance-decay collaboration patterns. The framework provides a reproducible testbed for analyzing cross-regional construction policies and their effects on collaboration networks and industry dynamics.

Introduction

The Guangdong–Hong Kong–Macao Greater Bay Area (GBA) is a "9+2" city-cluster initiative intended to strengthen regional connectivity and coordination. In construction, collaboration is increasingly cross-regional but remains shaped by differentiated city functions and institutional arrangements (Hui et al., 2020). To reduce these frictions, Mainland GBA jurisdictions have introduced record-filing and mutual-recognition arrangements, including pilot measures in Guangdong, Qianhai, and Hengqin (Guangdong Provincial Department of Housing and Urban-Rural Development, 2020). A central policy question is whether such measures can materially expand cross-border collaboration and reshape industry outcomes.

Ex ante assessment remains difficult. Macro approaches such as CGE and system dynamics provide transparent aggregate policy mappings, but are less suited to tracing heterogeneous behavior, repeated interaction, and institutionally differentiated responses (Shi et al., 2019; Shin et al., 2014). Agent-based modeling (ABM) addresses this limitation by representing heterogeneous actors and emergent system outcomes (Bonabeau, 2002). In construction, ABM has been used to study supply chains, labor productivity, and safety interactions (Min and Björnsson, 2008; Watkins et al., 2009; Zhang et al., 2019). However, most construction ABM still relies on manually specified heuristics or thresholds (Khodabandelu and Park, 2021). This becomes restrictive when decisions depend jointly on project stage, workload, partner history, policy friction, and compliance requirements, because rule sets grow quickly and remain brittle under newly combined conditions (Li et al., 2024; Wijermans et al., 2023).

Large language models (LLMs) provide a practical way to enrich ABM with more flexible and context-sensitive decision-making. Prior work shows that LLM agents can operate within structured environments under external constraints (Li et al., 2024; Dang et al., 2025), while memory-based LLM agents can support history-dependent adaptation (Park et al., 2023). This is useful in cross-jurisdiction construction settings, where firms must respond simultaneously to institutional heterogeneity, prior interactions, and changing project conditions. Table 1 summarizes the contrast among alternative approaches.

Two practical gaps remain. First, construction projects are process- and constraint-intensive: actions must satisfy stage gates, role dependencies, and compliance chains, so purely dialogue-oriented agents may not yield executable trajectories. Second, cross-jurisdiction policies act through computable mechanisms—entry friction, compliance burden, and scope constraints—so without explicit parameterization, simulations cannot trace effects from policy provisions to behavior and then to network and performance outcomes.

To address these gaps, we propose an LLM-driven ABM framework for evaluating cross-regional collaboration policies in the GBA construction sector. The framework combines an executable four-stage project lifecycle (INIT → SCHEME → AWARD → DELIVER), seven stakeholder roles operating through stage-feasible action sets, and a policy parameter vector embedded into gates and waiting times, cost–risk functions, and event/transition rules.

For validity, we adopt a stylized-facts consistency strategy. Rather than matching exact values, we test whether the simulation reproduces two robust empirical regularities of construction markets: (i) concentration with head-firm dominance and (ii) distance decay with local bias in cross-city collaboration. We then use the platform for counterfactual analysis of network stratification, diffusion paths, and directional asymmetries under alternative policy scenarios.

Methodology

Framework overview

We develop a micro–macro coupled agent-based simulation framework to characterize cross-regional collabora-

Table 1: Comparison of alternative simulation approaches for policy modeling

Model	Micro-level process-aware behavior	Policy heterogeneity	History / memory adaptation	Flexible under new contexts	Low manual rule burden
CGE / System Dynamics	✗	△	✗	✗	✓
Rule-based Agents	✓	△	△	✗	✗
LLM-driven Agents	✓	✓	✓	✓	△

Note: ✓ indicates strong support for the corresponding capability; △ indicates partial support, usually requiring simplified representations or additional manual assumptions; ✗ indicates that the capability is weakly supported or not explicitly represented.

Table 2: Fixed four-stage project lifecycle

Stage (s)	Purpose	Actions	Hard gates $g_s(\mathrm{x})$	Main outputs O_s
INIT	Formalize constraints and form the minimal team	OWN sets budget_ceiling; and schedule_target/risk_preference; QS derives cost_ceiling and cost_structure; ARC produces functional_brief; ENG produces feasibility_precheck.	brief_ready ∧ cost_ceiling_set ∧ team_ready (ARC,QS,ENG)	team_roster; budget_ceiling; functional_brief; risk_precheck.
SCHEME	Freeze scheme and close the cost loop	ARC generates scheme_package; ENG provides system_strategy; SUP provides price_band; and lead_time/availability; QS produces scheme_estimate; and budget_gap; OWN executes freeze_or_iterate.	scheme_frozen ∧ estimate ≤ budget_ceiling	frozen_scheme; tender_boundary; scheme_estimate; material_risk_signal.
AWARD	Mobilization gates: contract, safety, procurement	QS prepares BQ and contract_terms; CS submits bid (incl. risk premium); OWN awards and signs; SAFE outputs safety_plan; SUP confirms critical procurement terms.	contract_signed ∧ safety_plan_ready ∧ critical_supply_secured	signed_contract; safety_plan; procurement_terms; pre_start_delay.
DELIVER	Execute and close loops; handover and final account	CS executes construction; SAFE runs inspect→correct→reinspect; SUP triggers supply events; ARC/ENG initiate changes, QS prices, OWN approves/rejects; then commissioning, final account, and handover.	handover_complete ∧ final_account_closed	Outcome distributions; change_orders; compliance_log; supply_incidents; handover_docs.

tion in the GBA construction sector and evaluate policy impacts (Fig. 1). The model uses an executable, stage-gated project lifecycle as the process backbone, within which heterogeneous stakeholder decisions and interactions are embedded under hard gate conditions, producing auditable project trajectories and a time-varying collaboration network. A lightweight macro environment captures demand, capacity utilization, price pressure, and regulatory intensity, thereby coupling multi-project concurrency with micro execution outcomes. Cross-jurisdiction access and practice rules are encoded as a policy vector $\boldsymbol{\theta}(p)$ and embedded into (i) eligibility and waiting times, (ii) cost–risk functions, and (iii) event/transition mechanisms, yielding a traceable chain from policy provisions to behavioral change and system outputs, including network evolution, concentration trends, and distance-decay signatures.

Project lifecycle backbone: four-stage state machine

Each project follows a fixed four-stage state machine (INIT → SCHEME → AWARD → DELIVER), with transitions governed by hard gates defined on project states (cost, schedule, compliance, and supply). Agents may execute only stage-feasible actions, ensuring executability and direct logging of responsibilities and collaboration ties.

INIT sets budget, schedule, and team formation conditions. **SCHEME** freezes the scheme and closes the cost loop. **AWARD** finalizes mobilization prerequisites, including contract, safety, and procurement. **DELIVER** simulates execution through supply, inspection–correction, and change-management loops, propagating impacts to time–cost outcomes and network evolution.

LLM-driven agents and action execution

The framework includes seven heterogeneous, LLM-driven agent types: owner (OWN), architect (ARC), engineer (ENG), quantity surveyor (QS), contractor (CS),

Table 3: Policy provisions, quantified model parameters, and the initial baseline state

Region / regime	Entry friction	Compliance burden	Scope constraints	τ_p	π_p	σ_p	c_p	s_p
Initial state (2015 pre-policy baseline)	Long and uncertain cross-border approval/recognition procedures.	Higher recurring administrative burden and lower renewal predictability.	Narrow effective cross-border practice scope.	120	0.40	0.45	0.55	0.25
Guangdong provincial pilot (9 Mainland cities)	Online filing; registration/publication within **10 working days**; other procedural stages not uniformly specified.	Validity aligned with **Hong Kong registration validity**; change filing within **30 days**; renewal/annual reporting not explicitly specified.	Broad service coverage within the 9-city area, subject to qualification/capability.	20	0.71	0.20	0.25	0.85
Qianhai (Shen Qianhai Gui [2023] No. 6)	Preliminary review within **5 working days**; public notice ≥**5 working days**; objection handling **30 working days** (extendable).	Validity typically **5 years**; renewal within **90 days before** expiry; change filing within **90 days**.	Moderate scope constrained by practice-category filing and qualification mapping.	10	0.82	0.20	0.35	0.60
Hengqin (Bureau Doc. No. 6/2024)	Fully online; supplementation within **10 working days**; public notice ≥**5 working days**; objection review exists.	Validity aligned with **Hong Kong/Macao registration validity**; renewal within **90 days before** expiry; change filing within **30 days**; annual report by **Dec. 31**.	Broad scope covering construction and multiple professional services, subject to filing scope.	10	0.80	0.25	0.45	0.80
Hong Kong (AP/RSE/RGE registration)	Committee referral/scheduling within **2 months**; outcome notification within **3 months** after review/interview.	Validity **5 years**; renewal window from **4 months** to **28 days** before expiry; restoration within **2 years**.	Statutory scope strictly bounded by registration class.	150	0.85	0.10	0.30	0.20
Macao (urban architecture / engineering / planning qualification)	Hard entry gate requiring ≥**2 years** full-time or ≥**5 years** part-time internship before registration.	Renewal follows local rules; validity reported as **until the following January**.	Statutory scope bounded by recognized qualification and registration domain.	730	0.35	0.10	0.40	0.15

Note: τ_p is entry waiting time (days) and is set equal to the stated procedural time in the policy text, summing sequential stages where applicable. π_p is coded from normalized processing time, number of procedural stages, and whether the procedure contains unspecified or open-ended review components. σ_p is coded from the existence of extensions, objections, or discretionary review. c_p is coded from renewal frequency, annual reporting, and change-filing requirements. s_p is coded as the normalized breadth of recognized service categories and responsibility interfaces. All coded indices are scaled to $[0, 1]$. The initial state represents the pre-policy cross-border practice environment at the start of the simulation in 2015.

Table 4: 2015 empirical anchors and simulation initialization values of macro variables

	D_t	K_t	u_t	P_t	M_t	R_t
2015 real-data anchor	RMB 40.81 tn new-start investment	168,222 firms 51.15 m workers	12.43 bn m^2 / 51.15 m workers	98.2	98.9	442 accidents
Simulation init-value	40.81	168,222; 51.15	243	98.2	98.9	1.00

Note: tn = trillion; bn = billion; m = million. R_t is a constructed regulatory-intensity index, with the 2015 level set to 1.00.

safety/compliance entity (SAFE), and supplier (SUP). Each agent follows a role-consistent decision loop but acts only through the stage-feasible action set induced by the project state machine. The framework is therefore hybrid rather than purely generative: the LLM serves as a bounded behavioral policy module for context-sensitive action selection, while feasibility checks, state transitions, accounting updates, and regulatory enforcement are handled by the rule-based simulator. Agent calibration is implemented at the simulator level rather than through fine-tuning the LLM itself. Role populations, capacities, behavioral priors, and memory-update settings are initialized from empirical distributions or bounded assumptions and adjusted so that the baseline simulation reproduces key stylized collaboration patterns.

Memory mechanism. Each agent maintains two complementary memory stores. *Episodic memory* records short-horizon observations and time-stamped experience traces, including stage changes, gate outcomes, workload pressure, market or policy updates, and realized interaction outcomes such as invitations, bids, approvals, delays, violations, change orders, and partner-specific collaboration experiences. *Semantic memory* stores slower-changing summaries distilled from repeated episodes, including partner reliability, expected approval difficulty, coordination friction, effective bidding conditions, and self-assessed capability across jurisdictions.

Retrieval. At each decision step, the agent retrieves a compact subset of memories using recency–relevance scoring, with optional importance weighting for salient events.

Consolidation. Memory updating combines event-triggered and periodic summarization. Event-triggered consolidation follows high-impact milestones such as bid success or failure, project success or failure, major inspection or penalty events, and major policy changes. Periodic consolidation compresses recent episodic traces into higher-level summaries, allowing agents to revise beliefs about partners, jurisdictions, risks, and opportunities over time. After execution, realized outcomes are first written to episodic memory and may then update semantic memory through these mechanisms.

Workload modes. Agents operate in two modes: (i) *in-*

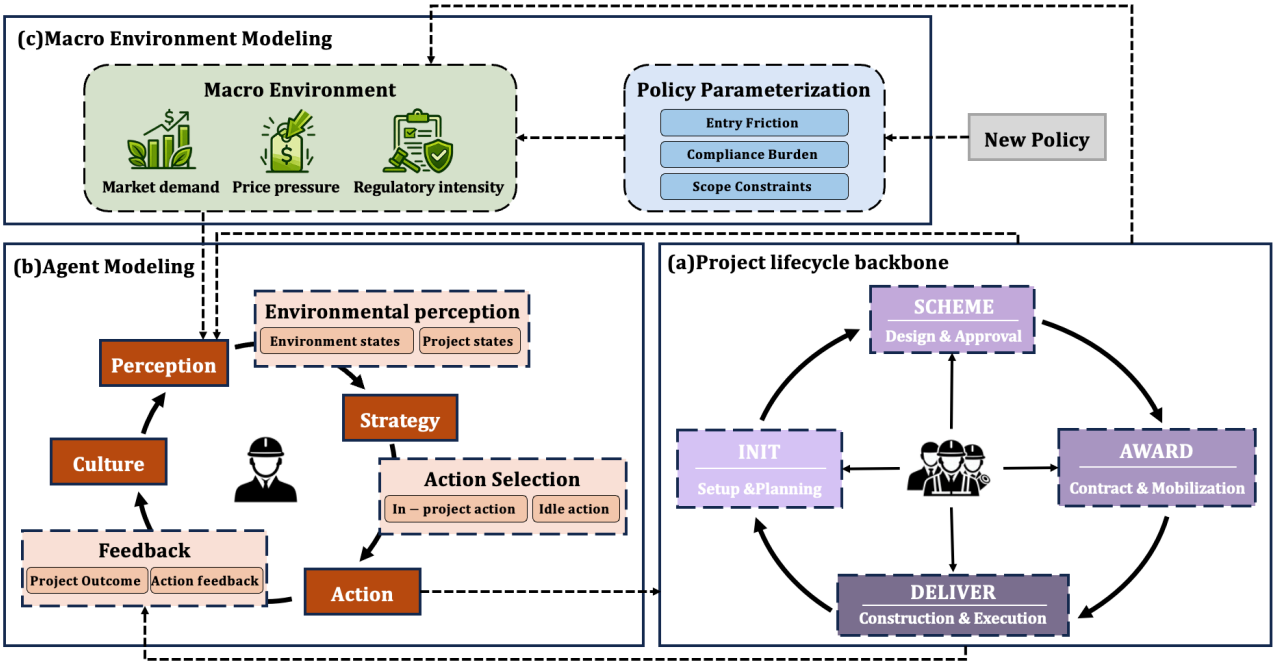

Figure 1: Overall micro–macro coupled agent-based simulation framework.

project, emphasizing resource lock-in, stage-dependent responsibilities, and reactive coordination; and (ii) *idle/out-of-project*, emphasizing opportunity search, teaming, eligibility maintenance, and bidding stance adjustment. When utilization exceeds capacity, agents enter a resource-constrained regime and apply interpretable load-shedding rules until capacity is released by project completion. This mechanism is important for reproducing concentration-upward dynamics (Fig. 3) through cumulative advantage under constrained capacity.

Decision pipeline. At each time step, the simulator builds the agent's decision context from three elements: **Perception**, **Culture**, and **Strategy**. **Perception** includes the observable state and retrieved memories, such as stage and gate status, workload and capacity, project states, macro signals, and partner reputation/availability. **Culture** captures stable value dispositions, such as baseline risk tolerance and cross-border inclination. **Strategy** captures short-horizon operating stances, such as expansion versus stability or profit-first versus scale-first. The simulator packages this context, together with role instruction and the admissible action set, into a structured prompt. The LLM selects one feasible action and returns it in a machine-parsable schema with a brief rationale. The simulator then executes the action and updates states, workloads, and memories through deterministic or stochastic transition rules.

Prompt structure and example. Each decision call is instantiated as a structured prompt with four components: (1) a *system layer* defining the agent's role, objectives, constraints, and behavioral style; (2) a *state layer* summarizing the current project stage, gate status, workload mode, key project indicators, and macro conditions; (3) a *memory layer* containing the retrieved episodic and semantic memories; and (4) an *action layer* listing the admissible actions and requiring one action with a brief rationale in a predefined output schema. Fig. 2 illustrates an example prompt template and decision interface for an LLM-driven agent.

Macro environment coupling

To couple micro execution with industry conditions, the macro state at time t is $z_t = \{D_t, \mathrm{K}_t, \mathrm{u}_t, P_t, M_t, R_t\}$, where D_t denotes market opportunity intensity, K_t role capacities, u_t utilization, P_t the general price level, M_t

the material price level, and R_t regulatory intensity. New projects are initiated endogenously as owners decide whether to launch projects under current macro conditions. Macro variables affect the simulation through three channels: *cost* (P_t, M_t), *delay/efficiency* (u_t), and *events* (M_t, u_t, R_t). Because the simulation starts in 2015, initial values are anchored to official data (Table 4) and then evolve through statistical inputs and endogenous feedback.
We use two parsimonious feedbacks:

$$P_{t+1} = P_t \left(1 + \kappa(\bar{u}_t - \bar{u}^\star)\right), \tag{1}$$

$$R_{t+1} = R_t + \eta \left(\mathrm{ViolationRate}_t - \rho^\star\right). \tag{2}$$

Policy parameterization and traceable embedding

For scenario evaluation, each policy regime p is represented by

$$\boldsymbol{\theta}(p) = \{\tau_p, \pi_p, \sigma_p, c_p, s_p\},$$

where τ_p denotes entry waiting time, π_p approval success probability, σ_p procedural uncertainty, c_p compliance burden, and s_p scope breadth. Table 3 reports both policy provisions and coded parameter values.
When a regional policy scenario is activated, the corresponding $\boldsymbol{\theta}(p)$ replaces the initial baseline state for that region. Specifically, τ_p is set from stated processing time; π_p is coded from normalized duration, procedural clarity, and review complexity:

$$\pi_p = \alpha_0 + \alpha_1 q_p - \alpha_2 \tilde{\tau}_p - \alpha_3 x_p,$$

procedural uncertainty is coded as

$$\sigma_p = \beta_1 u_p + \beta_2 x_p,$$

compliance burden is coded as

$$c_p = \gamma_1 \tilde{v}_p + \gamma_2 a_p + \gamma_3 f_p,$$

and scope breadth is coded as

$$s_p = \frac{m_p}{m_{\max}}.$$

These parameters enter the model through three channels: **(1) gates and waiting times,** where τ_p delays eligibility and cross-border readiness; **(2) cost and risk functions,** where π_p, σ_p, and c_p affect entry cost, compliance cost, and bid risk premia; and **(3) event and transition rules,** where c_p affects inspection, renewal, penalty, and disruption events, while s_p constrains the feasible cross-border action set.
This design yields a traceable mapping from *policy provisions → coded parameters → agent behavior → simulation outputs*.

Experiments and Analysis

The simulation is conducted in the GBA. The model includes seven heterogeneous agent types, with 100 agents per type (700 in total), allocated across cities according to observed firm distributions. Cross-jurisdiction policies are encoded as a parameter vector affecting entry friction, compliance burden, and scope constraints. The simulation spans 2015–2024 and generates multi-project concurrency and cross-city collaboration networks under a time-varying macro environment.
At the start of each run, agent populations, city allocation, macro initial values, and the pre-policy baseline are initialized using the calibration settings described earlier. A policy scenario is then activated by replacing the baseline policy state with the corresponding policy vector for the affected region. At each simulation step, owner agents decide whether to initiate new projects, while candidate partners make bounded LLM-driven decisions subject to workload, memory, policy constraints, and stage-feasible action sets. Feasible projects then advance through the lifecycle state machine, and repeated project-level interactions generate evolving collaboration networks and aggregate outputs for validation and policy analysis.

Simulation validity via stylized-facts consistency checks

We assess platform validity through *stylized-facts consistency*. Rather than targeting exact numerical matching, we test whether the model reproduces two robust empirical regularities of the construction industry: (i) market concentration with head-firm dominance and (ii) distance decay with local bias in cross-city collaboration.

Macro structure: concentration and head-firm dominance. Empirical evidence indicates rising concentration in the construction industry. For China, official statistics show that top-tier firms expanded their market share to 68.0% of output in 2021 (**?**), while the combined share of newly signed contracts held by the seven major central construction SOEs (CR7) reached 41.89% in 2023 (**?**). Consistent with these patterns, the simulation produces a clear concentration-upward trajectory (Fig. 3). We use the annual Top-10 share (CR10) as a regional proxy for GBA concentration and compare it with the national CR7 series. Both rise persistently, while the simulated CR10 exhibits a stable–accelerating–plateauing pattern driven by cumulative advantage under capacity, regulatory, and competitive constraints.

Spatial structure: distance decay and local bias. A second robust regularity is distance decay with strong local bias: cross-city collaboration becomes less frequent as distance increases, while same-city or nearby interactions remain dense. Similar patterns have been documented in large-scale procurement markets (Herz and Varela-Irimia, 2020). We conduct an analogous contract-level validation using simulated collaboration records. In Fig. 4, each point represents one collaboration contract, with inter-city distance on the x-axis and contract value on the y-axis. The scatter shows two stylized features: contracts become markedly sparser at longer distances, and contract values are heavy-tailed, with many small contracts and few large

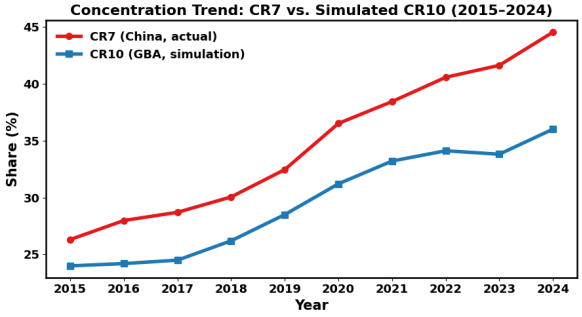

Figure 3: Concentration trend: national CR7 (China, actual) vs. simulated CR10 (GBA).

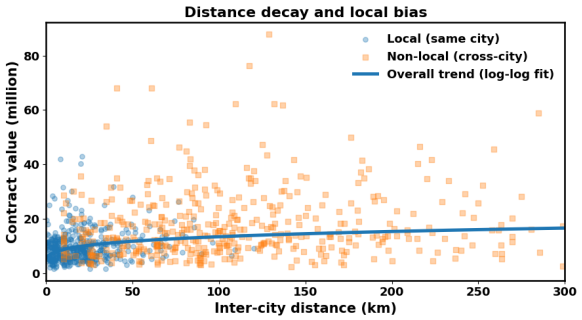

Figure 4: Distance decay and local bias in simulated collaboration contracts.

ones. Together, these results indicate that the platform reproduces representative industry regularities and therefore provides a credible baseline for counterfactual experiments.

Ablation study and stability. To assess the contribution of the proposed LLM-agent design, we compare three settings: (i) the full model with memory and intra-role heterogeneity, (ii) a variant without the memory module, and (iii) a variant without intra-role heterogeneity. Because the empirical benchmark is the national CR7 series whereas the simulation output is the GBA CR10 series, we compare normalized trajectories indexed to 2015 values. Similarity is evaluated using RMSE and trajectory correlation (ρ), and each setting is repeated three times. Table 5 reports mean values and relative variation across runs. The results show a stable ranking: the full model performs best, removing memory weakens performance, and removing intra-role heterogeneity weakens it further.

Cross-Regional Policy Analysis

After validating the platform against stylized facts, we use it to characterize the structure and city-level heterogeneity of cross-regional collaboration in the GBA, focusing on whether institutional differences yield interpretable spatial stratification and diffusion patterns.

Mainland-city collaboration network The simulated network among the nine Mainland GBA cities evolves into a clearer *core–semi-core–periphery* structure rather than expanding uniformly. Fig. 5 reports collaboration

Table 5: Ablation and stability results on concentration dynamics using normalized trajectories

Model setting	RMSE	Trajectory correlation (ρ)
Full model (memory + heterogeneity)	5.44 ± 28.47%	0.9913 ± 20.93%
Without memory module	9.62 ± 23.82%	0.9734 ± 16.39%
Without intra-role heterogeneity	11.44 ± 29.15%	0.9649 ± 23.68%

Note: The empirical benchmark is the national CR7 series, while the simulation output is the GBA CR10 series. Both series are indexed to their 2015 values before computing RMSE and trajectory correlation. Reported values are means over three repeated runs; percentages indicate relative variation across runs.

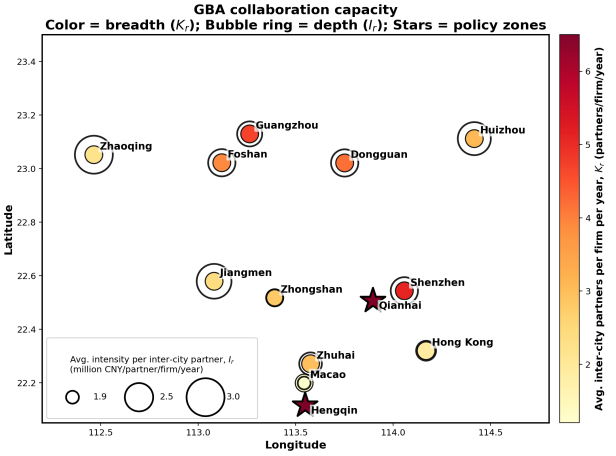

Figure 5: GBA collaboration capacity at the city level.

breadth K_r and collaboration depth I_r. Three patterns emerge: core hubs such as Guangzhou and Shenzhen exhibit high breadth; manufacturing and supply-chain cities such as Foshan and Dongguan form clustered collaboration anchored by stable division-of-labor ties; and peripheral cities such as Jiangmen, Zhaoqing, and Huizhou more often show lower breadth but higher depth, indicating fewer yet deeper channels.

Qianhai and Hengqin Qianhai and Hengqin function as *institutional gateways*. Their main role is to increase the arrival probability and diffusion speed of cross-border collaboration into the Mainland network by lowering institutional friction and improving procedural predictability. Two time-series signatures support this interpretation: (i) cross-border share rises earlier within the policy zones than in other cities (Fig. 6); and (ii) cross-border projects in other cities initially show a higher share linked to policy zones, which later declines as experience diffuses and projects shift from gateway-driven entry to broader localization (Fig. 7).

Hong Kong/Macao collaboration characteristics When institutional differences are explicitly modeled, Hong Kong/Macao shape the GBA collaboration landscape asymmetrically in both direction and intensity. Cross-border mobility becomes directional, with net inflow from Hong Kong/Macao to the Mainland—especially

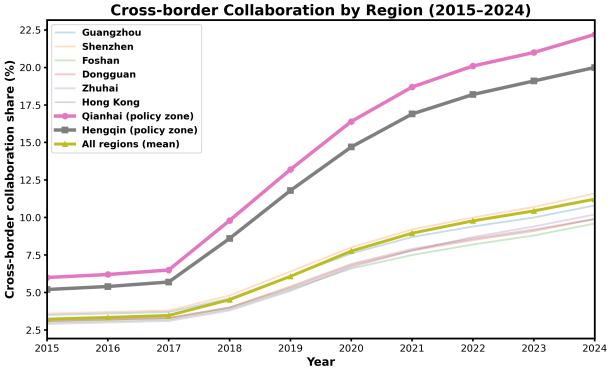

Figure 6: Cross-border collaboration by region (2015–2024).

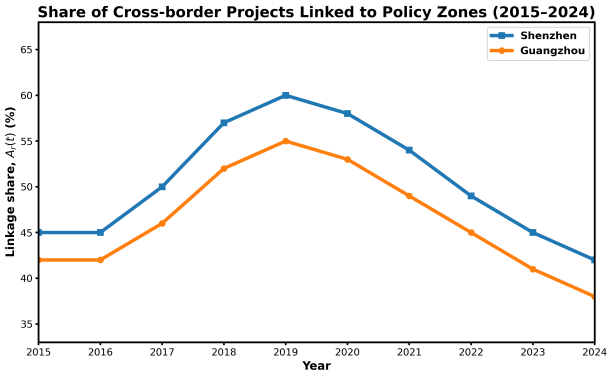

Figure 7: Share of cross-border projects linked to policy zones (2015–2024).

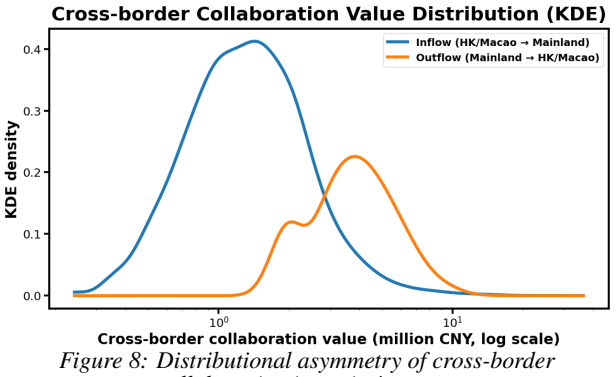

Figure 8: Distributional asymmetry of cross-border collaboration intensity/amount.

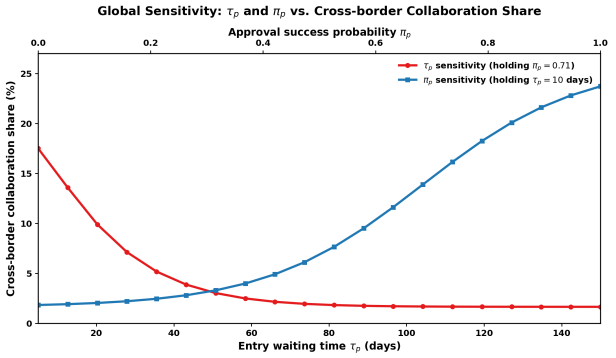

Figure 9: Global sensitivity of cross-border collaboration share.

via Qianhai and Hengqin—because Mainland-to-Hong Kong entry faces higher institutional costs and tighter constraints. Collaboration intensity also differs by direction: inflow is more concentrated in high-end professional and information/consulting services, whereas outflow is more constrained and tends to concentrate in price/efficiency-advantaged services and supply-chain cooperation.

Sensitivity analysis of key policy parameters

Global sensitivity of entry waiting time and approval success We first isolate entry waiting time τ_p and approval success probability π_p, holding other policy dimensions fixed, and record the resulting cross-border collaboration share (Fig. 9). The responses are nonlinear but smooth. For π_p, the curve flattens at both ends, indicating diminishing marginal effects. For τ_p, collaboration declines rapidly beyond the low-delay range and then approaches a floor. The model is therefore directionally sensitive but not dependent on knife-edge calibration.

Robustness of the Qianhai gateway effect under alternative friction gaps We further test whether Qianhai's gateway role remains robust when its friction advantage over the Guangdong baseline varies from 1% to 30%. For each setting, we compute the share of cross-border projects linked to Qianhai. As shown in Fig. 10, even a modest advantage increases Qianhai-linked projects, while marginal gains diminish as the advantage widens. The conclusion remains stable across the tested range: lower institutional friction systematically strengthens Qianhai's gateway role.

Conclusions

This paper proposes an LLM-driven agent-based simulation framework for evaluating cross-regional construction policies in the GBA. The framework combines an executable stage-gated project lifecycle, role-consistent agent action sets, and a lightweight macro environment, while encoding cross-jurisdiction practice rules as a policy vector embedded into gates, cost–risk functions, and event/transition rules. Stylized-facts consistency checks show that the platform reproduces two robust market regularities—increasing concentration with head-firm dominance and distance decay with strong local bias—thereby providing a credible baseline for counterfactual policy experiments. We further show how institutional differences and policy-zone mechanisms generate interpretable signatures in network stratification, diffusion paths, and directional asymmetries of cross-border collaboration intensity.

Beyond the GBA case, the framework is extensible and conditionally adaptable. While the core process backbone can be retained, applying it to other contexts would require context-specific adjustment of agent configuration parameters, macro-level parameters, and policy-vector settings to reflect local institutional arrangements, market conditions, and project structures. The framework should there-

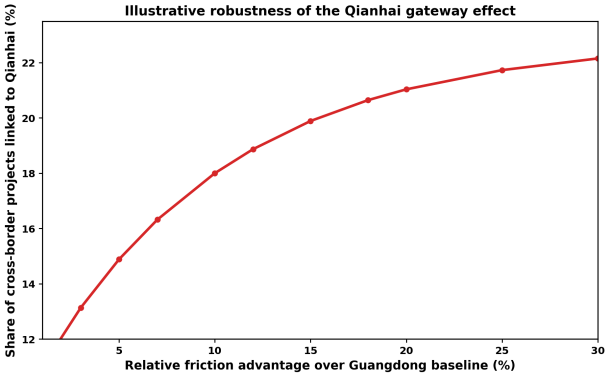

Figure 10: Qianhai gateway effect under alternative friction advantages.

fore be understood as a reproducible methodological template for comparative policy analysis, rather than a directly transferable model.

VLM-AUGMENTED RAG FRAMEWORK WITH ONTOLOGY-CONSTRAINED LLM REASONING FOR EXISTING BUILDING MATERIAL DOCUMENTATION

Julia Kaltenegger[1], Stavros Nousias[2], Ekaterina Petrova[1], André Borrmann[2] and Pieter Pauwels[1]
[1]Information Systems Built Environment, TU Eindhoven, Eindhoven, Netherlands
[2]Chair of Computing in Civil and Building Engineering, TU Munich, Munich, Germany

Abstract

Documenting information about materials in existing buildings is essential for circular construction and the reuse of elements. While multimodal Vision-Language Models (VLMs) can classify materials from images, they often lack the contextual semantic depth required for technical documentation. This article introduces a VLM-augmented Retrieval-Augmented Generation (RAG) framework that utilises ontology-constrained LLM reasoning to bridge this gap. By integrating domain-specific text retrieval and formal ontologies, the method enables the identification of building element layers and material types. The method is validated using a reference dataset of Dutch residential buildings and demonstrated by enriching semantic graphs with predicted material data.

Introduction

The built environment contributes significantly to resource depletion and waste generation. Addressing these impacts requires prioritising lifecycle material efficiency (reducing waste at the source), reducing the embodied carbon, and enabling reusability and assembly-disassembly models (European Commission, 2020). Consequently, systematic documentation of the existing building stock is essential to support material assessment and reuse, although such documentation remains challenging at scale. Building engineers typically assess materials in existing buildings through on-site inspections, manually documenting building characteristics, element details, and materials using images and text-based data sources (Smeyers and Mertens, 2022). As existing buildings usually lack Building Information Models (BIM) and diverse technical documentation, information is often retrieved from building codes, construction regulations, and archetype descriptions to infer probable construction types (Byers et al., 2024). Archetypes define building types as reference systems characterised by construction period, thermal and energy performance, average quantities of floor area, building-element surface area, and element thickness, thereby supporting top-down building and material stock modelling (Pei et al., 2024; Rijksdienst voor Ondernemend Nederland, 2022). For example, Dutch apartment buildings from the 1980s typically use prefabricated or cast-in-place concrete with low insulation, whereas single-family homes from the same period are predominantly constructed with insulated brick cavity walls. Therefore, the material composition of buildings varies between construction periods and building types.

With the advancement of digital technologies and Artificial Intelligence, existing buildings and their materials are increasingly documented using information-extraction methods such as image recognition, text-based reasoning, and semantic graph representations (Zeng et al., 2024; Pei et al., 2024). As such, computer vision for detecting and classifying building features, facades and materials has moved beyond solely using traditional deep neural networks (Gordon et al., 2023; Marin-Garcia et al., 2023) and has explored the use of Vision-Language Models (VLMs). By jointly learning image and text embeddings, VLMs enable prompt-based descriptive image classification, allowing, for example, the estimation of building age and energy efficiency from images and text (Zeng et al., 2024; Pan et al., 2025). Reasoning tasks based on other text data have shown success when using Large Language Models (LLM) alongside VLMs (Cooper et al., 2025). In this regard, Retrieval-Augmented Generation (RAG) is typically used to integrate domain-specific text corpora, providing natural-language rationales that support LLM-based reasoning (Oche et al., 2025). Methods for generating rationales include, among others, semantically aware sentence parsing (Chen et al., 2019) and studying textual similarities through text matching aligned with ontology definitions (Harispe et al., 2022). Semantic graphs using ontologies support context-based reasoning while integrating and contextualising heterogeneous, ambiguous data (Luo et al., 2023; Zheng et al., 2023). Research in the building materials domain has investigated a hybrid approach that combines text-based and ontology-based similarity matching to enrich material properties relevant to BIM data (Forth et al., 2025). These capabilities, in turn, support VLM-based image classification and LLM-based reasoning (Li et al., 2026; Chen et al., 2023).

This article recognises the potential of the interplay between VLM-based image classification, LLM inferencing, and ontologies to improve the formal description of visual content and enable further interpretation through linkable vocabularies. The aim of this article is to support the documentation of existing building stock using a semantic graph as the backbone, along with image and textual data enrichments. Therefore, this study investigates a VLM-augmented RAG framework for ontology-constrained LLM reasoning to enable the recognition, identification and inference of material information in existing buildings across archetypes . The proposed method

relies on (1) a VLM-based prediction using on-site images of buildings and structuring the corresponding predicted residential building types and material categories in a semantic graph; (2) a VLM-augmented RAG process that incorporates domain-specific knowledge, including construction regulations and archetype definitions; and (3) an ontology-constrained LLM-based reasoning that incorporates the RAG insights and parses the predicted information as semantic graph statements (Fig. 1). Together, these components enable a structured, semantically consistent representation of materials in existing buildings, thereby supporting reuse-oriented assessment.

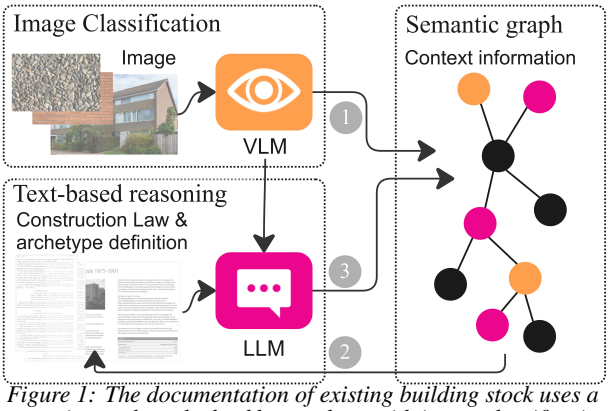

Figure 1: The documentation of existing building stock uses a semantic graph as the backbone, along with image classification and text-based reasoning.

State-of-the-Art

Related works are discussed on the topic of Vision Language Models (VLMs) and semantic-aware text processing in the context of LLM reasoning.

Vision Language models

Computer vision is the fundamental driver for understanding and accessing information from images. Methods such as image classification, semantic segmentation, and object detection are common practices in deep learning, often relying on Convolutional Neural Networks (CNNs). In Architecture, Engineering and Construction (AEC), computer vision for building material recognition supports, e.g., brick inventories by analysing replacement requirements and accounting for deterioration due to efflorescence (Marin-Garcia et al., 2023). Further, automated detection of building elements for deconstruction planning and material reuse has also been studied (Gordon et al., 2023).

Advances in computer vision have led to the development of Vision Language Models (VLMs), which jointly learn from image and text modalities. These generative models embed visual and textual information into a shared representation space, allowing image classification beyond predefined categories. VLMs are typically pre-trained on large-scale image–text pairs using transformer-based architectures. VLMs are based on vision transformers (ViT), using foundation models that transfer knowledge from seen to unseen classes by exploiting cosine similarity between vectors in the shared image–text embedding space (Hassija et al., 2025). Zero-shot VLMs enable object localisation and recognition without labelled target examples by using vision–text transformer architectures with prompt-based image inputs. In contrast, learning with few-shot VLMs predicts classes from a small number of labelled samples by guiding an LLM with limited task examples.

Application-specific studies have explored the use of a zero-shot classification for building-related tasks. For example, Zeng et al. (2024) employ GPT-4 to classify building age from images of buildings in London and predict the age epochs using a structured prompting strategy. Similarly, Pan et al. (2025) utilise GPT-4 as a pre-trained model to infer building energy efficiency levels from descriptive visual attributes, without prior task-specific training on labelled examples. In both cases, custom datasets comprising building images and corresponding labels (e.g., age or energy efficiency) are constructed to provide a baseline for validating the VLM's predictions. As a result, large VLMs can identify previously unseen objects in images using text prompts provided by an operator (Radford et al., 2021). Furthermore, the zero-shot model OWL-Vit (Minderer et al., 2022) is a simple open-vocabulary object-detection model with vision transformers trained on a variety of image-text pairs. It can query an image using one or more text prompts to detect target objects.

Semantically aware text processing for LLM reasoning on top of vision models

VLMs have proven successful in object recognition and classification tasks. However, research shows that using LLMs alongside VLMs can improve VLM performance on tasks that require reasoning from other text data (Cooper et al., 2025). Therefore, text corpora are created that store domain-specific, unstructured datasets, which can be used as natural-language rationale for LLM-based inferencing. The RAG framework is commonly applied in this context as it enables the integration of external data sources into a structured text corpus. Retrieval queries are used to guide the LLM reasoning, thus reducing hallucination (Oche et al., 2025). Methods for generating rationales, as part of the RAG framework, follow prompt engineering, such as Chain of Thought (CoT) (Wei et al., 2022) and semantically aware sentence parsing (Chen et al., 2019).

Semantically aware techniques measure semantic similarity through text matching and ontological alignment to capture conceptual relationships beyond lexical similarity (Harispe et al., 2022). Semantic awareness through text matching has been studied by Zhang et al. (2024). The authors use a RAG framework to enhance LLM-based reasoning on top of VLM image classification. The RAG incorporates context-specific information from an architecture knowledge base, thereby guiding the end user according to the logic of the original document. Semantic awareness through ontology alignments is enabled by Semantic Web technologies. Semantic graphs extend beyond structuring and organisation of domain knowledge

and enable context-based reasoning while ensuring the integration of heterogeneous and ambiguous data (Luo et al., 2023). Recent studies employ semantic graphs to support VLM- and LLM-based inference on construction data. For example, LLM-based question answering enables users to query semantic building data in natural language. Information from semantic graphs is accessed using SPARQL-based RAG queries (Li et al., 2026).

In addition, semantic graph entities and relations have been used as input for zero-shot image classification (Chen et al., 2023). Integrating image and text in semantic graphs is studied in the context of multimodal semantic graphs, which link entities that represent semantically similar concepts (Peng et al., 2023). As such, knowledge transfer strategies (Chen et al., 2023) can enable inference of semantic relationships between detected image classes or allow for semantic graph-based object detection (Chen et al., 2024). For instance, picture units that represent several entities such as buildings, trees, and cars, can be detected as classes and linked to the respective semantic entity in a graph database (Peng et al., 2023). Another approach is semantically aware object detection, proposed by Fang et al. (2017). There, the semantic similarity between two concepts is evaluated to determine the likelihood that they co-occur within the same image. Furthermore, ontological entities can be aligned with image-detected objects, thereby enriching image content with semantically related concepts in the semantic graph (Zeng et al., 2024; Zheng et al., 2023).

Method

In this article, images of buildings, taken on-site, and textual data on building archetypes and construction regulations documents are used to extract information about building element layers and possible materials. The paper proposes an image-text information generation process using a VLM-augmented RAG framework for ontology-constrained LLM reasoning, as shown in Fig. 2. A semantic graph is deployed as the backbone to integrate image-text data. The graph uses the Archetype ontology (at:)[1] and the Building Material Performance (bmp:) ontology[2], which describe the semantics of buildings, their elements, possible layer sets, and associated materials. The method is tested and validated on a ground-truth dataset comprising 75 Dutch residential buildings. The proposed method includes:

1. A zero-shot VLM model to classify building images by residential types and material categories.
2. A RAG process that integrates construction regulation and archetype definition.
3. A LLM-based reasoning process that uses the RAG results, Contrastive Language-Image Pre-training (CLIP) predictions, constrained to the ontology vocabulary. The results of the LLM reasoning are then parsed as Resource Description Framework (RDF) triples to enrich the semantic graph.

Zero-shot VLM model for image classification

Contrastive Language-Image Pre-training (CLIP) is used as it is a powerful foundation for zero-shot and few-shot classification. The CLIP framework utilises a dual-encoder architecture to bridge visual and textual data. Unlike traditional classifiers, CLIP is pre-trained on a massive dataset of image-text pairs to learn a shared vector space where related visual and textual concepts are mapped closely together. This article uses 'openai/clip-vit-base-patch32'[3], with an underlying architecture relying on the ViT-G/14 to encode images and a Transformer to encode text. CLIP predicts the residential building type y and the material category z with the function f that uses the input image x and visual prompts P_v to describe context and possible prediction classes in natural language, as shown in Eq. 1.

$$(y,z) = f(x;P_v)(x \in X) \tag{1}$$

The classification tasks for residential building types and material categories follow the formal semantics of the reused ontologies, the AT ontology[1] and the BMP ontology[2]. Prompts are used to introduce the ontology terms and definitions in natural language. Parsing the ontology solely as an RDF file, without descriptions, would result in VLM hallucinations. Therefore, definitions for building types 'Apartment House', 'Single Family House', and 'Terrace House' and for material categories, including 'Brick', 'Concrete', 'Glass', 'Natural stone', and 'Wood', are provided. Although the material categories can provide an estimate of the material origin, the classification of layer-specific material types depends on building-specific contexts, such as construction methods that vary by building type, construction year and country.

Retrieval augmentation process

The RAG pipeline comprises three steps: (2.1) building the text corpus; (2.2) constructing a retrieval query that uses the CLIP predictions and metadata of a building (construction year and country) as input; and (2.3) using textual similarity between the text corpus and the query to extract the most relevant text that the LLM can later use to support the reasoning process (Fig. 3). The text corpus includes building archetype descriptions (Rijksdienst voor Ondernemend Nederland, 2022) and building construction regulations, including building permit codes from 1904 (Schelling and van Gijn, 1904) and 1927 (Peerbolte and der Kaa, 1927). The original data sources are provided in PDF format as embedded bitmaps. Therefore, the optical character recognition (OCR) converter *pytesseract* is used to convert text to text format. The OCR extracts text sections based on the logic of the original document, depicted in Fig. 4. For example, the extracted text can

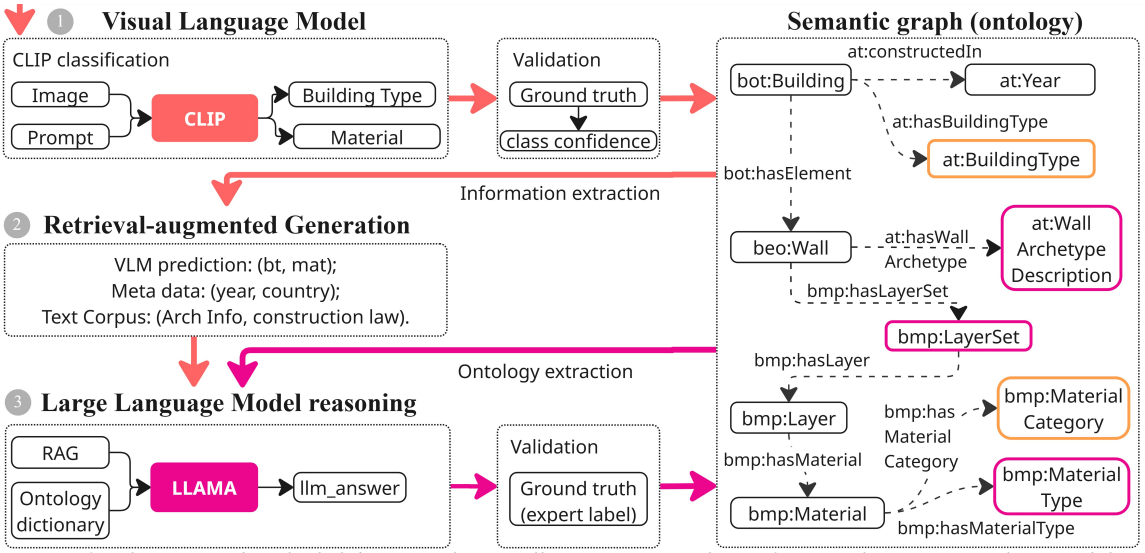

Figure 2: The proposed method elaborating the overall VLM-augmented RAG framework (in orange colour) and the ontology-constrained LLM reasoning (in pink colour).

be structured as a CSV table with columns for 'Building Type', 'Construction Year', 'Archetype Description', and the associated 'Wall Archetype Construction'. Each row of the CSV is extracted and converted to a vector as part of C, the 'Corpus embedding'. The text corpus is processed with the *SentenceTransformer* Python library to provide text embeddings.

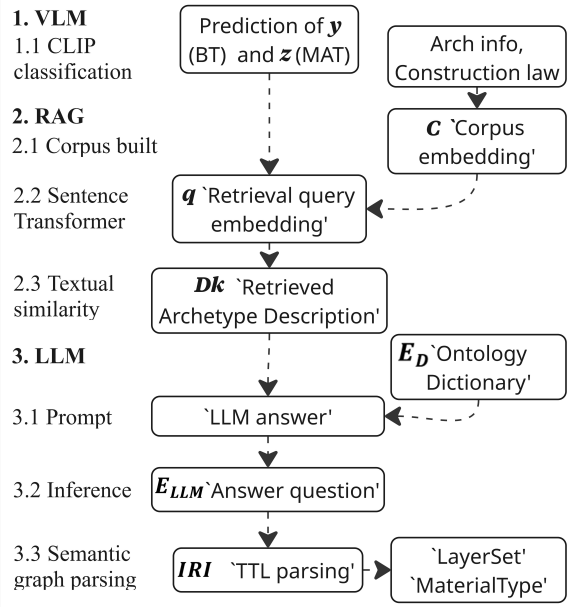

Figure 3: Sequential process of functions that enable VLM informed RAG for ontology-constrained LLM process

During inference, the function 'Retrieval query embedding' builds a query q that fetches the CLIP prediction results for building type y and material category z, and the metadata m (construction year and country) as input, and converts the results to a vector (Eq. 2). The function 'Retrieve archetype description' then extracts the embedded corpus C and the embedded query q, and computes cosine similarity between the two, denoted as Dk (Eq. 3). Dk represents the top-k largest elements of the input tensor (entries that best match the retrieval query with the highest similarity score). The cosine similarity between two vectors a and b is defined in Eq. 4.

$$q = g(y, z, m) \tag{2}$$

$$D_k = Retrieve(C, q) \tag{3}$$

$$S_C(a,b) = \frac{a * b}{||a|| ||b||} \tag{4}$$

The RAG pipeline provides the LLM with the building context information. By applying textual semantic similarity matching against the ontology definitions, the system identifies the most probable entities and integrates them into the semantic graph (Fig. 3).

LLM reasoning and ontology constraining

In the third part of the procedure (Fig.3), the LLM reasoning process, comprises three steps: (3.1) LLM answer template and prompt design; (3.2) LLM model inference of the 'LayerSet' and the 'Material Type'; and (3.3) parsing the LLM results in RDF Triples (TTL). First, the function 'LLM answer' is based on an LLM answering template in JSON notation and is constructed as the LLM prompt input. The prompt input relies on the CLIP prediction results and confidence for the 'building type' and 'material category', the metadata 'construction year' and 'country', the 'retrieved corpus text' from the RAG results and ontology embeddings 'ontology guidance'. The latter contains descriptions of ontology classes (bmp:MaterialType and bmp:LayerSet) represented as vectors. Further, the prompt describes the structure of the TTL file; an excerpt of the input prompt is shown in Listing 1.

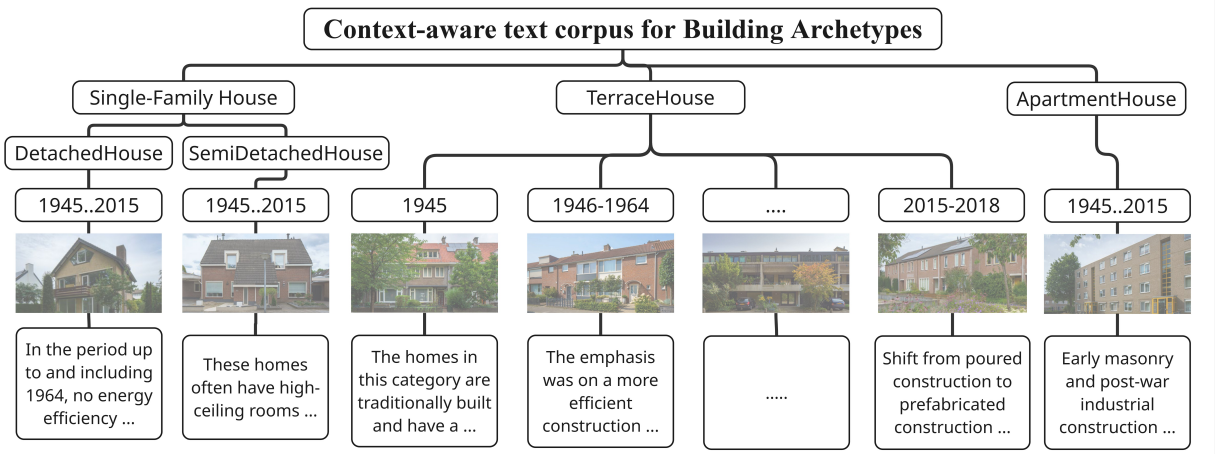

Figure 4: Archetype information structure as preparation for the RAG corpus embedding

    ['material_type']}
```

Next, the 'Answer question' function relies on the context information and the prompt; the LLM model infers the appropriate 'LayerSet' and, if applicable, the 'Material Type' for building archetypes. In the experiments, the LLM model 'llama3:8b' has been used; however, the methods can be applied with any LLM. The 'LayerSet' and 'MaterialType' are selected based on the highest cosine similarity between the retrieved text-based 'Wall description' and the ontology embedding. The final ontological grounding is achieved through a maximum-likelihood selection over the embedding space interpreted by Eq. 5. In the function 'TTL parsing', the IRI is the assigned OWL syntax based on cosine similarity between the embedded LLM results E_{LLM} and the embedded ontology class description E_D. D is the ontology description as a subset of the ontology classes O_E. A fallback logic is implemented, which, if the evidence (the provided text corpus) does not match an ontology-based IRI, causes the LLM to provide a descriptive string instead of generating a new ontology entity. As a result, the LLM writes a semantic graph in Terse RDF Triple Language (TTL) format that assigns the 'LayerSet' with the associated 'MaterialType' to the observed component. The full code and datasets are available on GitHub [3].

$$IRI = \underset{D \in \mathcal{O}\mathcal{E}}{\operatorname{argmax}} \left(\frac{E_{LLM} \cdot E_D}{\|E_{LLM}\| \cdot \|E_D\|} \right) \tag{5}$$

Validation corpus

For validation, a dataset is constructed that contains images and corresponding labels describing 75 Dutch residential buildings by country, construction year, building type, material types, and definitions of wall-layer sets. The data set is manually labelled in collaboration with domain experts; see an example entry in Listing 2. The validation process validates the zero-shot VLM predictions and second, the LLM reasoning using Precision, Recall and F1-Score.

Listing 2: JSON validation dataset

```

Results and validation

The results discuss zero-shot VLM classification, LLM reasoning on the validation dataset, and finally demonstrate

[3] https://github.com/JulKaltenegger/VLM-RAG-LLM-reasoning

the proposed methods on a use case.

Zero-shot VLM classification validation

The zero-shot VLM classification validates the CLIP-based predictions for building type and material category. For each image in the validation dataset, the CLIP generates top-3 predictions. Both classes are directly compared against the corresponding labels in the JSON validation dataset. The 'Single-family Housing' class exhibits the lowest stand-alone CLIP performance, largely due to its typological similarity to 'Terrace Houses'. In terms of material classification, CLIP achieves high precision (0.98) for 'Brick' but fails on 'Concrete' with a precision of only 0.33. This indicates a high rate of false positives, with the model correctly identifying concrete only one out of three times. This type of hallucination is likely caused by visual similarities with cement stucco or large-format stone elements. The confusion matrix for the CLIP prediction for building types is represented in Fig. 5. The precision, recall and the F1 score are presented in Tables 1 and 2.

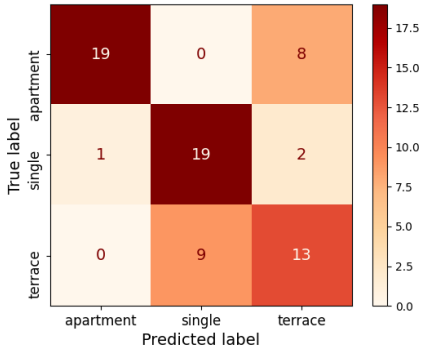

Figure 5: Confusion Matrix Clip Building Type classification

Table 1: Building type classification (CLIP-only)

Class	P	R	F1	Sup.
Apartment house	0.96	0.81	0.88	27
Single family house	0.53	0.83	0.65	12
Terrace house	0.63	0.55	0.59	22
Accuracy		0.72		61
Macro avg	0.70	0.73	0.70	61
Weighted avg	0.75	0.72	0.73	61

Table 2: Material category classification (CLIP-only)

Class	P	R	F1	Sup.
Brick	0.98	0.81	0.88	52
Concrete	0.33	0.86	0.48	7
Accuracy		0.79		61
Macro avg	0.44	0.55	0.45	61
Weighted avg	0.87	0.79	0.81	61

Detecting building type solely from facade images is often ambiguous, motivating the integration of contextual metadata and ontology-constrained reasoning in subsequent pipeline stages.

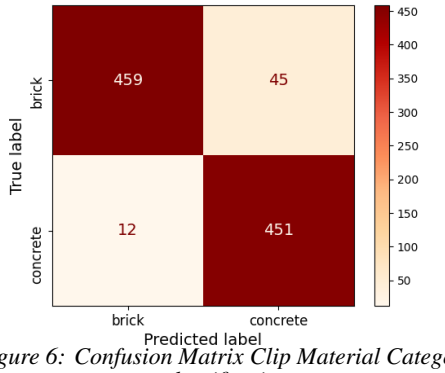

Figure 6: Confusion Matrix Clip Material Category classification

LLM reasoning validation

The VLM-augmented RAG and ontology-constrained LLM pipeline is validated on the validation dataset. Fig. 7 shows the validation performance for each image. This includes the CLIP predictions and context data (construction year and country), which are used to extract archetype descriptions from the text corpus. These retrieved descriptions are then used by the LLM to infer wall construction characteristics and to generate RDF/Turtle statements constrained by the ontology. The resulting RDF triples are parsed and compared against the JSON validation dataset. The cosine similarity is computed between the inferred information (the 'LayerSet' and the 'MaterialType') and the labelled JSON dataset, resulting in average similarity and confidence scores of 0.45 and 0.56, respectively.

Demonstration use case

The use case demonstrates how the proposed method can help construction engineers with large-scale building documentation, particularly in detecting wall layer sets and associated material definitions. A Dutch residential building, a terraced house from 1965, is selected to illustrate how insights from the reasoning process can enrich a semantic graph with entities and their associated confidence values (Fig. 8). A semantic graph is used to describe a building instance inst:Building001, and its associated elements, layer sets and materials. Fist, the semantic graph is enriched by the detected building type and material category, derived from the VLM model. The CLIP classification results with a confidence of 0.87 for 'Building type' at:TerraceHouse, and 0.98 for 'Material Category' bmp:Brick of the observed wall. Furthermore, the LLM's reasoning extracts the archetype description for each building element, in this case, the wall archetype. Furthermore, the LLM reasons that the 'WallLayerSet' and the outer layer is assigned by the 'MaterialType', with a confidence of 0.59 for bmp:CavityWall and 0.34 for bmp:ClayUnit.

This enrichment process relies on text-based documentation of building archetypes and ontology classes, including descriptive annotations. The confidence of the textual semantic matching depends on the degree of align-

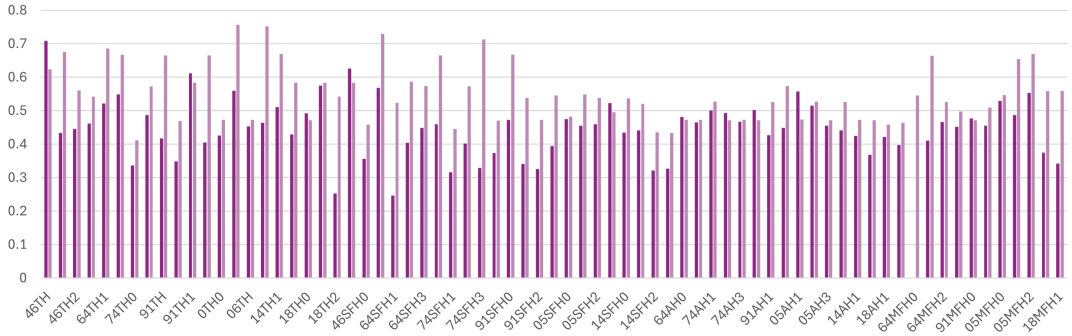

Figure 7: Validation of the complete pipeline with the validation dataset (N=75) showing the semantic similarity (dark purple) and the confidence score (light purple)

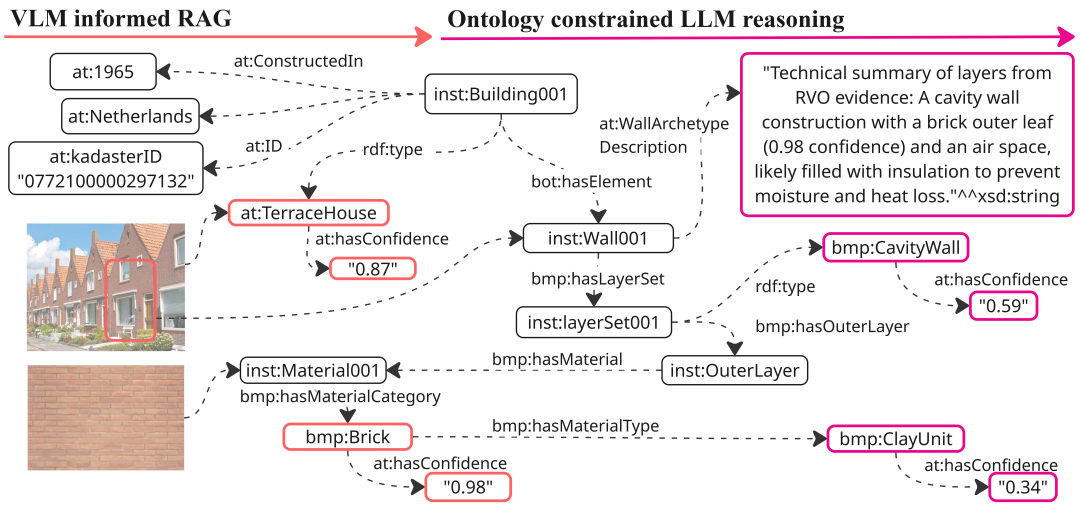

Figure 8: Results representing the enriched semantic graph with the deducted information from the VLM-augmented RAG framework (in orange colour) and the ontology-constrained LLM reasoning (in pink colour)

ment between these sources. The greater the alignment of sources in their descriptive annotations, the greater the likelihood of identifying meaningful semantic textual similarity and correctly assigning ontology classes. A key limitation of the proposed method is that the archetype descriptions require partial manual adjustment and verification to ensure terminological consistency with the ontology, which directly influences the cosine similarity scores in the embedding-based matching process. Therefore, a human-in-the-loop approach is strongly recommended, allowing building engineering experts to iteratively validate and refine LLM-generated results to ensure domain accuracy and methodological robustness.

Conclusion

Effective material-related reuse decisions in existing buildings depend on robust and well-structured documentation, which remains a challenge in current practice. Information retrieval technologies, including VLMs, LLMs, and semantic graphs, have emerged as viable approaches to modelling material information. In this context, the article explores a VLM-augmented RAG framework and ontology-constrained LLM reasoning to integrate unstructured text from building documents. The results show that the proposed VLM-informed RAG pipeline successfully extracts building-archetype text data, whereas ontology-constrained LLM reasoning yields only moderate performance. Therefore, future work will investigate advanced ontology embedding methods to fine-tune LLM reasoning.

MULTI-CLASS PREDICTION OF OCCUPATIONAL ACCIDENT TYPES USING XGBOOST IN PIPELINE CONSTRUCTION

Ahmet Eren Ünlü[1], Recep Özkan[2], and Onur Behzat Tokdemir[2]
[1]Istanbul Technical University, İstanbul, Türkiye
[2]Turkish-German University, İstanbul, Türkiye
[3]Artificial Intelligence and Data Science Research Center, Istanbul Technical University, İstanbul, Türkiye

Abstract

In this study, the XGBoost algorithm was chosen to predict accident types using data from incidents that occurred in pipeline construction projects, and a multi-class classification approach was presented. A model was trained on 1,184 real accident records obtained from pipeline construction projects. This data includes information such as the time of the accident and the type of treatment required. Classification results showed an overall accuracy of 83%, a macro-average F1 score of 0.82, and a weighted F1 score of 0.81. Some classes showed high recall rates, while recall was low in categories with limited data. The results demonstrate that XGBoost can be a suitable model for predicting accident types using historical incident datasets and can contribute to risk analysis in construction projects through artificial intelligence.

Introduction

Construction sites have the highest number of fatal work injuries of any private industry sector, accounting for approximately one in five occupational deaths (BLS, 2024). Therefore, the construction industry poses a significant risk to both human safety and property (Mostofi & Toğan, 2022). According to the International Labour Organization (ILO, 2023), construction workers in economically developed countries are three to four times more likely to experience fatal workplace accidents compared to those in other sectors. Globally, an estimated 2.93 million workers die annually from occupational accidents and work-related diseases, while an additional 395 million suffer from non-fatal injuries (ILO, 2023). The economic impact of these incidents is substantial, estimated at approximately 4% of global GDP, which is equivalent to nearly $3 trillion in direct and indirect costs (ILO, 2023). While construction work accounts for only about 7% of global employment, it is responsible for a disproportionate 30–40% of fatal occupational injuries (ILO, 2023). Beyond macroeconomic costs, workplace accidents directly impair corporate performance by reducing productivity, operating profit, and sales growth at the firm level (Dong Koo Kim & Park, 2021). In recent years, the growing global demand for transporting energy, water, and chemicals has accelerated the development of pipeline construction projects. However, this expansion has been accompanied by a significant rise in workplace accidents within the sector (Mammadov et al., 2023). Pipeline construction activities are categorized among the highest-risk subsectors, characterized by unique challenges such as exposure to pressurized systems, flammable substances, and geographically remote working environments (Mammadov et al., 2023). Despite these risks, data-driven approaches to accident prediction in pipeline construction remain limited, highlighting the critical need for targeted research in this domain.

Most current studies focus on estimating accident severity or risk levels rather than identifying specific accident types that may occur. However, accident type prediction offers a proactive approach to safety management, as it allows for the prediction of potential events that may occur on-site and the implementation of preventive measures before accidents happen. Therefore, accident type prediction can support more effective safety planning, training, and resource allocation, especially in high-risk environments.

Pipeline construction activities are categorized among the highest-risk subsectors, characterized by unique challenges such as exposure to pressurized systems, flammable substances, and geographically remote working environments (Mammadov et al., 2023). These types of hazards differentiate pipeline construction from other constructions. Despite these distinctive risks, data-driven approaches specifically focused on accident type prediction in pipeline construction remain limited. Therefore, the motivation for this study is to fill this gap by applying a multi-class classification model using XGBoost for accident types occurring in pipeline construction.

Literature Review

In the construction industry, the use of machine learning (ML) and artificial intelligence (AI)-based models as estimation and prediction methods is increasing (Doğan et al., 2022; Koc et al., 2024). Given the persistently high accident rates in the sector, the application of data-driven predictive models has become a practical necessity not only to reduce accident frequency but also to uncover complex causal relationships that traditional statistical methods fail to capture (Alkaissy et al., 2023).

Machine learning can be particularly beneficial because it excels with complex and large datasets (Wang et al.,

2022). As Sarkar and Maiti (2020) mention, tree-based ML models are increasingly used to improve accident prediction and support safety planning. XGBoost is a popular ensemble learning algorithm known for its speed, high predictive accuracy, and ability to handle large or complex datasets (Asselman et al., 2023). For example, Pang et al. (2024) developed an early-warning model for traffic accidents using XGBoost and achieved significant prediction accuracy.

Similarly, Mammadov et al. (2023) predicted accident outcomes in pipeline construction using 11 different ML algorithms across 12 sub-datasets created by considering different event types, outcomes, timings, and causes, demonstrating the value of ML in pipeline safety management. Unlike the present study, that work focused on predicting accident outcomes rather than accident types, with deep learning outperforming other algorithms in most configurations. The study proposed a prescriptive prevention model and provides a methodological basis relevant to the current work. Davoudi Kakhki et al. (2019) compared the performance of SVMs, boosted trees, and Naïve Bayes on over 33,000 compensation claims in the agribusiness sector. Their models achieved accuracy rates between 92% and 98% in predicting injury severity, demonstrating ML's effectiveness in modeling occupational injury outcomes. Similarly, Ayhan and Tokdemir (2019) used a hybrid model integrating artificial neural networks and fuzzy logic to predict construction accident outcomes with up to 84% accuracy. Although their focus was on outcome severity rather than accident types, their work bears methodological relevance to the present study. Recent innovations have turned toward graph-based ML models. Mostofi and Togan (2023) proposed a multi-head graph attention network (GAT) for construction safety prediction, achieving up to 87.1% accuracy. Building on earlier work in which a graph convolutional network achieved 94% accuracy in predicting accident severity outcomes (Mostofi et al., 2022), their approach improves the interpretability of accidents by connecting them, thereby providing a more detailed understanding of workplace accident risks.

In another large-scale study, Choi et al. (2020) analysed over 137,000 accident records from Korea, finding that Random Forest outperformed other algorithms, particularly when class imbalance was addressed with random oversampling, an approach conceptually aligned with the SMOTE (Synthetic Minority Oversampling Technique) technique used in the present study. Luo et al. (2023) achieved 82% accuracy in predicting accident severity using a Random Forest model trained with entropy-based text mining and SMOTE, identifying key risk factors including lack of supervision and inadequate training. More recently, Alsulamy et al. (2026) demonstrated that by including the nature of the incident (NOI) as an explanatory variable, the XGBoost model achieved 89% accuracy in predicting accident severity (SOI).

Yoo et al. (2024) developed a multi-class classification model for nine accident types in Korean construction sites using SMOTE and machine learning algorithms, achieving strong predictive performance and demonstrating that accident type classification is a viable and practically relevant prediction target. Alkaissy et al. (2023) further showed that ensemble methods including XGBoost can effectively classify injury types across large-scale construction accident datasets, highlighting the suitability of boosting algorithms for multi-class safety prediction tasks. Beyond conventional ML approaches, Park et al. (2026) compared ML and large language model (LLM) approaches for accident prediction, concluding that ML-based models remain highly effective for structured classification tasks even as newer language-based methods emerge.

While most of the mentioned studies focused on predicting the severity or consequences of accidents, this research aims to predict accident types using the XGBoost algorithm on a dataset of 1,184 pipeline construction accident records. Pipeline construction projects involve distinctive, dynamic, and complex working conditions that differ significantly from other construction types. Activities involving oil, gas, and chemicals introduce critical OHS risks such as fire, explosion, and chemical exposure, while factors such as limited worker experience, extensive geographic scope, and the high number of stakeholders further elevate accident risks (Mammadov et al., 2023). Despite this, pipeline construction remains a less-researched domain in the safety prediction literature, and this study aims to address this gap. Furthermore, this research incorporates a synthetic oversampling technique to mitigate class imbalance and its negative impacts on prediction performance.

Methodology

XGBoost was chosen in this study due to its scalability, high predictive accuracy, and ability to handle large and complex datasets. It employs a novel sparsity-aware algorithm for sparse data and directly handles missing values, making it robust in real-world applications. The algorithm builds an ensemble of decision trees in an additive manner, incorporating L1 and L2 regularization terms to prevent overfitting and enhance generalization performance. Additionally, XGBoost provides built-in feature importance scores, enabling interpretable insights into the key predictors of accident types (Chen & Guestrin, 2016). It builds models sequentially. Each new tree attempts to learn from the previous tree's errors to improve its results. The general form of the objective function in the t-iteration is defined as follows:

$$\sum_{i=1}^{n} l(y_i, \hat{y}_i{}^{(t-1)} + f_t(x_i)) + \Omega(f_i) \qquad (1)$$

where l is the loss function measuring the difference between the predicted and true labels, ft is the function (decision tree) added at iteration t, and Ω(ft) is the regularization term that penalizes model complexity to avoid overfitting. Unlike traditional gradient boosting methods, XGBoost incorporates second-order derivatives of the loss function to approximate gradients more accurately and directly incorporates regularization into the objective, which enhances generalization. Additionally, techniques such as column subsampling, sparsity-aware learning, and optimized handling of missing values contribute to its superior performance and computational efficiency. The workflow of the study is shown in Figure 1.

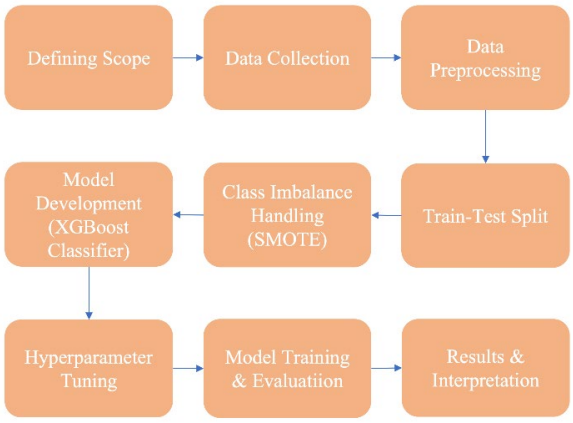

Figure 1: The workflow of the study.

Defining Scope and Data Collection

This study aims to develop a model to predict the types of accidents that may occur during pipeline construction. While results in the literature are generally predicted based on the causes of the accident, this study directly considers the type of accident as the target variable. To create the model, the necessary data were first determined, and then the data collection process was initiated. The data was collected by anonymizing it from a pipeline construction project spanning Asia to Europe, involving numerous countries and stakeholders. The organization of over 5000 unstructured accident reports resulted in 1184 structured accident records. The present study reuses this dataset with a distinct focus, rather than predicting accident outcomes, the current work utilizes root causes as input features to perform multi-class classification for predicting accident types using XGBoost. Each record is labelled with one of six predefined accident types (classes 0-5) and includes various categorical and temporal characteristics such as the accident outcome, primary causes, immediate causes, and time and date of occurrence. The six accident types used as classification targets are derived from event/exposure categories coded according to the OIICS (Occupational Injury and Illness Classification System) (United States. Bureau of Labor Statistics. (2007). The categories reflect the distribution of accident types recorded in pipeline construction projects. The classes and descriptions of the accident types are shown in Table 1.

Table 1: Class Types and Description.

Class	Description
0	Bodily reaction and exertion (Injuries resulting from physical stress, overexertion, heavy lifting, or repetitive motions)
1	Contacts with objects and equipment (Incidents where a worker is struck by, caught in, or crushed by moving machinery, equipment, or falling materials)
2	Exposure to harmful substances or environments (Incidents involving exposure to toxic chemicals)
3	Falls (Slips and trips on the same level, or falls from a higher level)
4	Fires and explosions (Accidents caused by the ignition of fiery gases)
5	Transportation accidents (Accidents involving vehicles in a construction zone)

Data Preprocessing

The data used included time information such as the hour (0–23), month (1–12), and day of the week (0: Monday – 6: Sunday). In addition, the accident's outcome (e.g., injury status), root causes (RC), and immediate causes (ICF) were also included in the model. These causes were coded according to the World Health Organization (WHO, 2001) classification system. All data was converted into numerical forms. Categorical variables and textual expressions were numerically encoded to facilitate processing by the algorithm. Missing data was removed to prevent any adverse impact on the model's results. The detailed descriptions and data types of the input features used in the proposed model are summarized in Table 2.

Table 2: Input Features.

Feature Name	Description	Data Type
Time_block	Time of the accident categorized into 4 blocks (Morning, Afternoon, Evening, Night)	Categorical
Season	Season of the accident (Winter, Spring, Summer, Autumn)	Categorical
Weekday	Day of the week (0: Monday - 6: Sunday)	Categorical
F/Injury /ADPD/NM	The immediate outcome/severity of the accident	Categorical
ICF1, ICF2	Immediate causes of the accident (based on WHO classification)	Categorical
RC1, RC2	Root causes of the accident (based on WHO classification)	Categorical

Handling Class Imbalance with SMOTE

During the analysis, it was observed that the dataset was unbalanced, meaning the available accident data was not evenly distributed, and therefore some types were underrepresented. To prevent data leakage, SMOTE (Synthetic Minority Oversampling Technique) was applied exclusively to the training subset (80%) after the train-test split. Specifically, the minority classes, such as Fires and Explosions (Class 4) and Transportation Accidents (Class 5), were oversampled to match the instance count of the majority class. Since the minority classes contained very few instances, k_neighbors were

set to 1 to ensure SMOTE could be applied without error, as a larger neighborhood size would exceed the available sample count in these classes, thereby ensuring the XGBoost model learns unbiased decision boundaries.

Hyperparameter Tuning

To obtain the results, the hyperparameters were first adjusted. One key parameter is the maximum depth, which determines how deep each decision tree can go. Deeper trees can learn more complex patterns, but they can also lead to overfitting. The learning rate determines how much each tree contributes to the overall prediction. A lower learning rate increases learning time but generally yields more consistent and accurate results. The N_estimators determine how many trees the model will build. Generally, using more trees improves performance but also increases training time. Finally, the subsampling parameter determines the proportion of training data used to build each tree. Using less than the full data adds randomness to the training process and reduces overfitting. Another important hyperparameter is `colsample_bytree`, which specifies the proportion of randomly selected features per tree. Using only a portion of the features allows the model to generalize better and reduces the likelihood of overfitting.

Several key XGBoost hyperparameters were selected to improve model performance. The maximum tree depth was adjusted to balance complexity and overfitting. A low learning rate was used to ensure reliable model learning. The number of estimators was appropriately chosen to increase accuracy without significantly increasing training time.

In addition, subsample and colsample_bytree settings were used to introduce randomness and improve generalization.

Model training was initially performed with the default hyperparameters, followed by a limited grid search to optimize them. The best model performance was obtained with the following parameter configuration: maximum tree depth 6, learning rate 0.1, N_estimators 200, subsampling rate 0.8, and column sampling rate per tree 0.8. The hyperparameter configuration established for the XGBoost model to balance complexity and prevent overfitting is presented in Table 3.

Table 3: Hyperparameters.

Hyperparameter	Value	Description
Max_depth	6	Maximum depth of a tree. Balances model complexity and overfitting.
Learning_rate	0.1	Step size shrinkage used in update to prevent overfitting.
N_estimators	200	Number of gradient boosted trees.
Subsample	0.8	Subsample ratio of the training instances.
Colsample_bytree	0.8	Subsample ratio of columns when constructing each tree.
Objective	Multi: softmax	Learning objective for multi-class classification.

Model Training and Evaluation

The final XGBoost model was trained on the preprocessed dataset following SMOTE-based augmentation. The model was trained with an 80%-20% training-to-test split. The model's performance was evaluated using metrics such as accuracy, recall, F1 score, and precision, which indicate how well the model predicted each type of accident. All analyses were conducted in Google Colab using Python. The following libraries were used: pandas and numpy for data processing, scikit-learn for model evaluation and train-test splitting, imbalanced-learn for SMOTE implementation, and xgboost for model training and prediction. Visualizations were generated using matplotlib and seaborn.

Results and Discussion

Precision, recall, F1-score, and overall accuracy metrics were used to obtain and evaluate the results. Precision measures how accurate the model's positive predictions are. Recall indicates how well the model captures all real samples of a class. The F1 score is the harmonic mean of precision and recall. It provides a balanced measure when both false positives and false negatives are significant. It is particularly useful when a single measure is needed that considers both precision and recall.

In accident type prediction using the XGBoost model, True Positive (TP) refers to correctly predicted accident types, False Positive (FP) refers to accident types that did not occur but were incorrectly predicted, and False Negative (FN) refers to actual accident types that the model could not predict; these terms are necessary to calculate recall, precision, and the F1 score to evaluate classification performance. The equations for calculating these metrics are given in Equations 2, 3 and 4.

$$\text{Recall} = \frac{TP}{TP+FN} \tag{2}$$

$$\text{Precision} = \frac{TP}{TP+FP} \tag{3}$$

$$\text{F1-Score} = \frac{2 \text{ x Precision} \cdot \text{Recall}}{\text{Precision}+\text{Recall}} \tag{4}$$

This study categorized 1184 pipeline construction accidents into 6 main types. We measured the XGBoost Classification algorithm's performance, which reached 83% overall accuracy. The macro average F1 score was 0.82, and the weighted F1 score was 0.81. The classification performance of the model across all classes is graphically represented in Figure 2.

In addition to the overall evaluation, the results obtained for each accident class were examined separately. The class in which the model was most successful in classification was Class 4, which refers to Fires and Explosions. In this class, the model achieved a precision of 0.96, a recall of 1.00, and an F1 score of 0.98. Fires and explosions are among the high-risk categories in pipeline

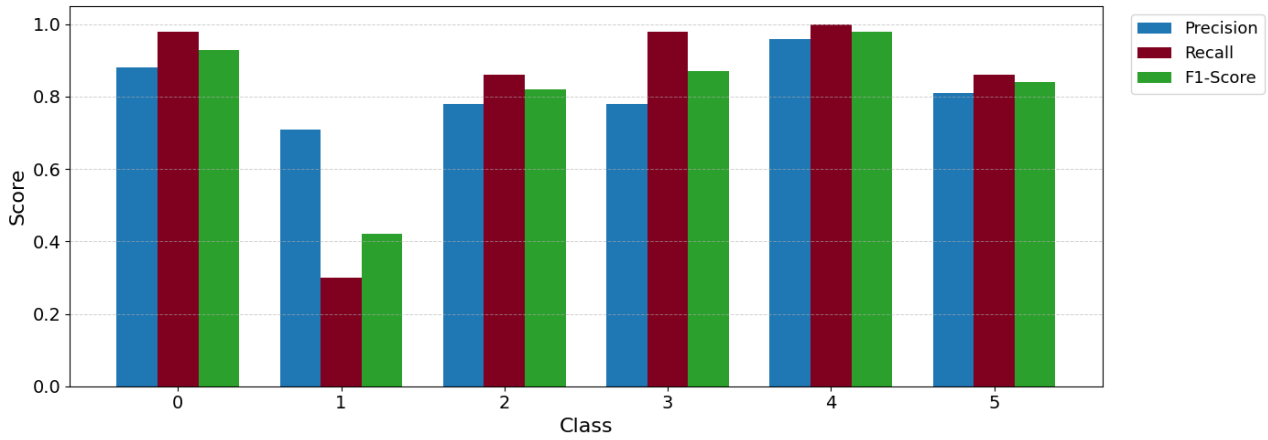

Figure 2: Class-wise classification performance of the XGBoost model

construction, and the model's successful predictive performance in this class is a noteworthy contribution to site safety.

Similarly, the recall value of 0.98 obtained for Class 3 (Falls), one of the most common and dangerous types of accidents in the construction industry, demonstrates that the model has an extremely low accident-risk skipping rate and offers a reliable monitoring mechanism. In this class, the precision was 0.78, and the F1 score was 0.87. Compared to binary classifications, the increase in the number of classes the model can choose in multi-class classifications brings with it the risk of misclassification. Therefore, achieving these metric values among 6 classes is a remarkable achievement.

When examining the results for Class 0 (Bodily reaction and exertion), the precision value was 0.88, while the recall and F1 score metrics were 0.98 and 0.93, respectively. The results show that the model can offer a reliable monitoring mechanism in this classification as well. The recall value of 0.86 and the F1 score of 0.84 obtained for Class 5 (Transportation accidents) show that the model can also distinguish these types of accidents with high accuracy.

Despite these successful results, the model's most significant weakness is its recall of 0.30 and F1 score of 0.42 in the Class 1 (Contact with Objects and Equipment) category. An examination of the predictions revealed that actual Class 1 instances were frequently misclassified as Class 3 (Falls). This misclassification largely stems from the fact that these accident types often share similar underlying causes or occur simultaneously on-site, which blurs the decision boundaries for the algorithm. Furthermore, since the SMOTE technique was primarily targeted at extreme minority categories (such as Classes 4 and 5) to match the majority class, the inherent data limitations of Class 1 remained. Combined with its lack of distinct predictive features, this prevented the model from effectively learning the unique patterns required to separate Class 1 from more dominant, similar classes like Class 3.

These results demonstrate that models like XGBoost can be used as a powerful monitoring tool for pipeline construction safety. Still, their performance may be inadequate for accidents with characteristics similar to other classes, such as Class 1. In future studies, working with more and diverse datasets in pipeline construction and testing the model for construction accidents across different areas will be meaningful for evaluating the model's success.

Compared to traditional safety analysis methods that typically rely on descriptive statistics or severity-based assessments, the proposed approach allows safety managers to understand accident patterns more proactively by identifying the likely type of incident before it occurs, helping project owners complete the project with less risk.

One of the most important strengths of this study is its focus on accident type prediction rather than accident severity prediction. While severity prediction is useful for post-incident assessment, predicting accident types provides more actionable information for safety planning, training programs, and preventive strategies. Specifically, identifying the most likely accident categories allows safety managers to allocate resources more effectively and design targeted interventions for high-risk activities.

Alongside these strengths, the study also has some limitations. The use of SMOTE to address class imbalance adds synthetic samples to the training data. While SMOTE was applied only to the training subset to prevent data leakage, the generated samples may not fully represent real-world accident scenarios and could introduce bias to the model. Although the study includes accident types from different construction sites, it focuses on a defined set of accident categories. While these categories reflect real-world classifications, future research could examine a broader or more detailed set of accident types to enhance the model's comprehensiveness.

Finally, although the model demonstrates strong classification performance, its practical application in real construction environments requires integration with real-time data collection systems and validation using live project data. Future work should focus on testing the model in operational environments and integrating it with

digital construction technologies such as BIM and IoT-based monitoring systems.

Overall, this work lays a foundation for the development of proactive, data-driven safety management tools in pipeline construction and highlights the potential of machine learning approaches to improve occupational safety outcomes.

Conclusion

This study investigated the success of the XGBoost model, trained on 1184 real-world accident data from pipeline construction sites, in predicting accident types using a multi-class classification method. Given the potential for both material and non-material damage from accidents in the construction sector, the study focused on predicting these types of accidents. Accident types were numerically translated from text and categorized into six classes. The model was trained on the accident data. Despite the relatively small dataset, the model achieved good prediction performance with 83% accuracy and a macro F1 score of 0.82. These findings validate the potential of machine learning approaches, such as XGBoost, for occupational safety analysis in the construction industry. The proposed model can be particularly beneficial for safety managers, site supervisors, and project owners by enabling automated classification of incident reports and helping uncover complex relationships between root causes and specific accident types, thereby strengthening post-incident analysis and future safety planning. Future studies could validate the model using larger, more diverse datasets in the pipeline field. It is also possible to make predictions on similar datasets using different ML algorithms. Furthermore, applying this model across different sub-sectors of the construction industry could yield interesting results. The current results provide a reliable reference point for ongoing developments in AI-assisted accident prevention.

PHYSICS-CONSTRAINED REINFORCEMENT LEARNING FOR INDIVIDUALIZED AND BIOMECHANICALLY FEASIBLE TASK-MOTION OPTIMIZATION

Kangrui Ren[1], Ali Golabchi[2], and Gaang Lee[1]
[1]University of Alberta, Canada
[2]Department of Mechanical Engineering, University of Alberta, Canada

Abstract

The construction industry faces high musculoskeletal disorder rates due to repetitive, awkward task-postures. Current manual corrections and static optimizations often ignore individual anthropometry and whole-body biomechanical interdependencies, leading to physically unfeasible results. This study explores Reinforcement Learning (RL) for tailored posture optimization by developing a pipeline that overcomes technical barriers like reward instability and high computational costs. The technique predicts joint-space residuals via a distilled, risk-aware RL policy within a physics simulator. Testing in construction-like scenarios showed significantly reduced mean risk and high-risk spikes while maintaining task fidelity. These findings demonstrate that RL can provide personalized, executable ergonomic interventions.

Introduction

The construction industry continues to experience a high prevalence of work-related musculoskeletal disorders (WMSDs), imposing a substantial burden on both worker health and operational productivity (Santos et al., 2025). These disorders are rarely the result of a single event; rather, they accumulate through sustained or repetitive exposure to risk factors such as awkward postures, forceful exertions, and repetitive motions during task performance (Hulshof et al., 2021). Since these contributing factors typically emerge from the complex interaction between poor work design and a worker's habitual postural patterns, effective mitigation requires not only work-redesign interventions but also, critically, systematic correction of workers' working postures during task performance.

Current industrial practices for assessing and correcting task postures rely heavily on manual processes. Assessment is typically conducted using self-reports or observational tools such as the Rapid Upper Limb Assessment (RULA) (McAtamney and Corlett, 1993) or the Rapid Entire Body Assessment (REBA) (Hignett and McAtamney, 2000). In practice, correction strategies are often limited to verbal, on-the-spot instructions delivered by safety managers. While intuitive, these local corrections often fail to account for whole-body biomechanical interdependencies; correcting a local issue (e.g., lowering an elbow) may inadvertently create or worsen risk elsewhere (e.g., increasing lower back torque) due to inherent human biomechanical coupling and task constraints (Belbeck et al., 2014; Nadon et al., 2018; Rören et al., 2024). Because these interventions depend on generic ergonomic guidelines, they often fail to consider individual anthropometric differences and habitual motion patterns, thereby making it difficult to provide posture corrections that are truly personalized and readily adoptable (Ji et al., 2023; Chen and Zhang, 2025). These limitations underscore a need for a systematic technique to generate biomechanically coherent, coordinated whole-body posture corrections that are customized to the individual's specific anthropometric characteristics within the given task context.

To derive whole-body-coordinated posture corrections, researchers have applied mathematical optimization, such as trajectory optimization (optimal control) (Dafarra et al., 2022), and inverse optimization (Westermann et al., 2020). However, these existing approaches often simplify whole-body risk as an additive sum of per-joint or angle-based scores in their equations, which limits their ability to account for the coupled constraints across the body (González-Alonso et al., 2025). By failing to enforce these coupled constraints, such approaches overlook critical factors such as load transfer, support stability, and contact maintenance (Zheng and Yumane, 2015), often resulting in "optimizations" that are non-actionable or physically impossible. Furthermore, on the optimization algorithm side, current approaches often rely on static, frame-based reasoning that does not account for individual anthropometric variabilities or the temporal flow of motion (Kee, 2022; Ciccarelli et al., 2026), prioritizing a raw "risk" score reduction without considering feasibility, motion smoothness, or workflow continuity.

Reinforcement learning (RL) offers a promising alternative to overcome these limitations by addressing the complexities of human motion that static optimization misses. Unlike frame-based techniques, RL is uniquely positioned to learn full-body coordinated actions, allowing it to discover posture adjustments that remain biomechanically feasible at the global level. What frame-based techniques miss is temporal coupling: feasibility constraints (stability, contact evolution, inter-joint coordination) are trajectory-level, not per-frame. It can also condition learned policies on individual user attributes, enabling the generation of personalized motion strategies rather than generic templates. This is because RL optimizes expected cumulative reward over time, not a single-step objective: the agent

is trained on long-horizon rollouts where feasibility violations and risk spikes occur downstream, enabling credit assignments that link later outcomes back to earlier posture choices. With a state representation that includes task context and user attributes, the learned policy becomes both temporally aware (trajectory-level) and personalized (user-conditioned) in a single decision-making loop. Crucially, RL handles sequential, history-dependent decision-making (Mnih et al., 2015; Schulman et al., 2015), which allows for the optimization of entire motion trajectories rather than isolated frames. By encoding multiple objectives within the reward function, RL agents can learn balanced posture strategies that reflect necessary real-world trade-offs between ergonomic risk, task efficiency, and motion smoothness.

Despite this theoretical promise, RL has not yet been sufficiently tested or validated as a technique for individually tailored task-posture optimization due to several technical barriers. A primary challenge is risk signal reliability and reward stability; MSD risk signals and video-based skeletal data can be noisy or non-smooth, often causing unstable learning processes or the development of "shortcut" behaviors that game the reward system without truly reducing risk (Ren, 2025). Furthermore, ensuring executability and safety remains difficult, as safety is often treated via soft penalties in RL; consequently, policies may violate strict joint limits, balance requirements, or contact constraints, resulting in failure during physics-based execution. The temporal nature of the problem also introduces long-horizon credit assignment issues, where risk reduction depends on early preparatory actions (e.g., foot placement) that are difficult to reinforce due to accumulated drift over long subtasks. Finally, the sample and computational costs of physics-based long-horizon RL might be overwhelming, requiring extensive rollouts that make training and tuning prohibitively expensive.

To address these gaps, this study aims to explore the potential of RL for individually tailored task-posture optimization by developing and testing the feasibility of a pipeline that effectively mitigates the technical barriers.

Proposed Posture Optimization Technique

Figure 1 provides an overview of the proposed RL-based individually tailored and biomechanically feasible posture optimization pipeline.

Problem Formulation

Individualized task-posture correction is formulated as a long-horizon, safety-constrained, multi-objective RL problem executed in a physics simulator. Rather than synthesizing motion from scratch, the policy predicts bounded joint-space residuals relative to a demonstration trajectory. At each control step, the action is applied as a joint-wise offset to the current demonstration pose target (i.e., the reference pose used as the tracking setpoint) and is clipped using conservative per-joint limits, ensuring that the corrections remain local and physically trackable by the simulated body. The corrected target is executed in a contact- and stability-aware simulator, and the post-contact state is evaluated to generate a risk signal for reward shaping.

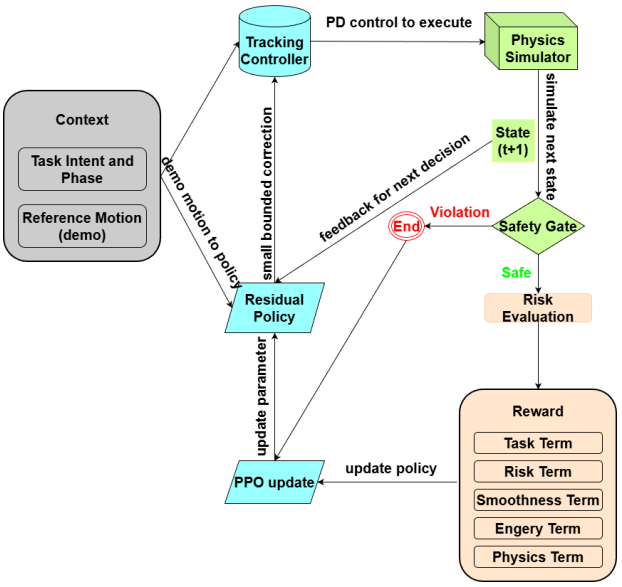

Figure 1: The proposed RL-based individually tailored and biomechanically feasible posture optimization pipeline.

To support distribution-aware risk shaping, the framework models both expected risk and the probability of high-risk events using a lightweight predictor distilled from a richer teacher model, making it practical for on-policy training. Safety is enforced through hard terminations triggered by simulator- and biomechanics-based checks (e.g., joint-limit violations, balance or contact failures, or spinal overload). Any such violation immediately terminates the episode and incurs a terminal penalty, thereby restricting exploration to physically executable behaviors. Finally, to discourage unrealistic reward shortcuts, policy updates are regularized toward a pretrained motion diffusion prior through a KL-divergence regularizer, encouraging outputs to remain within the manifold of human motion.

State Representation

A standardized kinematic encoding with explicit temporal context is used for state representation. All kinematic quantities are expressed in a consistent world frame and normalized using dataset-level statistics, while velocities are scaled by the control timestep to keep magnitudes comparable across terms. Each per-frame state s_t includes: (i) the root pose (position and orientation) and root linear/angular velocities; (ii) per-joint local rotations and angular velocities; and (iii) task-context features, including the goal pose, a phase ID (represented as a one-hot stage token), and a short reference snippet from the demonstration motion. The phase ID provides explicit stage information for indexing time-varying reference targets and disambiguating similar poses across different phases, which helps stabilize long-horizon imitation-style control (Peng

et al., 2018). Goal features are encoded as transforms relative to the pelvis (translation + 6D rotation). The reference snippet serves as a local motion anchor (e.g., a short horizon of target joint poses/velocities) to preserve task intent, while the policy is restricted to bounded corrections rather than free-form resynthesis.

Joint rotations are represented using the continuous 6D rotation encoding, defined by the first two columns of the rotation matrix, which avoids the singularities and discontinuities associated with Euler angles during learning. To provide short-term temporal context for contact and stability transitions and delayed biomechanical responses, the policy is conditioned on a stacked history window, where t indexes control timestep, H denotes the number of stacked frames, and s_k is the per-frame state at timestep k

$$\tilde{s}_t \triangleq [s_{t-H+1}, s_{t-H+2}, \ldots, s_t], \qquad H = 32. \tag{1}$$

With a 30 Hz control rate, $H = 32$ provides approximately 1.07 s of context while allowing the policy to remain feed-forward for stable on-policy learning. When personalization is enabled, the observation is augmented with subject descriptors (e.g., anthropometric measurements, range of motion indicators, and strength proxies), enabling capability-aware corrections rather than one-size-fits-all adjustments.

Action Representation

Actions are defined as continuous joint-space residuals (pose increments) bounded by joint-specific limits to enforce conservative, anatomically plausible corrections. Bounding is implemented through element-wise clipping (or tanh squashing) within predefined per-joint ranges. At each control step, the correction is added to the demonstration pose target and tracked by a stabilized PD controller in the physics simulator. Tracking is performed in joint space under torque limits and damping regularization to reduce overshoot and improve stability during contact switching. These bounds prevent implausible pose jumps and confine the corrections to a local feasible regime.

Given (s_t, a_t), where a_t is the pose correction applied at control timestep t, the simulator executes the correction-adjusted tracking command and advances the system:

$$s_{t+1} = F(s_t, a_t), \tag{2}$$

where $F(\cdot)$ denotes one physics rollout step, including contact resolution and internal integration substeps. After the transition, the risk student is queried using the updated history window $\tilde{s}_{t+1}$ (which includes the realized s_{t+1}). Evaluating risk after contact resolution and stabilization ties the reward signal to physically realized outcomes rather than to a pre-contact kinematic estimate and yields more consistent credit assignment when small corrections trigger compensation.

Risk-Awareness via Student–Teacher Distillation

The diffusion-based teacher builds upon the prior multimodal dynamic MSD-risk assessment framework, which fuses (i) skeleton dynamics, (ii) rule-based ergonomic indicators such as REBA-related cues and L5/S1-related loading proxies, (iii) visual-context features, and (iv) subject-related factors into a distributional risk representation. In the present pipeline, this upstream teacher provides supervisory targets for the mean risk and the probability of high-risk exceedance used in RL reward shaping. The upstream MSD risk evaluator represents uncertainty through a diffusion-based head and outputs a distribution over a scalar risk intensity u. Here, u denotes a normalized MSD-risk score derived from the upstream multimodal risk model. To make this risk signal numerically stable and comparable across motions and subjects during RL training, the raw teacher-side risk outputs are mapped to $[0, 1]$ using a monotonic calibration function fitted on the teacher training set. This mapping preserves the relative ordering of risk levels while placing them on a common scale for reward computation. Mean risk alone can obscure brief but hazardous spikes; therefore, the reward also penalizes the probability of exceeding a high-risk threshold. A tail event is defined using a fixed high-risk threshold $u_{\mathrm{hi}} = 0.8$, and the exceedance probability $\rho_t = \Pr(u \geq u_{\mathrm{hi}})$ is computed. This tail probability is explicitly penalized to discourage postures that retain non-negligible probability mass in the high-risk regime, thereby inducing risk-averse behavior. The threshold is selected to represent an upper-risk regime under the calibrated scale while keeping tail events sufficiently frequent for stable learning.

Under physics-based execution, contact events and safety terminations can abruptly end rollouts and amplify reward noise over long horizons. Proximal Policy Optimization (PPO) is adopted as the learning backbone because it provides stable, reliable optimization for long-horizon continuous control in such settings. However, PPO is on-policy and requires frequent rollout collection with step-wise reward evaluation, making the per-step cost of computing the risk signal a practical bottleneck. Estimating the tail probability via diffusion sampling at every environment step would be computationally prohibitive in the online PPO loop. This cost is removed from online training via teacher–student distillation: offline, a diffusion teacher produces distributional supervision targets, while online, a lightweight student predicts only the risk statistics required by the RL objective:

$$(\hat{\mu}_t, \hat{\rho}_t) = \mathrm{RiskStudent}(\tau_{t+1}). \tag{3}$$

This is sufficient because the RL objective depends on the expected risk level and the probability of entering the high-risk regime, rather than the full risk distribution. Here, $\hat{\mu}_t$ approximates the teacher mean risk and $\hat{\rho}_t$ approximates the teacher tail probability. The student is trained offline by MSE regression to teacher-derived targets, where the teacher's μ_t and ρ_t are estimated from diffusion samples per window (e.g., $S = 8$). During RL rollouts, diffusion sampling is not performed; the diffusion teacher is used only for evaluation and ablation studies.

Multi-Objective Reward & Safety Constraints

A unified multi-objective reward is optimized under hard safety enforcement:

$$r_t = \sum_{\star \in \Omega} w_\star(t) R_\star(t) - \lambda c_t, \qquad \Omega = \{\text{task, risk, smooth, energy, physics}\}. \tag{4}$$

The weights follow a fixed, deterministic curriculum, and λ is a safety multiplier. The curriculum emphasizes task fidelity and smoothness early in training (to preserve intent and stability) and gradually shifts weight toward risk reduction once reliable tracking is achieved. The indicator $c_t \in \{0, 1\}$ denotes a safety violation; when $c_t = 1$, the episode terminates immediately with an explicit terminal penalty. In implementation, the safety penalty is applied as a terminal cost with magnitude $P_{\text{term}} = 100$ (i.e., $-\lambda c_t$ is incurred only at termination).

The risk objective penalizes both the expected risk and the high-risk exceedance probability:

$$R_{\text{risk}}(t) = -\hat{\mu}_t - \alpha_{\text{tail}} \hat{\rho}_t. \tag{5}$$

where $\hat{\mu}_t$ is the predicted mean risk and $\hat{\rho}_t$ is the tail probability under the calibrated risk distribution.

The remaining objectives promote task fidelity and motion quality. The task term penalizes deviations from task intent and reference execution (e.g., goal-reaching errors, phase-dependent pose constraints, and trajectory deviation from the demonstration). The smoothness term discourages abrupt velocity and acceleration changes to suppress jerk-like corrections. The energy term penalizes actuation effort (e.g., the squared torque norm). The physics-realism term penalizes simulator-flagged artifacts such as stance-foot slip and excessive foot skating. Each term is normalized to a consistent scale before weighting to keep objectives comparable.

Safety termination is triggered by joint-limit exceedance, L5/S1 overload (excessive compressive loading at the L5/S1 junction, commonly used as a proxy for low-back injury risk), or balance/contact failure. Balance/contact failure is detected using simulator-resolved events such as falls, loss of required support contacts, or the center of mass leaving the support polygon. The L5/S1 load used for termination is computed by the physics/biomechanics engine, while the learned risk model is used only for reward shaping.

Training Loop

Training alternates between physics rollouts and policy updates. Offline, a diffusion-based risk teacher is trained and distilled into a lightweight risk student, and a separate motion diffusion model is trained as a realism prior. Online, each PPO iteration collects N episodes in the physics simulator using the stacked history input τ_t. After each transition, the risk student is queried on the updated window τ_{t+1} (which includes the realized s_{t+1}) and outputs $(\hat{\mu}_{t+1}, \hat{\rho}_{t+1})$ for distribution-aware reward shaping; hard violations trigger immediate termination with the terminal penalty. For brevity, the post-transition estimates $\text{RiskStudent}(\tau_{t+1})$ are denoted as $(\hat{\mu}_{t+1}, \hat{\rho}_{t+1})$. The policy is then updated using PPO for continuous control, with an additional KL regularizer between the policy distribution $\pi_\theta(a_t \mid \tau_t)$ and the prior distribution $\pi_{\text{prior}}(a_t \mid \tau_t)$, encouraging corrections to remain close to natural motion while still enabling risk reduction. The value function is updated by regression. Throughout training, a fixed deterministic curriculum schedules the objective weights $w_\star(t)$ to improve reproducibility and prevent weight oscillations under noisy on-policy returns.

Tests of the Proposed Technique

The framework was evaluated in physics-based, construction-like scenes along three criteria: (i) MSD risk reduction, measured in a distribution-aware manner (both the average risk level and the frequency of high-risk spikes via exceedance probability), (ii) task and motion preservation, measured by task-fidelity errors and motion-quality statistics relative to the reference motion, and (iii) safety and feasibility, measured by violation rates and rollout success/failure.

Test Setup

All evaluations were performed on a desktop with an NVIDIA RTX 5090 (32 GB VRAM), 64 GB RAM, and an Intel Core Ultra 7 265K CPU. Policies were trained in PyTorch using PPO, with rollouts executed in Isaac Lab (NVIDIA Omniverse Isaac Sim / PhysX). The simulator used $\Delta t_{\text{phys}} = 1/120$ s with decimation $d = 4$, yielding a 30 Hz control rate ($\Delta t_{\text{ctrl}} = 1/30$ s) and an episode horizon of $H = 240$ control steps (8 s). The default Isaac Lab HumanoidAMP configuration ($n_q = 28$ actuated DOFs) was used with joint limits enabled; reference targets were tracked via stabilized PD control with torque limits, using the default HumanoidAMP gains fixed across methods for fair comparison.

Results were averaged over 5 training seeds. Each seed was evaluated under 40 randomized initializations (200 runs total); metrics were averaged within each seed and reported as mean ± standard deviation (SD) across seeds. PPO updates used 4096 environment steps per iteration collected from parallel rollouts; episodes could terminate early due to hard-safety constraints, so sampling continued until the step budget was reached. Standard continuous-control PPO hyperparameters were used ($\gamma = 0.99$, $\lambda_{\text{GAE}} = 0.95$, $\epsilon = 0.2$, learning rate 3×10^{-4}, 10 epochs per update, minibatch size 256) to avoid tuning to a specific scene configuration. The risk student was queried at each timestep on the post-transition window τ_{t+1} (including the realized s_{t+1}) for reward shaping, with negligible overhead relative to physics simulation.

Test Data

Reference motion clips were drawn from AMASS (Mahmood et al., 2019), a large unified corpus of MoCap sequences represented in a common model parameterization (e.g., SMPL), which provides large-scale MoCap sequences in a standardized body-model parameterization (e.g., SMPL) for consistent kinematic processing and retargeting. Action semantics and temporal segmentation were obtained from BABEL (Punnakkal et al., 2021), which supplies sequence- and frame-level action labels aligned with AMASS motions. Using BABEL labels, clips relevant to construction-like activities were selected (e.g., turning locomotion, bending/stooping, crouching, reaching, and overhead arm motion). Sequences were resampled to 30 Hz, segmented into 8 s clips (240 frames), and retargeted to the simulator humanoid via offline constrained inverse kinematics with joint-limit enforcement (joint mapping, scale normalization, and root alignment). Root motion was normalized (heading alignment and floor-height correction) to enable consistent reuse across scene layouts and randomized initializations.

Test Configuration

Episodes were initialized from reference clips and executed in parameterized construction-like layouts (e.g., corridor-to-corner navigation and low-clearance passage traversal) that require physically feasible locomotion and posture adaptation. Task objectives were specified by scene geometry and goal conditions, such as reaching a target region, progressing along a prescribed path, and satisfying clearance constraints. Scene parameters were randomized across episodes (e.g., corridor width, turn angle, and target location) to assess robustness under layout variation. To induce MSD-relevant mechanical demand without object handling, an equivalent virtual payload was applied during rollouts (e.g., a constant downward load at the hand frame), producing trunk moments and L5/S1 loading during stooping and reaching.

Representative examples of whole-body postures relevant to these task settings are shown in Figure 2. The three poses are included to visually clarify the representative posture demands and whole-body configurations considered in this study.

Baselines and Metrics

The technique is compared against three representative baselines: (i) reference tracking only (RTO), (ii) PPO without risk shaping (SPO), and (iii) mean-risk-only PPO (tail term removed). To examine whether subject-specific inputs contribute to individualized optimization, we additionally include a descriptor-ablated variant of the proposed method, in which subject descriptors are removed while all other components and training settings are kept unchanged. This comparison is used as a targeted individualization check rather than as a separate baseline family. Reported metrics include distributional risk (mean risk and exceedance probability), safety/feasibility (success rate), task fidelity (goal-reaching error and trajectory deviation), motion quality (smoothness and correction magnitude), and effort (mean squared torque, $\|\tau\|_2^2$). Results are reported for (1) overall effectiveness under physics-based execution (risk reduction with task fidelity and feasibility), (2) risk aversion by removing the tail term (change in high-risk exceedance), and (3) an individualization check based on the descriptor-ablated comparison.

Figure 2: Representative whole-body posture categories relevant to task-motion optimization.

Results and Discussions

As shown in Table 1, the proposed technique achieved the best overall trade-off under physics-based execution. It reduced mean risk from 10.88 (RTO) and 9.93 (SPO) to 6.15, and lowered tail probability from 0.25 to 0.14, while maintaining strong task completion (success 0.85) and the lowest task error (0.19). Corrections remained bounded (residual magnitude 0.19) and smoothness stayed comparable to the baselines (1.03 vs. 1.00–1.10), supporting local, physically plausible posture adaptation rather than rewriting the reference motion.

Table 1: Overall effectiveness

Metrics	RTO	SPO	PPO	Proposed
Mean risk	10.88 ± 0.27	9.93 ± 0.33	8.32 ± 0.26	**6.15 ± 0.23**
Tail prob.	0.25 ± 0.01	0.22 ± 0.02	0.20 ± 0.02	**0.14 ± 0.01**
Task error	0.38 ± 0.01	0.29 ± 0.01	0.23 ± 0.01	**0.19 ± 0.01**
Success	0.62 ± 0.02	0.82 ± 0.02	0.84 ± 0.02	**0.85 ± 0.01**
Res. mag.	0.00	0.15 ± 0.01	0.21 ± 0.02	**0.19 ± 0.01**
Smoothness	1.00 ± 0.03	1.07 ± 0.05	1.10 ± 0.04	**1.03 ± 0.03**

The reduction in risk (without compromising success rates) demonstrates that the hard safety constraints and physics-based simulation act as a critical filter, ensuring that all suggested posture corrections remain within the user's biomechanical limits. Unlike the SPO baseline, which fails to prioritize health, or the PPO baseline, which lacks robustness against extreme risk, the proposed method identifies a "safe manifold" for human motion.

Furthermore, the low residual magnitude (0.19) and high task fidelity (0.19 error) confirm that the technique achieves optimization by actively incorporating the user's habitual motion patterns. This suggests that the pipeline

does not impose a generic, "one-size-fits-all" posture; instead, it provides a personalized refinement that preserves the worker's unique motor profile while systematically hedging against both average and tail-end MSD risks. Consequently, the framework proves to be a viable bridge between complex biomechanical theory and practical, actionable interventions in labor-intensive environments.

Beyond improving average ergonomic scores, the necessity of this distribution-aware approach is most clearly evidenced by its performance in extreme scenarios. As shown in Table 2, the proposed technique significantly reduced rare-but-severe outcomes that standard RL methods often overlook. While the SPO and PPO baselines exhibited high-risk episode frequencies of 0.34 and 0.29, respectively, the proposed framework lowered this incidence to 0.12, flattening the tail of the risk distribution.

Table 2: Tail-sensitive outcomes for risk-aversion ablation

Method	P95 risk	High-risk episodes
SPO	12.18 ± 0.42	0.34 ± 0.05
PPO	11.64 ± 0.47	0.29 ± 0.04
Proposed	**9.63 ± 0.27**	**0.12 ± 0.02**

The reduction of P95 risk to 9.63 (compared to 12.18 for SPO and 11.64 for PPO) further confirms that the pipeline does not just lower the mean burden but proactively avoids the most hazardous postural configurations. This demonstrates that by penalizing tail-event probabilities through the distilled risk student, the system provides a level of safety reliability that is essential for real-world deployment, where injury prevention must be absolute. These findings ultimately validate that the proposed RL-based pipeline effectively hedges against the technical barriers of risk-reward instability and safety enforcement in complex task environments.

Table 3: Subject-conditioning ablation

Method	Mean risk	Tail prob.	Success
W/o Subject	9.92 ± 0.41	0.23 ± 0.02	0.81 ± 0.04
Proposed	**6.15 ± 0.23**	**0.14 ± 0.01**	**0.85 ± 0.01**

As shown in Table 3, the descriptor-ablated variant produced a substantially higher mean risk (9.92 ± 0.41) than the full subject-conditioned policy (6.15 ± 0.23), while task success remained broadly comparable (0.81 ± 0.04 vs. 0.85 ± 0.01). The relatively small change in success is likely because the evaluated task settings are not highly failure-prone, so the main effect of subject conditioning is expressed more clearly through risk reduction than through task completion rate. This result suggests that subject-specific descriptors contribute materially to the optimization outcome rather than acting as inactive auxiliary inputs. The pronounced increase in risk after removing individual information indicates that the learned correction strategy is not purely generic but is meaningfully shaped by subject-conditioned features. These findings provide additional evidence for the individualized character of the proposed optimization framework.

Conclusions

An RL-based pipeline is presented for individualized posture correction under physics-based execution and hard safety constraints. Rather than synthesizing motion from scratch, the policy outputs bounded joint-space residuals that produce local, actionable corrections while preserving task intent. A distilled risk student provides mean risk and high-risk exceedance probability for distribution-aware reward shaping, enabling explicit suppression of tail events beyond mean-only optimization.

The tests demonstrate that this design effectively reduces MSD risk while maintaining high task success and physical feasibility under the given task settings. The added subject-conditioning ablation further shows that removing individual descriptors substantially increases mean risk without yielding a meaningful improvement in task success, indicating that subject-specific inputs contribute materially to the learned correction strategy and supporting the individualized nature of the proposed framework. Ablations further indicate that hard safety enforcement and tail-risk shaping are key to stabilizing long-horizon rollouts under biomechanical constraints.

These findings indicate that integrating temporal context with distribution-aware reward shaping allows RL to generate corrections that are both ergonomically superior and physically executable. Ultimately, this research provides a scalable pathway for transitioning from generic ergonomic guidelines to personalized, biomechanically coherent digital interventions that can reduce the long-term burden of MSDs in labor-intensive industries. Future work will extend the framework to more contact-rich activities and integrate higher-fidelity musculoskeletal models to better support real-world ergonomic interpretation.

Abstract

Home remodeling often relies on sketches and informal discussions, causing miscommunication, rework, and added cost. Existing AR tools are typically proprietary and limited to predefined 3D asset libraries. This study develops and validates an executable end-to-end pipeline that converts free-form homeowner text into AR-compatible 3D remodeling visualizations. A sofa case study evaluates generated assets across image resolution, input type, and quality condition using SSIM and dimensional metrics. Results show visually coherent assets suitable for early-stage communication, while highlighting depth and scale limitations for future environment-aware AR remodeling tools.

Introduction

The home remodeling market has expanded significantly in the post-pandemic period, exceeding $880 billion globally in 2022 and projected to surpass $1.1 trillion by 2027, (ReportLinker, 2023). The United States alone accounted for $567 billion in 2022 (Joint Center for Housing Studies of Harvard University, 2023). This growth has accelerated digital and remote planning workflows, with increasing reliance on immersive tools such as VR and AR, now accessible via consumer devices (Brown, 2020). Augmented Reality (AR) overlays digital elements onto real-world environments, enabling users to visualize furnishings and design changes within their own spaces before implementation (Azuma, 1997; IKEA, 2017; Inc., 2018).

Consumer applications such as IKEA Place and Houzz's "View in My Room 3D" demonstrate the growing adoption of AR in residential design. These tools improve decision-making and purchasing likelihood, with Houzz reporting significantly higher engagement and conversion rates among AR users (IKEA, 2017; Inc., 2018). However, these systems rely on proprietary, pre-modeled catalogs, limiting scalability, customization, and the ability to handle free-form user inputs (e.g., "two-seater U-shaped red sofa") (Boopathy et al., 2024).

AR is also being explored in construction workflows, such as the Augmented Carpentry project, which overlays fabrication guidance directly onto materials, demonstrating integration of digital design with physical execution (Coxworth, 2025). This AR-assisted production method adeptly merges human skill with computational precision, actualizing digital designs on the workpiece. These advancements indicate a wider trend of employing AR to seamlessly incorporate design information into actual construction processes, extending beyond mere screen visualization. Despite these advances, remodeling remains communication-intensive, particularly for homeowners with limited technical expertise. Reliance on informal sketches and verbal descriptions often leads to misinterpretation, delays, and increased costs (for Housing Studies of Harvard University, 2014). With only basic visualization support, homeowners often with little to no construction experience, frequently rely on hand-drawn sketches from imagination and informal discussions at home to explain their ideas. These ad hoc methods can make it difficult to convince the remodeler of the intended design, increasing the likelihood of miscommunication, design inaccuracies, and inefficient implementations. Many existing tools assume user familiarity with design principles or rely on fixed 3D asset libraries, limiting creativity and personalization. Even AI-based systems typically provide predefined options rather than enabling translation of nuanced, real-world inspirations into customized designs. Furthermore, end-to-end pipelines converting free-form input into AR visualizations remain largely unavailable (Höllein et al., 2023).

To address these gaps, this study presents a first-step toward automating interior remodeling visualization by converting free-form user descriptions into AR-compatible 3D models. The goal is to reduce communication barriers between non-expert homeowners and professional stakeholders including contractors, sub contractors, suppliers, interior designers, and architects. The proposed system enables users to describe desired designs in natural language and generates corresponding AR visualizations that are projected onto the real world environments. It integrates natural language processing (NLP), text-to-image generation, multi-view synthesis, 3D reconstruction, and AR deployment into a unified pipeline, generating content dynamically rather than relying on pre-built assets. The aims of this research are to (1) streamline and accelerate early-stage ideation by producing realistic previews from textual or image descriptions, (2) reduce the cost and specialized expertise typically required to create custom 3D remodeling visualizations, and (3) demonstrate the feasibility of end-to-end automation from text or image input to AR output.

Literature Review

Advances in generative AI, computer vision, and AR have expanded automated content creation in interior design. This review synthesizes progress in text-to-image, multi-view synthesis, and text-to-3D reconstruction, highlighting limitations in achieving end-to-end AR workflows for homeowner use. Diffusion-based models such as Stable Diffusion (Rombach et al., 2022) and Imagen (Saharia et al., 2022) generate high-quality images from text, with domain adaptations enabling interior design visualization (Chen et al., 2023). However, outputs remain 2D and unsuitable for AR interaction.

Multi-view synthesis methods such as SceneScape (Fridman et al., 2023) and FlexGen (Zhang and Lee, 2023b) improve geometric consistency across viewpoints. However, they remain computationally intensive and prone to inconsistencies, with limited support for iterative refinement. 3D reconstruction methods such as NeRF (Mildenhall et al., 2020b), Text2Room (Höllein et al., 2023), DreamFusion (Poole et al., 2022), and Magic3D (Lin et al., 2023) enable text-driven 3D generation. However, outputs typically require extensive post-processing (e.g., mesh cleanup, texturing), limiting usability for non-experts. A key limitation is AR integration, as generated 3D assets often require manual conversion for real-time deployment. Existing research pipelines rarely support direct AR-ready outputs, limiting scalability (Poole et al., 2022; Lin et al., 2023).

The proposed pipeline addresses this gap by integrating text input, multi-view synthesis, 3D reconstruction, and direct export to AR-compatible formats (e.g., USDZ), enabling iterative and scalable remodeling visualization. Table 1 summarizes how representative recent studies cover the major components required for a text-to-AR workflow. Prior work shows strong progress in individual stages such as text-to-image generation, multi-view synthesis, and text-to-3D reconstruction. However, most approaches do not provide a complete path to AR-ready deployment and often offer limited support for iterative refinement that matches real remodeling conversations.

Table 1: Comparative analysis of recent text-to-AR methodologies

Study	Text-to-Image	Multi-view Synthesis	3D Reconstruction	AR Integration	Iterative Refinement
(Chen et al., 2023)	Yes	No	No	No	Yes
(Fridman et al., 2023)	Yes	Yes	Yes	No	Limited
(Höllein et al., 2023)	Yes	Yes	Yes	No	No

Magic3D (Lin et al., 2023)	No	No	Yes	No	No
Our Proposed Pipeline	**Yes**	**Yes**	**Yes**	**Yes**	**Yes**

Reliable 3D Reconstruction as a Practical Requirement

Reliable 3D reconstruction is essential in remodeling, as decisions depend on spatial accuracy and scale rather than visual plausibility alone. Single-image reconstruction methods suffer from missing geometry due to occlusions (Mildenhall et al., 2020a; Gkioxari and Malik, 2019), while traditional multi-view approaches require extensive image capture (Seitz and Curless, 2021; Schönberger and Frahm, 2016). Generative multi-view synthesis offers a promising alternative by producing consistent viewpoints from text, reducing data requirements while improving reconstruction fidelity (Ho and Salimans, 2023; Zhang and Lee, 2023a). These observations motivate the need for workflows that couple multi-view consistency with efficient reconstruction and deployment constraints, aligning with the introduction's goal of advancing toward automated transformation from free-form user intent into AR-compatible 3D assets for remodeling visualization.

Methodology

This study presents a first-step exploration toward an end-to-end text-to-AR workflow for home remodeling visualization. The goal is not to introduce new generative or reconstruction models, but to establish an executable baseline and clarify what is practically required to translate a homeowner's free-form natural language intent into an AR-ready 3D asset that can be viewed within the real home environment. The contribution of this work is therefore the integration of established components into a deployable workflow with inspectable intermediate outputs, which supports intent alignment and helps identify where failures and quality limitations arise in practice. In this context, the pipeline is designed to reduce the homeowner–professional communication gap by turning ambiguous verbal descriptions into shared, inspectable visual artifacts that can be iteratively refined during early-stage remodeling discussions. This methodology aims to establish an end-to-end workflow that transforms free-form natural language descriptions into AR-ready 3D assets for early-stage home remodeling visualization. It further seeks to characterize how practical input conditions and key pipeline settings influence output quality, particularly reconstruction robustness and dimensional plausibility. Finally, the workflow introduces intermediate quality checks to limit error propagation and documents where human refinement remains necessary to resolve intent ambiguity and support clearer homeowner–professional communication.

Pipeline Overview

The workflow consists of four interrelated phases that progressively convert language into deployable AR content: (1) Text-to-2D Synthesis, (2) Image Enhancement and Multiview Generation, (3) 2D-to-3D Reconstruction, and (4) 3D-to-AR Integration. Each phase produces a tangible intermediate output (candidate images, processed multiview sets, reconstructed meshes, AR-compatible assets) that can be inspected and improved before moving forward, which supports faster alignment between user intent and the generated visualization. This staged design is used as a practical first step because it produces inspectable intermediate outputs and an explicit mesh for AR deployment, which is important for maintaining geometric consistency and dimensionally plausible visualization in remodeling contexts.

Figure 1: Overview of the proposed Text-to-AR pipeline. The shaded components indicate the phases evaluated in the case study.

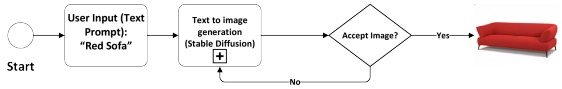

Figure 2: Phase 1: Text-to-2D synthesis workflow.

Phase 1: Text-to-2D Synthesis

Phase 1 translates a user's natural language description (e.g., "modern red two-seater sofa") into an initial set of candidate images that serve as the visual starting point for later multiview generation and reconstruction. Stable Diffusion is used as the text-to-image engine, and multiple candidates are produced per prompt by varying seed values and guidance settings to capture reasonable visual interpretations of the same intent. In this study, a Stable Diffusion model (v1.5) is used to generate candidate images, with multiple outputs produced by varying random seed values to support iterative selection. To directly support remodeling conversations, this phase is treated as an iterative intent-clarification step. Rather than assuming the first output is correct, users can select the closest candidate and refine the description to better match their target appearance. This human-in-the-loop selection is intentionally positioned as a lightweight communication mechanism: it reduces ambiguity early, before downstream 3D reconstruction amplifies errors or inconsistencies.

The current implementation does not explicitly encode metric dimensions in text prompts, as diffusion generation operates in a scale agnostic space. However, preliminary tests with dimension aware prompts (e.g., approximate size or capacity) showed improved proportional consistency.

Phase 2: Image Enhancement and Multiview Generation

After Phase 1, the selected image is conditioned to better support downstream 3D reconstruction. This step focuses on improving visual clarity and isolating the object so that later multiview synthesis and reconstruction are less sensitive to background clutter and image artifacts. Multiview synthesis is implemented using Zero123++ (sudo-ai/zero123plus-v1.2) with an Euler Ancestral scheduler and 75 inference steps, generating six consistent viewpoints per input. First, denoising and super-resolution are applied to improve sharpness and reduce noise, using ESRGAN to enhance spatial detail when needed. Next, background removal is performed using the Rembg toolbox to foreground the target object and produce cleaner object boundaries for subsequent processing. Background removal is performed using Rembg, and super resolution is applied using Real-ESRGAN (RealESRGAN_x4plus, 4× upscaling) to improve image quality prior to multiview

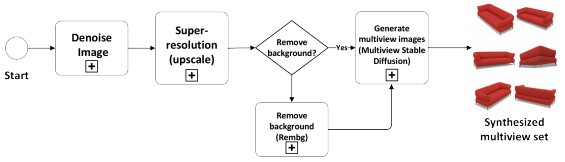

Figure 3: Phase 2: Image enhancement and multiview generation workflow.

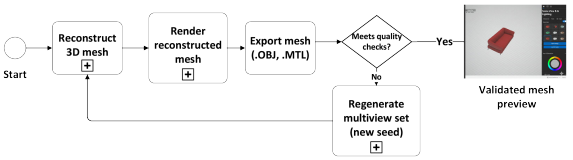

Figure 4: Phase 3: 2D-to-3D reconstruction workflow.

generation.

Following enhancement and segmentation, multiview synthesis is performed using Multiview Stable Diffusion to generate additional viewpoints of the same object. These synthetic views approximate photographs captured from different camera angles and provide the multi-perspective observations required for sparse-view 3D reconstruction. The overall sequence of enhancement, isolation, and multiview generation is summarized in Figure 3.

Phase 3: 2D-to-3D Reconstruction

Phase 3 converts the enhanced multiview image set into a 3D mesh representation. The processed views from Phase 2 are provided as input to a sparse-view reconstruction workflow (Instant Mesh), which generates a textured mesh by estimating object geometry from limited viewpoints. Reconstruction is performed using InstantMesh (instant_mesh_large.ckpt) with default configuration settings, operating on six synthesized views arranged in a 3×2 grid. Because reconstruction quality is sensitive to view consistency and segmentation quality, the resulting mesh is inspected using basic quality checks focused on geometric completeness and surface stability. When reconstruction artifacts are observed, the pipeline returns to Phase 2 to regenerate the multiview set with adjusted seeds, producing a new view collection for reconstruction. The reconstruction loop and decision point are illustrated in Figure 4. Final validated meshes are exported as `.OBJ` and `.MTL` files, preserving both geometry and associated material information for AR deployment.

The reconstruction process operates in a normalized coordinate space, and the metric scale is not inherently preserved. A configurable scale parameter is applied post reconstruction, allowing the generated mesh to be resized relative to the target scene.

Phase 4: 3D-to-AR Integration

Phase 4 prepares the reconstructed mesh for deployment in an AR environment. During AR integration, reconstructed meshes can be interactively rescaled to align with user defined spatial constraints and real-world placement requirements. The exported `.OBJ` and `.MTL` assets are con-

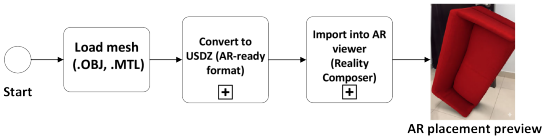

Figure 5: Phase 4: 3D-to-AR integration workflow.

verted into the USDZ format using Aspose 3D, enabling compatibility with common mobile AR workflows. After conversion, the asset is calibrated to ensure correct scale and orientation for placement in real indoor spaces. The calibrated USDZ model is then imported into Apple Reality Composer to support spatial anchoring and interactive visualization, including consistent placement within the physical environment and realistic rendering behavior. This integration sequence is summarized in Figure 5, and it produces an AR-ready asset that can be deployed on consumer-grade mobile devices for remodeling visualization.

This methodology establishes a practical baseline workflow for translating free-form user intent into AR-ready remodeling visualizations. Rather than proposing new foundation models, the contribution of this section is the structured integration of existing components into a reproducible sequence with clear intermediate outputs, enabling inspection and iteration before AR deployment. Evaluation procedures, parameter sensitivity observations, and quality outcomes are reported in the subsequent case study to assess visual plausibility, reconstruction robustness, and AR deployability in consumer-grade environments.

Unless otherwise specified, all models are used with default pretrained weights and configurations, with stochastic variation controlled through seed initialization.

Case Study: Results and Discussion

To evaluate the practical effectiveness of the proposed text-to-AR workflow, this study conducts a case study that examines how reliably visually coherent and dimensionally plausible 3D assets can be produced from limited two-dimensional inputs. The proposed methodology is fully executable, and the complete end-to-end pipeline was implemented and run as presented, from text prompting through AR-ready deployment. This evaluation is essential for home remodeling use cases where the objective is not fabrication-level precision, but the ability to translate homeowner intent into a shared visual artifact that supports clearer communication during early-stage design discussions. Accordingly, the case study assesses the pipeline's performance under varied input conditions, identifies key bottlenecks, and establishes baseline benchmarks that inform future improvements.

Experiment Overview

The primary objective of this experiment is to evaluate the robustness of the pipeline's 2D-to-3D reconstruction stage under diverse input conditions relevant to remodeling scenarios. Within the scope of this paper, the case study focuses on the most failure-prone and decision-critical portion of the workflow, Phases 2 and 3 (image preprocessing and multiview generation, and 2D-to-3D reconstruction), since these steps largely determine whether the final AR asset is usable for remodeling visualization. Sofa objects were selected because they are common in interior design tasks and present geometric challenges (curvature, occlusions, and complex silhouettes) that stress reconstruction quality in ways that are meaningful for AR-based space planning.

The dataset comprises sofa images organized into three categories namely a) Front-view images: frontal perspectives that preserve symmetry and provide clear visibility of primary features. b) Side-view images: lateral perspec-

Figure 6: Complete workflow visualization for four representative sofas. Each row shows: (a) original input image, (b) one representative view from the generated multiview set, and (c) final AR placement in a real room environment.

tives that introduce occlusion and asymmetry challenges; c) Synthetic images: controlled images collected for systematic evaluation under consistent conditions.

Real images were captured in front and side views to approximate practical acquisition conditions. In total, 12 distinct sofa models were evaluated to ensure variation in shape, style, and visual complexity. Synthetic sofa images were additionally collected from an online store to support controlled comparisons across consistent viewpoints and visual conditions.

To evaluate robustness under practical acquisition conditions, we applied controlled augmentations that vary image scale and quality. Each sofa image was resized to three resolutions (256, 512, and 1024 pixels) to assess sensitivity to input scale. For each resolution, two quality conditions were created. High-quality samples preserved sharpness and minimal noise to approximate favorable capture conditions. Low-quality samples were intentionally degraded using Gaussian blur (standard deviation = 2.0) with additional controlled noise to simulate common imperfections such as slight defocus and sensor noise, consistent with prior imaging literature (Roboflow, 2023; Gonzalez and Woods, 2023; Shorten and Khoshgoftaar, 2019). Controlled lighting variations were also introduced to reflect typical indoor capture variability. Figure 6 illustrates a representative sample processed through the complete workflow, showing the input image, preprocessing and background removal, multiview synthesis output, and the resulting reconstructed 3D mesh prepared for AR visualization.

All augmented inputs were processed through the full reconstruction workflow, including multiview synthesis, mesh reconstruction, and final rendering. This design enabled systematic comparison of pipeline performance across viewpoint type, resolution, and quality condition, providing an interpretable baseline for assessing reconstruction stability and identifying failure modes relevant to AR remodeling visualization.

Evaluation Metrics

To assess the proposed 2D-to-3D reconstruction workflow in a manner aligned with home remodeling visualization, we evaluate both (1) perceptual visual fidelity, which supports visually plausible AR previews for homeowner–professional alignment, and (2) geometric dimensional accuracy, which supports spatial plausibility during placement and scale interpretation in AR. Accordingly, we report one perceptual metric (SSIM) and two complementary dimension-based error metrics (NAE and NRMSE).

Perceptual visual fidelity (SSIM): The Structural Similarity Index Measure (SSIM), introduced by Wang et al. (Wang et al., 2004), evaluates image similarity using luminance, contrast, and structural components and is widely used in image synthesis and super-resolution research due to its correlation with human perception (Ledig et al., 2017; Zhang et al., 2018). In this study, SSIM is computed by comparing rendered projections of the reconstructed 3D mesh against the original input image and against its background-removed counterpart. The latter comparison reduces background influence and better isolates the reconstruction quality of the foreground object. SSIM values range from 0 to 1, where higher values indicate greater perceptual similarity.

Geometric dimensional accuracy (NAE and NRMSE): To evaluate dimensional plausibility, we adopt two metrics commonly used in object reconstruction and modeling studies (Tatarchenko et al., 2017; Wu et al., 2016). First, Normalized Absolute Error (NAE) measures the relative deviation between predicted and ground-truth dimensions (width, depth, and height):

$$E_{dim} = \left| \frac{D_{pred} - D_{true}}{D_{true}} \right| \tag{1}$$

where D_{pred} is the reconstructed dimension and D_{true} is the ground-truth measurement. This normalized form enables consistent comparison across objects of different sizes. Second, we use Normalized Root Mean Squared Error (NRMSE) as a scale-independent aggregate measure of dimensional accuracy:

$$NRMSE = \frac{\sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(D_{pred}^{(i)} - D_{true}^{(i)}\right)^2}}{\bar{D_{true}}} \tag{2}$$

where N denotes the number of evaluated samples and $\bar{D_{true}}$ denotes the mean of the ground-truth dimensions across the dataset. Lower NAE and NRMSE values indicate improved dimensional agreement.

Together, SSIM, NAE, and NRMSE provide a concise and complementary evaluation of visual plausibility and dimensional deviations. Results are reported across viewpoint type, resolution, and quality condition to characterize reconstruction robustness under varied input scenarios.

Results

Following data acquisition and augmentation, all samples were processed through the complete evaluation workflow. SSIM was computed to quantify perceptual fidelity by comparing rendered projections of the reconstructed meshes against the original input images and their background-removed counterparts. Geometric accuracy was assessed by comparing reconstructed object dimensions (width, depth, and height) against ground truth measurements across the 12 sofa models. Results are reported across image resolution (256, 512, and 1024 pixels), input type (front-view, side-view, and synthetic), and quality condition (high vs. low) to capture performance variability under realistic acquisition conditions. These results provide a baseline characterization of the tradeoff between perceptual plausibility and dimensional plausibility for AR-ready assets generated from limited inputs, which is critical for determining when such outputs are usable for early-stage remodeling communication.

Across all samples, the average SSIM between rendered meshes and original input images was 0.556, indicating

that the reconstructed outputs preserved key structural characteristics despite texture and mesh granularity limitations. When SSIM was computed against background-removed inputs, the average increased slightly to 0.564, suggesting that background complexity can depress perceptual similarity scores and that foreground isolation provides a clearer assessment of reconstruction quality. These SSIM values are consistent with ranges reported in prior single-input-view 3D reconstruction studies (Richardson et al., 2016; Wu et al., 2016). Dimensional accuracy was evaluated using NAE and NRMSE. Across the dataset, NAE values for width, depth, and height typically ranged from 20% to 60%, with width generally exhibiting greater stability. Table 2 reports the consolidated, scale-independent NRMSE values for each dimension. The results indicate that proportional structure is often preserved, while depth remains the most challenging dimension to recover reliably due to occlusion and limited visual cues.

Table 2: NRMSE by dimension across all evaluated sofa models.

Dimension	NRMSE
Width	30.98%
Depth	39.40%
Height	19.16%

Table 3: Per-sofa reconstruction quality across input conditions. SSIM is reported against original inputs. NAE is reported per dimension (W = width, D = depth, H = height).

Sofa	Input Type	Resolution (px)	SSIM (Orig.)	NAE_W (%)	NAE_D (%)	NAE_H (%)
S1	Front	512	0.325	30.0	70.0	2.6
S2	Side (Synthetic)	512	0.652	6.7	17.7	5.3
S3	Front	512	0.443	37.5	15.6	7.0
S4	Side	512	0.493	5.6	1.0	3.8
Average			**0.478**	**20.0**	**26.1**	**4.7**

To illustrate variability across representative cases and input conditions, Table 3 reports SSIM and dimensional errors for four sofa models at 512×512 resolution. The results show that height reconstruction is highly accurate (4.7% average error), while depth remains the most challenging dimension (26.1% average error), particularly for front-view inputs where occluded rear geometry must be inferred.

The results highlight the relationship between perceptual fidelity, geometric accuracy, and practical usability for AR remodeling visualization. Key observations are summarized below.

Visual plausibility is consistently maintained: The average SSIM values of 0.556 (against original inputs) and 0.564 (against background-removed inputs) indicate that reconstructed meshes preserve the primary structural features of the sofas. The slight improvement after background removal suggests that background complexity can suppress perceptual similarity scores and that foreground isolation provides a clearer assessment of reconstruction quality.

Depth remains the dominant source of dimensional error: Dimension-based evaluation shows larger discrepancies in depth compared to width and height. This outcome is expected when reconstruction begins from a single input view and relies on synthesized viewpoints, as occluded regions provide limited cues for recovering true depth.

Input view and resolution influence reconstruction stability: Reconstructions from front-view inputs are generally more stable than those from side views, where asymmetry and occlusion introduce additional ambiguity. Higher resolutions tend to improve SSIM and modestly reduce dimensional errors, although gains diminish at higher resolutions.

Implications for AR remodeling use: The pipeline produces visually coherent assets that support early-stage ideation, AR-based exploration, and communication of intent. However, the observed dimensional inaccuracies indicate that the current workflow is not intended for high-precision tasks such as fabrication or construction detailing.

Overall trade-off: The results demonstrate a clear trade-off between visual plausibility and geometric accuracy. The pipeline is effective for generating AR-ready previews for communication, while future improvements should prioritize scale awareness, depth reliability, and constraint-based reconstruction.

Conclusions and Future Research Directions

This paper implements an executable first-step text-to-AR workflow aimed at reducing the homeowner–professional communication gap in early-stage home remodeling by translating free-form user intent into an AR-ready 3D visualization. The primary contribution is the practical integration of established components (text-to-image generation, image preprocessing and multiview synthesis, sparse-view reconstruction, and USDZ-based AR deployment) into a reproducible pipeline with inspectable intermediate outputs that support iterative refinement and reduce reliance on manual 3D modeling expertise. While the full workflow is implemented end to end, the quantitative evaluation is intentionally focused on the most failure-prone and decision-critical stages that govern reconstruction quality and dimensional plausibility.

A sofa case study was selected as a conservative test object due to curved geometry and frequent occlusions, which stress multiview consistency and depth recovery more than common rectilinear interior elements. The results show that the implemented workflow can produce visually coherent assets suitable for AR ideation and communication, with average SSIM values of 0.556 against original inputs and 0.564 against background-removed inputs. However, geometric accuracy remains limited, particularly for depth, indicating that the current workflow is best positioned as an intent-alignment and early visualization tool rather than a substitute for precision measurement or fabrication-ready modeling. Overall, these findings support the feasibility of producing AR-ready previews from limited inputs and clarify the primary technical limitations that must be addressed in future work to improve dimensional plausibility and environment-aware placement.

Future work will focus on four directions: (1) environment-aware capture and spatial reasoning (e.g.,

leveraging mobile camera/LiDAR) to support scale- and fit-aware placement and basic clearance checking; (2) room-scale, multi-object scene generation with stronger geometric constraints and priors (standard dimensions and optional user measurements) to reduce depth ambiguity; (3) user-centered AR evaluation to quantify usability, perceived realism, and the impact on homeowner–professional decision-making; and (4) benchmarking direct text-to-3D methods within the same AR deployment constraints to compare dimensional plausibility and post-processing requirements against the staged workflow used in this study. Future work will also expand evaluation beyond sofas by collecting and labeling diverse furniture and interior asset datasets across multiple viewpoints to more rigorously assess generalizability and robustness. In addition, we are exploring user-captured imagery as input by integrating grounded detection and segmentation methods (e.g., Grounding DINO and Grounded SAM) to isolate real objects and evaluate projection fidelity in AR under practical conditions. Future work will also focus on incorporating explicit scale control into the pipeline, including user-defined dimensional inputs to guide scaling, automated dimension estimation from images, and scale-aware normalization prior to evaluation. Providing users with structured prompt templates that include dimensional cues is also expected to improve the generation of dimensionally plausible AR assets. Finally, we are investigating more controllable and open model alternatives to enable stronger user control over key design attributes such as dimensions and color.

A ZERO-SHOT APPROACH TO DECOMPOSING GRAPHICAL RULES IN ACCESSIBILITY REGULATIONS

Yonghan Kim[1], Ghang Lee[1,2], and André Borrmann[2]
[1]Technical University of Munich, Munich, Germany
[2]Yonsei University, Seoul, South Korea

Abstract

Composite graphical rules hinder interpretation by multimodal large language models (MLLMs), and existing annotation-isolation methods require labeled training data. To address this, we propose a training-free approach using the Segment Anything Model 3 (SAM3) to automatically isolate annotations, remove cross-rule visual clutter, and reconstruct individual rules. Using manually decomposed rules as ground truth, we compared our method against prompt-based generative baselines. Results indicate that while baselines produce visually cleaner diagrams, MLLM-as-a-judge evaluations demonstrate our SAM3-based approach more reliably preserves the original regulatory semantics.

Introduction

Normative knowledge in regulatory documents appears in multiple forms, including natural language text, tables, illustrations, calculation methods, and commentaries (Amor and Dimyadi, 2021). Among these, illustrations play a critical role in conveying requirements that are difficult to express using text alone. In this work, we define illustrated provisions that explicitly encode declarative regulatory requirements as *graphical rules*.

However, graphical rules are often presented as composite diagrams that contain multiple regulatory requirements within a single illustration. Such composite representations can hinder rule interpretation, particularly when multimodal large language models (MLLMs) are used to analyze regulatory documents. Decomposing composite diagrams into atomic, rule-level units is therefore necessary for improving the interpretability and downstream usability of graphical regulatory knowledge.

Existing approaches, however, have important limitations. First, annotation-isolation methods typically rely on supervised learning with labeled datasets, which are costly and difficult to generalize to new regulatory domains (Zhang et al., 2023; Maupou et al., 2024). Second, prompt-based generative approaches can modify diagrams without a trained annotation-isolation model, relying instead on image regeneration, which may fail to preserve the original geometry and introduce semantic distortion (Wu et al., 2023).

To address these challenges, this paper proposes a zero-shot framework for decomposing composite graphical rules and pairing them with corresponding textual provisions. The proposed method leverages the zero-shot segmentation capability of SAM3 (Carion et al., 2025) to isolate annotation elements without labeled training data. These elements are grouped by spatial proximity, and a base image is reconstructed by removing annotations via inpainting. Each annotation group is then overlaid onto the base image to produce rule-level graphical units. Finally, the reconstructed graphical rules are paired with textual provisions using semantic similarity.

Related Works

LLM and MLLM for Rule Interpretation

Recent studies have explored the use of LLMs as reasoning engines for automated code compliance checking (ACC), enabling direct interpretation of regulatory text without explicit rule formalization (N. Chen et al., 2024; Ying and Sacks, 2024; Madireddy et al., 2025; Li, 2026; Iversen and Huang, 2026).

Extending this paradigm, recent work has investigated multimodal large language models (MLLMs) to incorporate graphical regulatory information alongside text (Kim et al., 2025). However, empirical findings show that MLLM performance degrades as visual complexity increases (Hou et al., 2025), particularly when multiple regulatory requirements are encoded within a single diagram.

This limitation is especially pronounced in tasks requiring precise spatial grounding. While MLLMs can often recognize numerical annotations, they frequently fail to associate them with the correct geometric entities or spatial context (Khan et al., 2025; Picard et al., 2025). These observations highlight the need for preprocessing strategies that reduce visual complexity and disentangle composite graphical rules prior to model interpretation.

Annotation isolation on a technical drawing

Annotation isolation aims to separate annotation elements (e.g., text, dimensions, symbols) from geometric content so that each component can be analyzed independently. Because regulatory semantics are primarily conveyed through annotations, this step is essential for interpreting graphical rules.

Early approaches relied on rule-based segmentation using drafting standards and geometric constraints (Dori and Velkovitch, 1998; Lin and Ting, 1997). While effective

under controlled conditions, these methods depend on strong assumptions about drawing regularity and are difficult to generalize across heterogeneous regulatory documents.

More recent approaches formulate annotation isolation as a supervised learning problem, using deep neural networks to detect and segment annotation elements (Zhang et al., 2023; Maupou et al., 2024). Although these methods improve robustness, they require large, labeled datasets and are therefore limited in scalability across domains.

Generative and Prompt-based Diagram Manipulation

Recent generative approaches enable selective modification of diagrams using natural language prompts (Jeong et al., 2025; Goswami et al., 2025; Yang et al., 2025). While these methods can simplify visual content, they rely on image regeneration rather than explicit decomposition. As a result, they may fail to preserve the original geometry and can introduce semantic distortions. This limitation is critical in regulatory contexts, where even minor visual changes may alter the intended meaning of a rule.

Positioning of This Work

In contrast to prior studies, this work focuses on the zero-shot decomposition of composite graphical rules in regulatory documents. Rather than introducing new algorithms, the contribution lies in framing graphical rule decomposition as a zero-shot problem, motivated by the high variability of regulatory drawings, which makes large-scale labeled training impractical.

Unlike annotation-isolation approaches that focus on segmenting individual elements, the proposed method reconstructs rule-level graphical units and pairs them with corresponding textual provisions. Furthermore, in contrast to generative diagram editing methods, it preserves the original diagram structure through decomposition rather than image synthesis.

By leveraging a general-purpose segmentation model without labeled training data, the method enables rule-level understanding while maintaining fidelity to the original illustration.

Proposed Method

The proposed method aims to decompose composite graphical rules into atomic rule-level graphical units and pair them with corresponding textual rules. To achieve this without labeled training data, the framework leverages the zero-shot segmentation capability of SAM3 (Carion et al., 2025), together with geometric and semantic post-processing steps.

As illustrated in Figure 2, the pipeline consists of four main stages. First, graphical and textual provisions are extracted from regulatory documents. Second, composite graphical rules are decomposed through zero-shot annotation segmentation. Third, textual provisions are decomposed into atomic rules. Finally, graphical and textual rules are paired based on semantic similarity.

Extraction of graphical rules and textual provisions

The input to the pipeline is a regulatory document in PDF format. Graphical rules and textual provisions are extracted using PyMuPDF (McKie, 2024), which provides structured access to page-level elements.

Graphical rules are identified by detecting raster images and vector graphics within PDF pages. Each detected graphical region is treated as a candidate composite graphical rule, and its bounding box and page index are preserved to maintain contextual consistency.

Textual provisions are extracted from the same pages and segmented at the paragraph level. To associate text with graphical rules, text blocks are filtered based on layout proximity, without relying on predefined templates or rule identifiers.

Graphical Rule Decomposition

Each composite graphical rule is processed independently to isolate annotation elements. Zero-shot annotation segmentation is performed using SAM3, guided by a fixed set of annotation-related prompts (e.g., arrows, dimension lines, and text labels).

To improve detection of small elements such as arrowheads and numeric annotations, Slicing Aided Hyper Inference (SAHI) (Akyon et al., 2022) is applied. SAM3 generates multiple candidate masks, which are filtered using geometric and visual heuristics (e.g., area, aspect ratio, and stroke density).

The extracted annotation elements are then grouped into rule-level units. Since individual regulatory requirements are typically represented by clusters of annotations, masks are grouped based on spatial proximity using distance-based clustering.A base image is constructed by removing annotation elements via image inpainting. A classical, non-learning-based inpainting method is used to preserve geometric

Textual rule decomposition

Textual provisions associated with a graphical rule often describe multiple regulatory requirements within a single paragraph. To align textual granularity with rule-level graphical units, each textual provision is decomposed into atomic textual rules using a two-stage, instruction-only prompt chaining strategy.

In the first stage, *requirement identification*, the language model is instructed to identify all independent regulatory requirements contained within the input provision. The system prompt explicitly guides the model to separate requirements based on distinct compliance conditions and to report the total number of identified requirements together with brief summaries. This stage focuses on structural decomposition, without modifying the original regulatory intent.

In the second stage, *rule normalization*, each identified requirement is reformulated into a standalone textual rule. The system prompt enforces normalization constraints, requiring that (1) each rule is understandable in isolation, (2) regulatory language using “shall” is consistently applied, (3) only one requirement is expressed per rule,

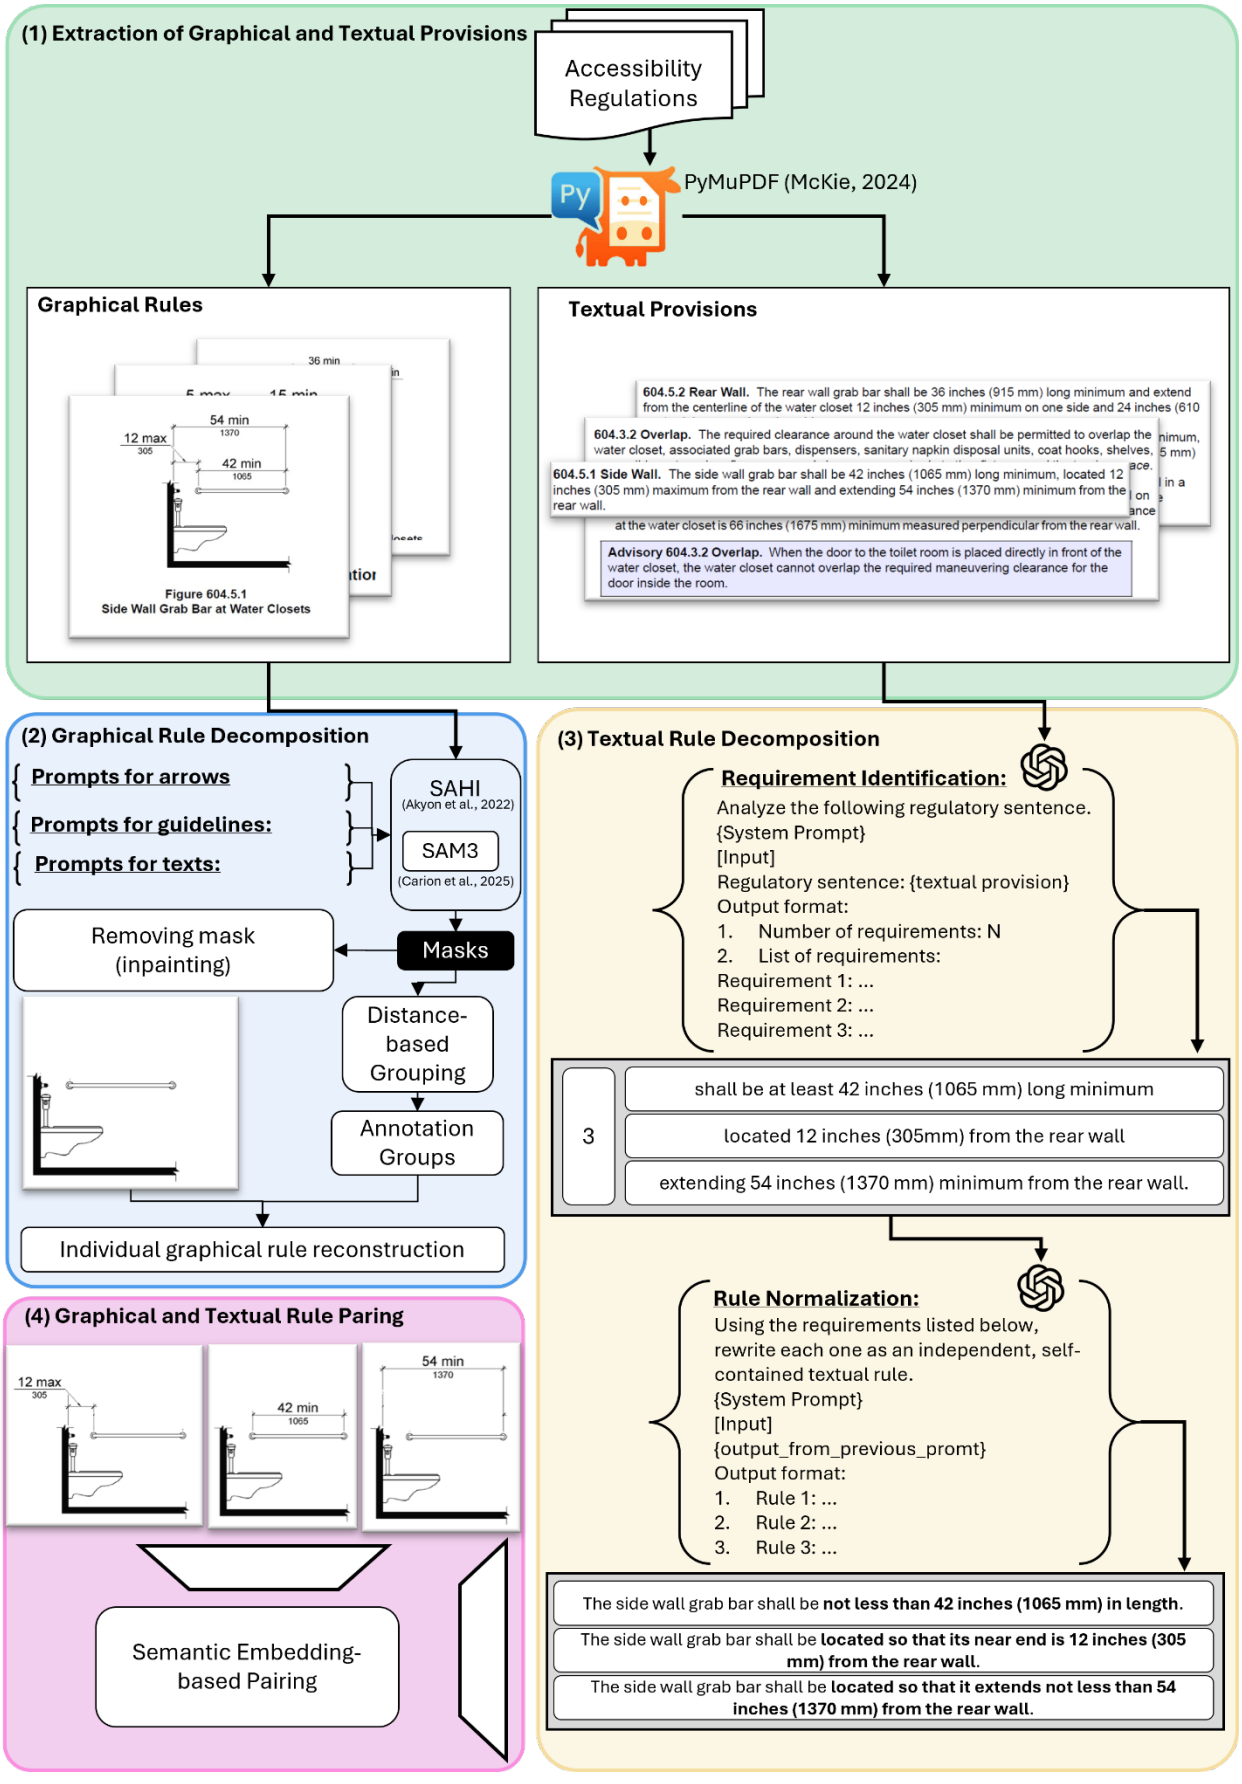

Figure 1: Overview of the proposed framework for graphical rule decomposition and pairing

and (4) all relevant measurement references and conditions are explicitly stated in a concise manner.

An instruction-only prompting strategy is adopted throughout both stages, without using any few-shot examples. The output of the requirement identification stage is provided as input to the rule normalization stage, enabling progressive refinement of the textual decomposition while preserving the original normative meaning.

Graphical and textual rule pairing

Finally, each reconstructed graphical rule is paired with its corresponding textual rule. To achieve this, semantic embeddings are computed using a pretrained CLIP model (ViT-B/32), which maps images and text into a shared embedding space.

Rule pairing is performed by maximizing cosine similarity between graphical and textual embeddings. The resulting graphical–textual rule pairs can be directly used for downstream interpretation by MLLMs.

Experimental design

The experimental evaluation focuses on assessing whether the proposed method correctly decomposes composite graphical rules into atomic, rule-level graphical rules that each correspond to a single regulatory requirement.

Based on the proposed method, this section describes the experimental design used to evaluate its effectiveness.

The evaluation is designed to assess two key aspects: (1) whether the decomposed diagrams represent a single regulatory requirement, and (2) whether they preserve the same regulatory meaning as the ground truth.

To this end, an MLLM-as-a-judge framework (D. Chen et al., 2024) is employed as the primary evaluation method. The framework is used to compare automatically decomposed graphical rules with manually decomposed ground-truth diagrams and to assess whether the predicted results preserve the intended regulatory meaning.

Ground truth generation

For each composite graphical rule, a set of ground-truth rule-level diagrams was manually generated using image editing software. Each ground-truth diagram isolates exactly one regulatory requirement by retaining only the annotation elements relevant to that requirement, together with the minimal graphical context necessary for interpretation.

In total, ground truth was constructed from 48 composite graphical rules, resulting in 134 individual graphical rules. The manual decomposition process was guided by the semantics of the corresponding textual provisions to ensure that each ground-truth diagram represents a single, independent regulatory rule without ambiguity or overlap.

These manually decomposed rule-level diagrams serve as the reference standard for evaluating the correctness of graphical rule decomposition.

Baseline definition

To contextualize the performance of the proposed method, a prompt-based annotation filtering baseline is employed. The baseline adopts a multi-step prompting strategy using a multimodal generative model to produce rule-specific diagrams by selectively suppressing irrelevant annotations in the original composite graphical rule.

First, the model is prompted to identify and enumerate the individual regulatory requirements encoded in the input composite diagram. These extracted requirements are organized into a structured list and serve as the basis for subsequent annotation filtering.

Next, for each identified regulatory requirement, the original composite diagram is provided again, and the model is instructed to remove all annotation elements that are unrelated to the target requirement, while preserving the original geometric drawing and the annotation elements corresponding to the selected rule. In this step, the model is explicitly guided to retain only the dimensional markers, symbols, and textual annotations necessary to convey the target regulatory requirement, and to suppress all others.

As a result, the baseline produces a set of rule-specific diagrams modified from the original image, each intended to express a single, self-contained regulatory requirement.

This baseline reflects recent prompt-driven approaches to diagram editing and controlled visual abstraction using generative multimodal models.

Evaluation metrics

The evaluation employs an MLLM-as-a-judge framework to assess rule-level semantic correctness.
For each decomposed graphical rule, the MLLM is first asked to determine whether the diagram represents exactly one regulatory requirement.
Next, the MLLM compares the automatically decomposed graphical rule with the manually decomposed ground-truth diagram and determines whether both convey the same regulatory requirement.

In addition to this semantic evaluation, we incorporate objective segmentation-level metrics to assess the quality of annotation isolation. Specifically, the mask-level intersection of union (IoU) is computed against manually annotated ground truth to quantitatively evaluate the accuracy of the extracted annotation elements.

Results and discussion

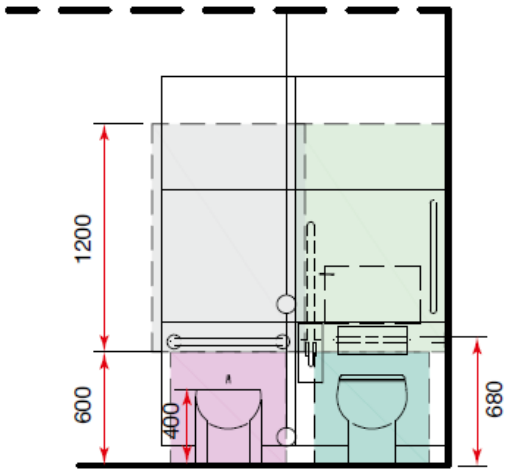
Experiment results

Table 1 summarizes the evaluation results obtained using the MLLM-as-a-judge framework.

Among the images generated by the proposed method, 84% were judged to contain exactly one regulatory requirement. In contrast, all images produced by the prompt-based baseline were classified as single-requirement diagrams. However, when comparing the regulatory semantics conveyed by each generated image with the manually decomposed ground truth, the proposed

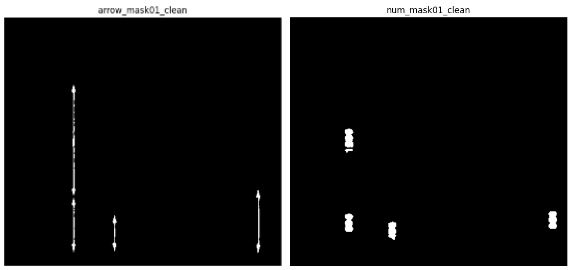
Table 1: Overall experiment results from MLLM-as-a-Judge

MLLM-as-a-Judge	Proposed Method	Baseline
Has a single requirement	84 %	100 %
Same as ground truth	82 %	78 %



method achieved a higher agreement rate, showing a modest improvement (+4%) compared to the baseline.

In addition to semantic evaluation, we further assessed the quality of annotation isolation using segmentation-level metrics. The proposed method achieved a mask-level IoU of 88%, highlighting that segmentation quality remains a key bottleneck, and further improvements are required to achieve more reliable rule-level decomposition.



Discussions

To provide a clearer understanding of how the proposed method operates, we first present an intermediate example illustrating the decomposition process.

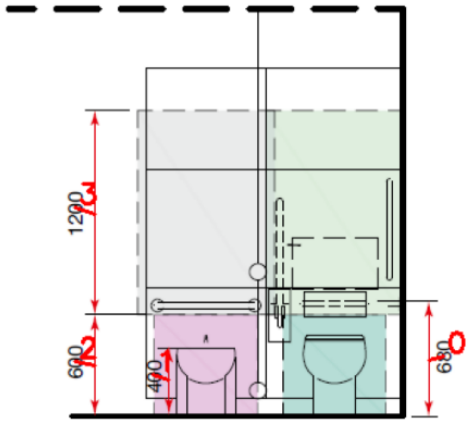


Figure 2 shows the intermediate results of the proposed pipeline, including annotation segmentation, clustering, and reconstruction.

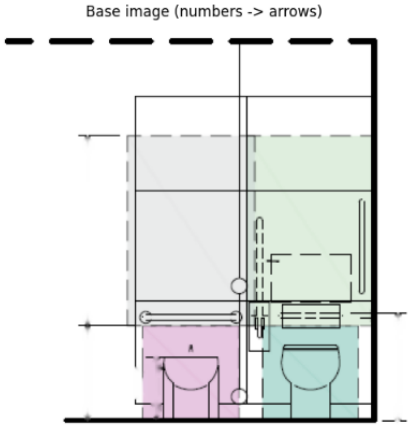
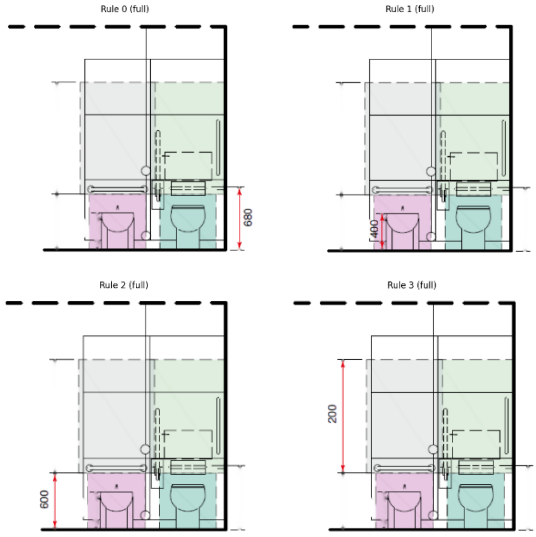
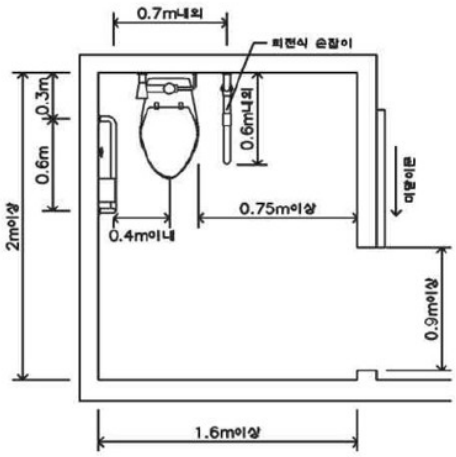


(a) Original composite graphical rule

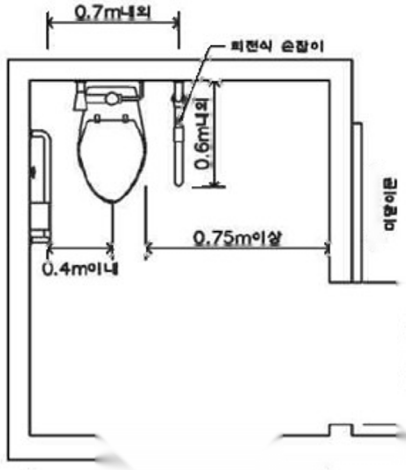


(b) Annotation segmentation results

(c) Grouping

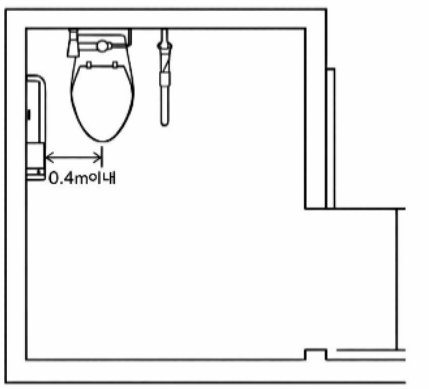


(d) Base image



(e) Rule decomposition results

Figure 2: Intermediate results of the proposed pipeline for graphical rule decomposition. (a) Original composite graphical rule. (b) Annotation segmentation results generated by SAM3. (c) Grouping of annotation elements into rule-level clusters based on spatial proximity. (d) Base image obtained by removing annotation elements through inpainting. (e) Final rule-level graphical unit reconstructed by overlaying clustered annotations onto the base image.



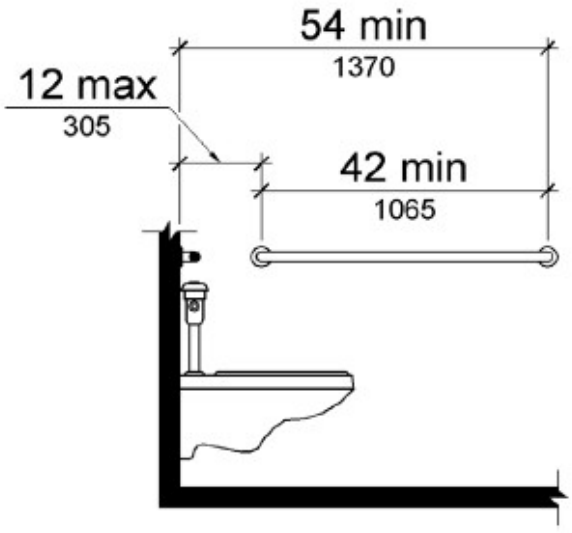
The experimental results indicate that the proposed method is less robust than the baseline in strictly decomposing composite diagrams into visually clean single-rule images. This limitation is particularly evident in challenging input cases, such as the example shown in Figure 3-(a), where failures occur during the annotation segmentation and grouping stages.

(a) A composite graphical rule for the decomposition

(b) A decomposition output from the proposed method

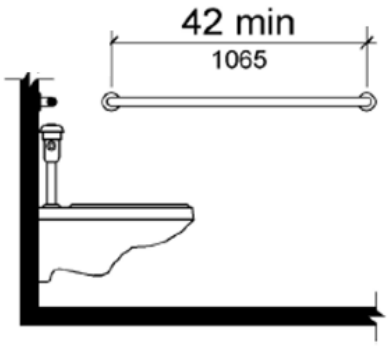
(c) A decomposition output from the baseline method

Figure 3: Example of a composite graphical rule (a) where the proposed method (b) fails to isolate single requirements, while the baseline succeeds in isolating single requirements and preserving the regulatory meaning.



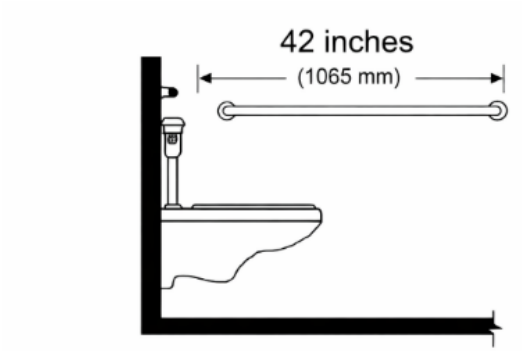
As shown in Figure 3, the baseline successfully isolates the regulation specifying that the spacing between the handrail and the toilet should be approximately 0.4 m, yielding a clear, self-contained graphical rule. In contrast, the diagram produced by the proposed method retains residual non-target graphical elements in the base drawing, indicating that unrelated annotations were not fully removed. Consequently, the resulting image does not form a fully isolated single graphical rule.

This failure mode is consistently observed in source images with low resolution or very small annotation elements, where reliable segmentation and grouping become particularly difficult.



Despite this limitation, the proposed method demonstrates a complementary strength in preserving the regulatory semantics of the original graphical rules, as shown in Figure 4, where prompt-based baselines result in semantic distortion.

The diagram generated by the proposed method preserves the essential spatial relationships and numerical constraints required to convey the target regulation, despite minor visual imperfections introduced during the annotation isolation process. In contrast, the baseline produces a visually clean but semantically incorrect diagram that conveys a substantially different regulatory interpretation from the ground truth.



This tendency is also supported by the “same as ground truth” metric in Table 1, where the proposed method achieves 82%, slightly outperforming the baseline (78%). Although the numerical improvement is modest, it indicates that the proposed method more reliably preserves the intended regulatory meaning.

(a) A composite graphical rule for the decomposition

(b) A decomposition output from the proposed method

(c) A decomposition output from the baseline method

Figure 4: Example of a composite graphical rule (a) where the baseline (c) fails to preserve the regulatory meaning, while the proposed method (b) maintains semantic consistency with the ground truth.

Taken together, these results reveal a clear trade-off between the two approaches. The baseline is more effective at producing visually clean, strictly isolated single-rule diagrams, whereas the proposed method is more reliable at preserving regulatory semantics by maintaining the original geometric structure.

This behavior can be attributed to the reliance of the baseline on generative image synthesis, which reconstructs the diagram from scratch. While this enables strong visual simplification, it also increases susceptibility to hallucinations and unintended misinterpretation of regulatory constraints, leading to semantic drift.

In contrast, the proposed method operates by decomposing and reconstructing the original diagram, which can compromise visual cleanliness in some cases but helps prevent semantic distortion.

Conclusions

This paper presented a zero-shot framework for decomposing composite graphical rules into atomic graphical rules and pairing them with corresponding textual rules. By leveraging text-prompt-guided zero-shot segmentation with SAM3, context-aware inpainting for faithful graphical reconstruction, and instruction-only prompt chaining for textual rule decomposition, the proposed method enables rule-level understanding of graphical regulations without requiring labeled training data.

Experimental results suggest that the proposed method exhibits a trade-off compared to prompt-based image generation approaches. While it is less robust in enforcing visually clean single-rule isolation, it tends to better preserve regulatory intent and semantic consistency with the ground truth.

The evaluation combines semantic assessment using an MLLM-as-a-judge framework with segmentation-level metrics (e.g., IoU), but remains limited in several aspects, including reliance on a single MLLM-based evaluation, the absence of human validation and inter-rater reliability analysis, and a relatively small dataset.

Future work will incorporate human expert evaluation, in which domain experts define ground-truth interpretations of graphical rules and assess whether the decomposed outputs correctly match these references. Such an evaluation will enable more reliable validation of the proposed method.

Moreover, the current study focuses on dimensional technical drawings in which regulatory requirements are primarily conveyed through distance-based annotations, specifically within accessibility regulations for disabled restroom facilities. While this scope reflects a common form of graphical regulation, the experimental validation remains limited to a single facility type. In particular, the present study does not yet account for variations in drawing configurations. Therefore, extending the framework to a wider range of facility conditions and drawing variations, as well as to other types of graphical rules, remains for future work.

SHARED EMBEDDING SPACES FOR AEC ONTOLOGIES: AN EMPIRICAL STUDY OF DISCOVERY AND ALIGNMENT

Tobias Heimig-Elschner[1,2], Jyrki Oraskari[2,3], and Jakob Beetz[2]

Abstract

The adoption of ontologies in the AEC domain is increasing, yet ontology reuse remains constrained because identifying suitable ontologies and concepts is still largely manual. This paper investigates whether shared embedding spaces can capture semantic relatedness across AEC ontologies, thereby supporting ontology discovery and alignment. We test three hypotheses regarding expert-aligned similarity, the spatial proximity of related classes and the superiority of structure-aware over purely lexical models. We embedded several widely used AEC ontologies and evaluated ontology and class-level similarities. Results suggest that embeddings operationalize expert intuition and lower barriers to ontology reuse.

Introduction

A significant obstacle to ontology reuse is how many ontologies are designed: they often lack adequate documentation and provide no human-readable specifications, thereby imposing unnecessary friction on anyone attempting to adopt or extend them (Fernández-López et al., 2019). Many built-environment ontologies have been created recently, but users find it difficult to locate suitable ones, which limits their practical application (Akbarieh et al., 2025). Identifying suitable ontologies and concepts is still largely manual.

We assume that ontologies and their constituent entities can be represented in a vector space such that semantic relatedness systematically correlates with geometric proximity. We explore hypotheses about how the embeddings of lexical ontology notations relate to expert assessments and known alignments. Specifically, we suggest that:

- **H1 (Ontology-level similarity correlates with expert recommendations).** If ontology embeddings capture domain structure, then similarity in the embedding space should align with expert judgments of task or domain suitability.
- **H2 (Semantically corresponding classes are closer than unrelated classes).** Useful ontology embeddings must preserve class-relatedness.
- **H3 (Context-enriched lexical representations improve embedding quality).** Ontologies provide structural context, such as class connectivity and local relations.

We evaluate our hypotheses by embedding a curated set of widely used AEC ontologies and their classes using both text-based (labels + descriptions) and graph-based (RDF/OWL) strategies. These embeddings are employed for similarity-based ontology search and class-level alignment suggestions. Expert-guided evaluations and quantitative analyses of the embedding space reveal how closely the embeddings reflect expert judgment and semantic structure, and demonstrate that they can streamline ontology engineering workflows by lowering barriers to ontology reuse and integration in construction informatics.

Our main contributions include: (i) an LLM embedding–based, ontology-level semantic search framework; (ii) a class-level alignment method using similarity neighborhoods for an ontology base; (iii) an expert-aligned evaluation approach for comparing and assessing embedding spaces and (iv) the validation and development of a foundational embedding hypothesis for AEC ontologies.

Related Work

Linked Open Vocabularies (LOV) is a curated registry of RDF vocabularies that shows how they link, tracks usage in the Linked Data cloud, and offers search, SPARQL, and API access to find and reuse vocabularies. Despite strong reuse of LOV's core vocabularies, domain-specific vocabularies remain underlinked within and across domains (Maratsi et al., 2023). More recently, Akbarieh et al. (2025) presented BE-OLS, a built-environment-specific ontology lookup service that catalogs and organizes over 100 ontologies in the building environment domain with structured metadata and search/filter functions. It provides a custom, domain-aware evaluation framework (connectivity, accessibility, and documentation/reuse). Current limitations include an incomplete ontology collection, manually applied evaluation, and no LLM-based assistance for ontology search and analysis.

LLM embeddings (Tao et al., 2024) used in semantic searches encode text as high-dimensional vectors that capture semantic meaning. Models like BERT or all-MiniLM-L6-v2 (Reimers and Gurevych, 2024) convert text into vector representations, ensuring that semantically similar content is aligned closely and facilitating comparison based on meaning rather than exact words.

Wang et al. (2015) presented a method for short text categorization that combines semantic clustering with convolutional neural networks (CNN). Although newer tech-

niques such as transformers and large language models (LLMs) now outperform this approach, it remains effective for lightweight applications. This method employs a small, supervised CNN operating on semantic matrices, in contrast to LLMs that produce embeddings via unsupervised transformer pretraining with attention mechanisms, which offer richer context but require more computational resources.

A more recent method, introduced by Khan et al. (2020), uses sentence-embedding-based clustering to summarize discussion threads. It leverages Word2Vec[1] to create sentence embeddings and applies K-medoids clustering—a partitioning technique that selects actual data points as cluster centers—to group replies that are semantically similar. A ranking mechanism based on quality-related textual features then determines the most relevant responses for the summary. This fully automatic, domain-independent approach performs well on precision, recall, and F-measure. However, its reliance on Word2Vec and traditional clustering may limit its ability to capture complex semantic nuances compared with more advanced models, such as large language models (LLMs).

Teymurova et al. (2024) introduced OWL2Vec4OA, a version of OWL2Vec* tailored for ontology alignment by integrating confidence-weighted seed mappings into the random-walk process. This makes the learned embeddings more alignment-aware and improves matching performance in experiments. Its main limitations are dependence on seed-mapping quality, added computational complexity, and sensitivity to hyperparameters.

Methodology

Problem Setting and Representation Framework

To make the decisions made in representation and evaluation explicit, we introduce the following formal setting:

Let an ontology artifact be denoted by O. Let $\mathcal{D} = \{O_1, \ldots, O_N\}$ denote the ontology dataset, i.e. a finite collection of ontology artifacts processed jointly.

For each ontology O we assume a materialized RDF graph:

$$\mathcal{G}_O = (V, E) \tag{1}$$

where V denotes the set of RDF nodes and E the set of triples with predicates P. A triple is written as $(s, p, o) \in E$ with $s, o \in V$ and $p \in P$. Based on this, let C_O be the set of classes declared in O (e.g., resources typed as `owl:Class` or `rdfs:Class`) and P_O be the set of properties declared in O (e.g., `owl:ObjectProperty`, `owl:DatatypeProperty`, `rdf:Property`).

We define the set of representable entities [2] at both dataset and ontology level:

$$\mathcal{X}_O := \{O\} \cup C_O \cup P_O \tag{2}$$

$$C_{\mathcal{D}} := \bigcup_{O \in \mathcal{D}} C_O, \quad P_{\mathcal{D}} := \bigcup_{O \in \mathcal{D}} P_O, \quad \mathcal{X}_{\mathcal{D}} := \bigcup_{O \in \mathcal{D}} \mathcal{X}_O. \tag{3}$$

The formalism for representation and embeddings is defined as follows: Let $\mathcal{T}$ be the space of textual representations (strings), $f : \mathcal{T} \to \mathbb{R}^d$ be an embedding function and $\mathrm{t}_m : \mathcal{X} \to \mathcal{T}$ be a representation variant m. The embedding of an entity $x \in \mathcal{X}$ under variant m is:

$$\mathrm{v}_x^{(m)} := f(\mathrm{t}_m(x)) \tag{4}$$

All embeddings of interest for a fixed representation variant m live in a shared dataset-level embedding space

$$\mathcal{E} := \mathcal{E}_m = \{\mathrm{v}_x^{(m)} \mid x \in \mathcal{X}_{\mathcal{D}}\}. \tag{5}$$

Let $\delta(\cdot, \cdot)$ denote cosine distance on $\mathcal{E}$.

For any entity $x \in \mathcal{X}$, define three optional lexical fields: $\ell(x)$ – label or title string (identifier-like), $d(x)$– description or definition string (content-like) and $c(x)$– comment or remark string (additional notes). Extraction is performed via documented, stable predicate lists (implementation detail), but the formalism assumes only that $\ell(x), d(x), c(x)$ are string-valued or empty.

Use-case descriptions U are treated as external textual queries embedded via the same function f, but are not elements of $\mathcal{X}_O$.

Throughout the remainder of this section, $\mathbb{E}[\cdot]$ denotes the empirical expectation with respect to the sampling procedure specified in each context. Unless stated otherwise, sampling is performed uniformly over dataset-level entities $x \in \mathcal{X}_{\mathcal{D}}$ (or over constrained subsets such as relation-defined pairs).

Definition of a Well-Formed Embedding Space

Based on the foundational hypothesis that: *There exists an embedding space in which semantic relatedness between ontologies and ontology entities is reflected by geometric proximity*. We define a set of geometric (*G1–G3* and semantic properties *S1 & S2* that suggest that such an embedding space is well-formed. The following criteria define necessary geometric and semantic properties that an embedding space must satisfy to be considered suitable for ontology discovery and alignment tasks. G1–G3 are treated as necessary but not sufficient conditions for semantic validity.

G1 – Global Discriminability

In high-dimensional spaces, distances tend to concentrate, making nearest-neighbor relations unreliable; measuring distance contrast provides a global diagnostic of whether the embedding space preserves discriminative power (Beyer et al., 1999; Aggarwal et al., 2001). A well-formed embedding space must exhibit sufficient distance contrast, such that semantic distinctions are not lost due to high-dimensional distance concentration. This is operationalized via a distance contrast measure introduced by Beyer et al. (1999):

[1] `https://code.google.com/archive/p/word2vec/`

[2] When the context is clear, we write $\mathcal{X}$ for $\mathcal{X}_{\mathcal{D}}$ (dataset-level entities) and use $\mathcal{X}_O$ when referring to a specific ontology.

$$D = \{\delta(\mathrm{v}_i, \mathrm{v}_j) \mid i \neq j\}. \tag{6}$$

$$RC_q = \frac{\mathbb{E}[D] - Q_5(D)}{Q_5(D)} \tag{7}$$

where δ ranges over all pairwise distances in $\mathcal{E}$, with i, j indexing embeddings corresponding to entities $x_i, x_j \in \mathcal{X}_\mathcal{D}$.

G2 – Local Semantic Coherence

Relative neighborhood statistics remain meaningful in high-dimensional spaces because they rely on comparative distances rather than absolute magnitudes (Beyer et al., 1999; Radovanović et al., 2009). They serve as a robust replacement for classical clusterability tests (e.g. Hopkins (Hopkins and Skellam, 1954)), which degrade in high dimensions (Adolfsson et al., 2019). A well-formed embedding space must exhibit locally coherent neighborhoods, such that nearby vectors are significantly closer than randomly chosen vectors. To capture local coherence robustly, we adopt *relative k-nearest-neighbor distance ratio*, which compares expected distances to k nearest neighbors (k-NN) against those drawn from random pairs, in the spirit of neighborhood preserving metrics used in embedding evaluation (Boggust et al., 2022).

$$\bar{\delta}_k(x) := \frac{1}{k} \sum_{x' \in k\text{-NN}(x)} \delta(\mathrm{v}_x, \mathrm{v}_{x'}) \tag{8}$$

$$R_k = \frac{\mathbb{E}[\bar{\delta}_k(x)]}{\mathbb{E}[\delta(\mathrm{v}_x, \mathrm{v}_{x'})]} \quad \text{with} \quad R_k \ll 1 \tag{9}$$

where k-NN(x) denotes the set of the k nearest neighbors of x in $\mathcal{E}$, (x, x') a uniformly sampled random pair of entities, and expectations are taken over uniformly sampled entities $x \in \mathcal{X}_\mathcal{D}$. The parameter k controls the neighborhood size.

G3 – Non-Degenerated Dimensionality

Effective dimensionality captures whether embeddings meaningfully occupy a structured manifold rather than degenerating into noise or redundancy (Recanatesi et al., 2022; Giaffar et al., 2024) which can be assessed via the *participation ratio (effective dimensionality)* as proposed by Recanatesi et al. (2022):

$$D_{\text{eff}} = \frac{(\sum_i \lambda_i)^2}{\sum_i \lambda_i^2} \tag{10}$$

where λ_i are the eigenvalues of the covariance matrix of the embedding vectors in $\mathcal{E}$.
Following this, a well-formed embedding space satisfies:

$$1 \ll D_{\text{eff}} \ll d \tag{11}$$

While G1–G3 assess geometric well-formedness independently of domain semantics, S1 and S2 evaluate whether the embedding space aligns with ontological meaning and expert judgment.

S1 – Ontology-Aware Semantic Alignment

An intrinsic characteristic of ontologies is the explicit declaration of semantic relations between classes (intra- and inter-ontology), such as equivalence mappings, subsumption, and domain-specific predicates. A meaningful embedding space should preserve these relations, embedding semantically related classes closer together than unrelated ones. Intrinsic evaluation frameworks for ontology embeddings therefore emphasize explicit measurement of relational preservation (Alshargi et al., 2019).
Formally, let $\mathcal{R}$ denote the set of declared semantic relations between classes in the ontology dataset $\mathcal{D}$:

$$\mathcal{R} := \bigcup_{O \in \mathcal{D}} \mathcal{R}_O \cup \mathcal{R}_{\text{cross}}, \quad \mathcal{R} \subseteq C_\mathcal{D} \times C_\mathcal{D} \tag{12}$$

where $\mathcal{R}_O$ contains intra-ontology class pairs and $\mathcal{R}_{\text{cross}}$ inter-ontology class pairs. Class pairs $(i, j) \in C_\mathcal{D} \times C_\mathcal{D}$ are induced by predicate assertions (i, p, j) or (j, p, i). No logical inference or reasoning closure is applied. Let the binary semantic relatedness indicator $s_{ij} \in \{0, 1\}$ be

$$s_{ij} := \begin{cases} 1 & \text{if } (i, j) \in \mathcal{R}, \\ 0 & \text{otherwise.} \end{cases} \tag{13}$$

Define the sets of *related* and *unrelated* class pairs:

$$P_{\text{rel}} = \{(i, j) \mid s_{ij} = 1\}, \quad P_{\text{unrel}} = \{(i, j) \mid s_{ij} = 0\} \tag{14}$$

Pairs in P_{unrel} are uniformly sampled such that $|P_{\text{rel}}| = |P_{\text{unrel}}|$. Let $d_{ij} := \delta(\mathrm{v}_i, \mathrm{v}_j)$.
A well-formed embedding space satisfies

$$\mathbb{E}_{(i,j) \in P_{\text{rel}}}[d_{ij}] \; < \; \mathbb{E}_{(i,j) \in P_{\text{unrel}}}[d_{ij}]. \tag{15}$$

We further define the alignment ratio

$$R_{\text{align}} := \frac{\mathbb{E}_{(i,j) \in P_{\text{unrel}}}[d_{ij}]}{\mathbb{E}_{(i,j) \in P_{\text{rel}}}[d_{ij}]} \tag{16}$$

$R_{\text{align}} > 1$ indicates ontology-aware semantic alignment. Statistical significance is assessed via a stratified class-identity permutation test ($K = 1000$), where class identities are shuffled within ontology strata while distances are held fixed. The empirical one-sided p-value $P(\rho_{\text{null}} \geq \rho_{\text{obs}} \mid H_0)$ is computed from the resulting null distribution of Spearman $\rho(-d_{ij}, s_{ij})$.

S2 – External Semantic Consistency

While S1 evaluates semantic alignment intrinsic to the ontology structure, external semantic consistency assesses whether embedding-based similarity aligns with expert intuition in practical ontology selection scenarios. If an embedding space is well-formed, ontologies deemed relevant by domain experts for a given use case should appear among the most similar ontologies according to embedding-based rankings. Ontology-level similarity is computed using lexical and context-enriched lexical representations. Ontology embeddings are obtained directly from the corresponding textual representations.

Let U denote a use-case description and O the set of candidate ontologies. Let $E_U \subseteq O$ denote the set of ontologies identified as relevant by domain experts for use case U, allowing multiple ontologies to be considered equally relevant.

Let $r_{\text{embed}}(U) = (o_1, o_2, \dots)$ be the ontology ranking induced by embedding similarity between U and ontology representations, where $o_i \in O$. Define the set of top-k retrieved ontologies using precision-at-k and recall-at-k using the top-k set $R_k(U) := \text{TopK}(r_{\text{embed}}(U), k)$:

$$P_k(U) = \frac{1}{k} \sum_{o \in R_k(U)} 1[\, o \in E_U \,], \tag{17}$$

$$R_k(U) = \frac{1}{|E_U|} \sum_{o \in R_k(U)} 1[\, o \in E_U \,]. \tag{18}$$

Here, Precision@k measures the proportion of relevant ontologies among the top-k retrieved results, while Recall@k measures the proportion of all expert-relevant ontologies retrieved within the top-k. Since expert relevance sets may contain fewer than k ontologies, the maximum achievable precision is bounded by $|E_U|/k$, while recall remains unaffected.

To assess whether retrieval performance exceeds chance, observed $P_k(U)$ values are compared against a random baseline. Under random selection, the number of relevant ontologies among the top-k follows a hypergeometric distribution, with expected precision $\mathbb{E}[P_k(U)] = |E_U|/|O|$. A well-formed embedding space exhibits consistently high precision and recall values across use cases, indicating that expert-relevant ontologies are ranked among the most similar results, and achieves precision values that systematically exceed the corresponding random baseline, reflecting performance beyond chance.

Ontology Representations and Embeddings

In this paper, we define and evaluate two complementary lexical representations for ontologies O and their associated classes C_O. These representations rely solely on human-readable lexical information such as labels, descriptions, and comments, or enrich this information with bounded contextual signals derived from related entities. In addition, we include a purely structural RDF2Vec-based representation - as introduced by Ristoski and Paulheim (2016) - as an established baseline focusing on graph structure, used for comparative evaluation under criteria *G1–G3* and *S1*.

Lexical embedding v_{lex}

The *lexical representation* variant t_{lex} captures only the immediate human-readable lexical documentation attached to an entity, without incorporating any explicit structural context. For any $x \in \mathcal{X}$:

$$t_{\text{lex}}(x) := \text{concatFields}\big(\ell(x),\ d(x),\ c(x)\big) \tag{19}$$

Here, $\text{concatFields}(\cdot)$ denotes deterministic concatenation with a fixed ordering and separators.

The representation t_{lex} is deterministic, structure-independent, and fully interpretable. It serves as the lexical baseline for evaluating embedding quality and semantic alignment.

$$v_{\text{lex}}(x) = f(t_{\text{lex}}(x)) \text{ for all } x \in \mathcal{X} \tag{20}$$

Context-Enriched Lexical embedding v_{conlex}

The *context-enriched lexical representation* variant t_{conlex} extends t_{lex} by incorporating bounded and deterministic lexical context derived from related entities, while remaining text-based. For an ontology O, let $\bigoplus$ denote deterministic aggregation (concatenation) with a fixed ordering:

$$t_{\text{conlex}}(O) := \text{concatFields}\Big(t_{\text{lex}}(O),\ \bigoplus_{c \in C'_O} t_{\text{lex}}(c)\Big) \tag{21}$$

where $C'_O \subseteq C_O$ is a fixed, deterministic subset of representative classes. In this work, classes are ranked by first-order connectivity (number of RDF edges), with ties resolved by alphabetical ordering of IRIs. The top $\min(50, |C_O|)$ classes are selected.

For a class $c \in C_O$:

$$t_{\text{conlex}}(c) := \text{concatFields}\Big(t_{\text{lex}}(c),\ \bigoplus_{p \in P_c^{(n)}} t_{\text{lex}}(p)\Big) \tag{22}$$

where $P_c^{(n)} \subseteq P_O$ denotes properties connected to c within RDF graph depth n under a fixed neighborhood policy; depth $n = 1$ is used by default.

The representation t_{conlex} remains deterministic and human-interpretable, while introducing controlled local contextual signal in a reproducible manner.

$$v_{\text{conlex}}(x) = f(t_{\text{conlex}}(x)) \text{ for all } x \in \mathcal{X} \tag{23}$$

Structural Embedding v_{struct}

In addition to the lexical representation variants, we include a purely structural embedding baseline based on RDF2Vec. In contrast to v_{lex} and v_{conlex}, which follow the mapping $v_x^{(\bullet)} = f(t_\bullet(x))$, the structural variant directly induces embeddings from RDF graph structure. Formally, v_{struct} is defined only for class-level entities $c \in C_{\mathcal{D}}$, yielding embeddings $\mathrm{v}_c^{(\text{struct})} \in \mathbb{R}^d$. Ontology-level embeddings are derived via aggregation over class-level embeddings:

$$\mathrm{v}_O^{(\text{struct})} := \frac{1}{|C_O|} \sum_{c \in C_O} \mathrm{v}_c^{(\text{struct})}. \tag{24}$$

The resulting embeddings capture global structural patterns of the RDF graph, are stochastic but reproducible under fixed seeds, and are not directly human-interpretable.

Results

Implementation and Dataset

Implementation

The methodology was instantiated as a modular processing pipeline with separated responsibilities for identity management, semantic storage, and representation. Ontology identity and provenance are maintained via a JSON-based registry. Resolved ontology serializations are loaded into an Apache Jena Fuseki triple store[3], which serves as the authoritative semantic state and supports SPARQL-based querying. Normalized ontology artifacts and intermediate results are persisted as file-based materializations to ensure reproducibility. Vector representations derived from textual and graph-based encodings are stored separately in a Weaviate vector database, allowing symbolic semantic data and learned embeddings to be managed independently while remaining linked through stable ontology identifiers. Vector representations are derived from both textual and graph-based encodings. Textual embeddings are computed using the transformer-based model `snowflake-arctic-embed2` (1024 dimensions), selected as a representative open-weight model for semantic similarity tasks Yu et al. (2024). Structural embeddings are generated using RDF2Vec (100 dimensions) with random walks (depth $d = 4$, 100 walks per entity) and a Word2Vec backend, consistent with commonly used configurations in prior RDF2Vec studies. Traversal excludes high-degree hub predicates (e.g., `rdf:type`) to reduce structural noise Ristoski and Paulheim (2016). Full embedding configurations are provided in the appendix [4] .

Dataset

From the 144 ontologies listed in the Built Environment Ontology Lookup Service (BE-OLS) (Akbarieh et al., 2025), 101 ontologies provided a reachable reference or download URL. Of these, 100 could be successfully resolved and parsed. Two ontologies were fully contained as subgraphs of others already included and were therefore not treated as independent artifacts. The resulting dataset comprises 98 distinct ontologies.

To characterize the availability of lexical information, ontologies were classified as **meta** (no class definitions), **formal** (classes without lexical signals, i.e., only blank nodes or unlabeled IRIs), **structural** (fewer than 25% of classes provide at least one lexical signal (e.g., `rdfs:label`, `skos:prefLabel`, `rdfs:comment`, `dc:description`)), or **lexical** (at least 25% of classes provide lexical information). In addition, we assessed whether available lexical information follows common, human-readable documentation patterns suitable for downstream processing by large language models.

For inclusion in the vectorization experiments, ontologies were required to provide ontology-level lexical information, a resolvable serialization (i.e., not metadata-only), and a lexical profile classified as either structural or lexical. Applying these criteria yields a final subset of 84 ontologies, comprising 7,086 classes.

Evaluation of the Embedding Space

This section reports the results for three global well-formedness criteria (G1–G3) introduced above. All evaluations are reported for ontology-level and class-level embeddings and for all three representation variants (Lex, ConLex, Struct).

G1 – Global Discriminability

G1 evaluates global discriminability by measuring distance contrast across the embedding space. All representations satisfy this criterion at both the ontology and class levels, indicating that none of the embedding spaces suffers from distance concentration effects. Structural embeddings exhibit the highest contrast, reflecting the sparse and the role-oriented nature of graph-based representations, while lexical and contextualized lexical embeddings show moderate but stable contrast characteristic of dense language-model spaces. The consistency of G1 across granularities confirms that subsequent local semantic analyses are not confounded by degenerate global geometry. (see Table 1)

Table 1: G1 – Global discriminability (distance contrast).

Level	v_{lex}	v_{conlex}	v_{struct}
O	0.71 ✓	0.55 ✓	2.18 ✓
C_O	0.64 ✓	0.66 ✓	2.22 ✓

G2 – Local Semantic Correspondence ($\tau = 0.5$)

Table 2: G2 – Local semantic correspondence for $k = 10$.

Level	v_{lex}	v_{conlex}	v_{struct}
O	0.68 ×	0.73 ×	0.55 ×
C_O	0.42 ✓	0.43 ✓	0.06 ✓

G2 reveals a clear granularity effect (see Table 2). While none of the representations satisfy the criterion at the ontology level, all representations consistently meet G2 at the class level. This indicates that semantic correspondence is preserved locally between individual ontology entities, but not necessarily when embeddings aggregate heterogeneous concepts at the ontology scale. Rather than indicating a deficiency, this result confirms that class-level embeddings are the appropriate resolution for evaluating fine-grained semantic relatedness, whereas ontology-level embeddings primarily capture broader thematic or structural similarity.

G3 – Non-Degenerated Dimensionality

G3 evaluates whether embedding spaces exhibit non-degenerate effective dimensionality (see Table 3). All representations pass this criterion at both the ontology and class levels, with effective dimensionalities substantially

[3] `https://jena.apache.org/documentation/fuseki2/`

[4] The appendix is provided online at `https://git-ce.rwth-aachen.de/Tobias1/ec3-2026-shared-embedding-spaces-for-aec-ontologies/-/tree/v1.0-ec3-paper-2026`.

greater than one and far below the nominal embedding dimension. Lexical and contextualized lexical embeddings occupy a relatively low- dimensional subspace of the original 1024-dimensional space, reflecting semantic compression through aggregation, while structural embeddings exhibit even more compact but information-dense representations. The increase in effective dimensionality from ontology to the class level aligns with higher semantic granularity and complements the G2 findings.

Table 3: G3 – Effective dimensionality of embedding spaces.

Level	v_{lex}	v_{conlex}	v_{struct}
O	25.58 ✓	36.30 ✓	16.82 ✓
C_O	59.47 ✓	65.26 ✓	13.20 ✓

S1 – Ontology-Aware Semantic Alignment

All representations achieve statistically significant alignment ($R_{\text{align}} > 1$, $p < 10^{-3}$), with semantically related pairs consistently closer than unrelated ones. Lexical and context-enriched representations show moderate alignment ($R_{\text{align}} \approx 1.55$), while the structural embedding yields substantially stronger separation ($R_{\text{align}} = 2.94$), indicating that graph-based context reinforces semantic correspondence. The observed rank correlations ($\rho \approx 0.56$–0.60) confirm robust but non-trivial alignment between embedding distances and relatedness (see Table 4).

Table 4: S1 - Ontology-Aware Semantic Alignment Evaluation.

Metric	v_{lex}	v_{conlex}	v_{struct}
R_{align}	1.56	1.55	2.94
Spearman ρ	0.58	0.56	0.60
p_{perm}	$< 10^{-3}$	$< 10^{-3}$	$< 10^{-3}$
$\mu_{\rho,\text{null}}$	0.08	0.06	0.05
Significance	✓	✓	✓

S2 - External Semantic Consistency

Across the five evaluated use cases, both lexical and contextualized lexical representations achieve precision@5 values above the random baseline, indicating that embedding-based retrieval captures some degree of expert-relevant signal. However, absolute performance remains low (P@5 ≈ 0.24–0.28), and no statistically significant results are observed across use cases. Lexical representations exhibit higher recall, while contextualized lexical representations achieve slightly higher precision (see Table 5), suggesting a trade-off between coverage and selectivity. Nevertheless, the overall performance indicates that ontology-level embeddings alone are insufficient to reliably reproduce expert ontology selection behavior under the tested conditions.

In contrast to S1, which evaluates intrinsic semantic alignment at the class level, S2 operates on highly aggregated ontology representations and sparse, non-ranked expert feedback, resulting in reduced discriminative power. Consequently, S2 does not provide confirmatory evidence for external semantic consistency in this setting.

Table 5: S2 – External semantic consistency (P@5 and R@5).

Metric	v_{lex}	v_{conlex}
Mean P@5	0.24	0.28
Mean R@5	0.30	0.15
Baseline $E[P@5]$	0.11	0.11
Baseline $E[R@5]$	0.07	0.07
$\Delta P@5$	0.13	0.17
$\Delta R@5$	0.23	0.08
Significant	0/5	0/5

Discussion

We investigated whether shared embedding spaces facilitate ontology discovery and alignment in the AEC domain (hypotheses H1–H3). All embedding variants met the geometric well-formedness criteria G1–G3, confirming stable, non-degenerate spaces. Semantic alignment at the class level (S1) was consistently observed across lexical, context-enriched lexical, and structural representations. In contrast, ontology-level semantic consistency (S2) yielded weak but above-random results, insufficient for reliable ontology selection. Thus, embedding-based similarity is valid primarily at the class-level abstraction, supporting the core hypothesis that semantic relatedness in ontologies is reflected by geometric proximity, while highlighting the abstraction levels where this relationship holds reliably.

With respect to H1, which hypothesizes that ontology-level embedding similarity correlates with expert recommendations, the results do not provide confirmatory evidence under the current evaluation setup. A primary limiting factor is the statistical underpowering of S2: unlike S1, which operates over thousands of class-level relation pairs, S2 relies on a small number of use cases and sparse, largely unranked expert relevance judgments. Combined with the strong aggregation inherent in ontology-level embeddings, this substantially reduces the sensitivity of retrieval-based evaluation measures such as precision@k and recall@k. Consequently, H1 cannot be rejected outright, but remains unconfirmed within the scope of this study and should be revisited using larger and more structured expert evaluations.

Beyond methodological considerations, the inconclusive results for H1 highlight a fundamental issue affecting ontology reuse. Ontology-level embeddings, derived solely from explicit information like labels, descriptions, and structure, fail to replicate expert selection behavior. This suggests that many ontologies lack sufficient information for reuse decisions, as experts also consider contextual factors like maturity, adoption, tooling, conventions, and experience—not encoded in standard documentation. This deficiency indicates broader communication issues within ontology ecosystems, echoing barriers caused by inadequate documentation. Additionally, S2 results imply that expert selection depends more on high-level lexical descriptions of scope and application than on detailed internal content, which is mainly reflected in class structure and relations.

The results strongly support H2, showing that semantic classes are embedded closer together when related, across all variants, and confirming that embedding spaces preserve fine-grained semantic relations within and across ontologies. This demonstrates their suitability for class alignment, correspondence discovery, and semantic exploration. The evaluation focuses on explicitly declared relations, isolating the effect of representation learning from reasoning variability. Including inferred relations could further improve semantic alignment by revealing implicit structures, highlighting the potential of knowledge graphs. The consistent results across different representations suggest that class-level semantic relatedness is a stable property of the embedding space, largely independent of the representation used.

The results support H3, which suggests that adding structural context improves embedding quality. Context-enriched lexical representations achieve results comparable to purely lexical ones in semantic alignment while remaining deterministic and interpretable, indicating that additional contextual aggregation does not consistently translate into improved alignment. Structural RDF2Vec embeddings have the highest alignment ratios, showing the importance of graph structure in maintaining ontological relations. Interestingly, large language model–based lexical embeddings already meet all geometric criteria (G1–G3) and achieve strong semantic alignment (S1), even though they weren't trained specifically for ontology embedding. This suggests that modern language models encode substantial latent domain knowledge, allowing them to recover meaningful semantic structures from sparse, diverse ontology data.

Taken together, these findings clarify the appropriate role of embedding-based methods in ontology engineering workflows. Embeddings should not be viewed as replacements for expert judgment at the ontology selection level (H1), but as powerful instruments for semantic exploration and alignment at the class level (H2), particularly when enriched with bounded structural context (H3). The context depth is intentionally limited to one hop ($n = 1$), focusing on directly related classes and properties while avoiding noise propagation and cyclic dependencies in graph traversal. Exploring deeper contextual representations may further enrich semantic signals, but introduces increased structural variance and is left for future work. By making explicit where semantic information is preserved and where it is absent, embedding-based representations both support ontology reuse and expose documentation gaps that warrant further attention.

Conclusion

This paper explored whether embedding-based representations can support ontology discovery and alignment in the AEC domain. Across all evaluated representations, the geometric well-formedness criteria (G1–G3) are satisfied, indicating that the resulting embedding spaces are stable and suitable for semantic analysis. At the class level, ontology-aware semantic alignment (S1) is consistently observed: semantically related classes are embedded closer together than unrelated ones, independent of representation choice. This confirms that embeddings preserve fine-grained semantic relationswithin and across ontologies and are well suited for class-level exploration and alignment tasks. These results further provide empirical support for the foundational hypothesis that semantic relatedness between ontology entities can, to a meaningful extent, be reflected by geometric proximity in a shared embedding space.

A key empirical finding is that LLM-based lexical embeddings perform surprisingly well in this setting, despite not being trained on ontologies or formal knowledge graphs. Even without explicit access to ontological structure, these embeddings satisfy all geometric criteria and exhibit statistically significant semantic alignment. While context-enriched lexical representations do not yield a significant improvement, incorporating structural information enhances alignment performance. Purely structural embeddings achieve the strongest alignment effects, albeit at the cost of interpretability.

At the ontology level, external semantic consistency with expert recommendations (S2) remains inconclusive. This result reflects both methodological limitations—strong aggregation and sparse expert feedback—and fundamental constraints on ontology reuse, where expert selection relies on contextual factors not explicitly encoded in ontology artifacts. Overall, the results support embeddings as a reliable semantic substrate for exploration and alignment at appropriate levels of abstraction, while clarifying their limitations for ontology-level decision-making.

Future Work

Future work should extend this study along three complementary directions. First, external semantic consistency (S2) should be evaluated using more mature and statistically robust designs, including a larger set of use cases, ranked or graded expert judgments, and repeated evaluations across expert groups. Such designs would enable stronger conclusions about ontology-level similarity and better isolate the factors influencing expert ontology selection. Second, the role of embeddings in concrete alignment tasks warrants systematic investigation. This includes evaluating their utility for candidate correspondence generation, semi-automated class alignment, and expert-in-the-loop alignment workflows, where embeddings serve as a semantic prior rather than a definitive decision mechanism. Third, embedding-based representations open the door to two-dimensional semantic mappings of the AEC ontology ecosystem. Future research should examine the stability, interpretability, and analytical value of such maps for ecosystem-level exploration, comparison, and gap analysis. Together, these directions would further clarify the scope and limits of embedding-based methods and support their principled integration into ontology engineering practice without overextending their claims.

Abstract

Fire safety compliance checks in existing buildings are often labor-intensive and prone to error, due to the lack of design data and the reliance on traditional inspection tools. This work proposes an alternative to conventional approaches through a semi-automated Scan-to-BIM methodology to create a BIM model directly from point cloud data. The methodology demonstrates robustness when applied to benchmark datasets. The results confirm the efficiency and accuracy of the methodology in developing early design and BIM models suited to support fire safety engineering and verification of compliance with fire safety regulations.

Introduction

According to the Portuguese National Emergency and Civil Protection Authority (ANEPC – Autoridade Nacionalk de Emergência e Proteção Civil) (Civil, 2024), 6,844 urban fires were confirmed, 603 of which occurred in unoccupied buildings of Portugal. Most of these buildings tend to be old and generally lack digital or even digitized geometrical information. These constraints create significant difficulties on the development of retrofitting projects, as building characteristics are typically obtained using traditional/manual methods that require excessive human intervention. One possible solution to overcome this challenge is the use of remote sensing methods, which enable the creation of point cloud data for generating *as is* geometric information (Oliveira et al., 2023, Ventura et al., 2026). For many building types, e.g. residential, office, or hotel, laser scanning is the standard, as it can accurately capture detailed reality with accurate dimensions in relatively straightforward field campaigns. The obtained raw data is the input for digital models' generation that can be further enriched to create BIM models and digital twins.

Fire safety is a critical aspect of building management, encompassing a comprehensive set of measures aimed at preventing and controlling fires Schönfelder et al. (2024). Among these measures, this work focuses on fire compartmentation requirements, in which a building is subdivided into compartments to isolated occupants and/or confine fire spread, thereby enhancing occupant safety. To address this issue, the present study proposes a semi-automated Scan-to-BIM methodology for generating BIM models promoting the implementation and assessment of fire compartmentation.

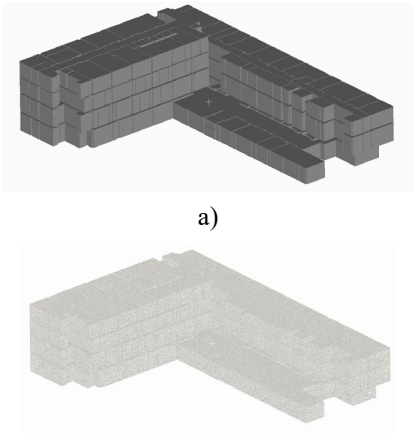
The Scan-to-BIM approach has become a prominent research topic in recent years. The scientific community has proposed several methods and alternatives to automate this process, though several approaches are still semi-automated and need manual intervention to identify structural elements (Zbirovský and Nežerka, 2025). The key step of this methodology is the contour extraction process. The point cloud contour extraction of a building seeks to obtain a clear description of the building's geometry, including aspects like shape, size, spatial positioning and internal layout. The existing building point cloud contour extraction methods mainly include image-based methods, geometric feature-based methods, and surface segmentation-based methods (Chen et al., 2025). Image-based methods consist of converting point cloud data into images for processing (Gao et al., 2024, Zbirovský and Nežerka, 2025). Geometric feature-based methods rely on extracting planes and line segments (Wang et al., 2022, Li et al., 2023), where the Random Sample Consensus (RANSAC) algorithm is the most used option for this end. Surface segmentation-based methods can be done by traditional point cloud segmentation strategies (edge detection, graph theory, clustering, hypervoxel) and Artificial Intelligence (AI) techniques (Chen et al., 2026, Mehranfar et al., 2024).

The transition toward full BIM adoption begins with the conversion of these models into the Industry Foundation Classes (IFC) standard, where building elements are explicitly classified into semantic entities and can be further enriched with structured parameters and properties. Zbirovský and Nežerka (2025) developed an open-source Scan-to-BIM tool, named Cloud2BIM, that automates the conversion of large-scale point clouds into BIM models in the IFC format. More recently, Chen et al. (2026) developed a framework that combines deep learning-based semantic segmentation with unsupervised clustering to generate models in IFC from point cloud data. This step is particularly relevant in the fire-safety domain, where Scan-to-BIM workflows are often limited to geometric reconstruction. Converting reconstructed models into IFC enables fire-safety engineers to

systematically augment *as is* models with domain-specific information, such as the fire resistance classes of construction elements and the fire reaction classes of linings the fire reaction classes of linings, supporting analysis, compliance verification, and decision-making processes.

Based on these findings and considering the diversity of building typologies, the automated generation of BIM models from existing buildings continues to be a prominent research topic and remains a challenging task. Moreover, point cloud data acquisition in buildings that are still in service often results in increased noise levels and incomplete geometric information, which can adversely affect the robustness of Scan-to-BIM frameworks. In the fire safety domain, the availability of BIM models for existing buildings can significantly enhance fire safety analyses, particularly in the assessment of compartmentation, where retrofit interventions may alter the original geometric layout.

The present work proposes a semi-automated Scan-to-BIM approach suitable for retrofit projects. The resulting digital models provide a semantic volumetric representation of the building structure at schematic design level, corresponding to a Level of Development (LOD) 200 (American Institute of Architects and buildingSMART International), and are intended to support decision-making processes related to fire compartmentation requirements. The conversion of point cloud data into BIM is evaluated using the IFC format, with a specific focus on the entities IFCSpace, IFCWall, and IFCSlab.



Proposed Methodology

The methodology is structured by four main steps, as shown on Figure 1. The step-by-step explanation will be illustrated by its implementation on a synthetic dataset composed of a part of Vilnius Gediminas Technical University (VILNIUS TECH). This data is characterized as an early design BIM model similar to indoor point clouds of empty buildings. The development was based on Python algorithms and applicable to multi-level Manhattan-world structures (Mehranfar et al., 2024).

Point cloud acquisition and registration

Point cloud acquisition and registration is characterized by transferring information from the real world into an available digital format. Terrestrial laser scanning (TLS) is typically the most suitable method for acquiring indoor point clouds. Normally, this procedure is performed in the proprietary software of the scanner brand used.

In the case of synthetic data, acquisition is performed through mesh disassociation, where a 3D model is converted into a point cloud based on a specified point density or number of points. Figure 2 presents the case study that supports the results of the application of the proposed framework.

a)

b)

Figure 2. VILNIUS TECH: a) Early design BIM model; b) point cloud.

Point cloud processing

Point cloud processing begins with a global reorientation of the dataset based on the clustering of estimated surface normal vectors. Surface normals were computed using a KD-tree–based hybrid neighborhood search, combining k-nearest neighbor (KNN) and radius-based criteria. Subsequently, the estimated absolute normal vectors were grouped using the k-means clustering algorithm.

The resulting clusters represent dominant surface orientations within the point cloud and are used to infer a consistent global orientation of the dataset. This procedure guarantees that the point cloud is centered and aligned with the orthogonal axis, which prevents aleatory

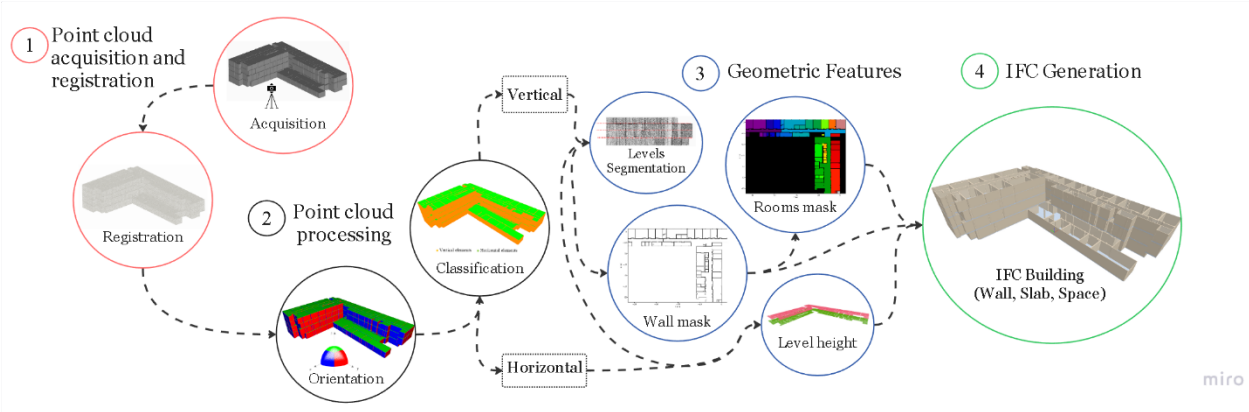


Figure 1. Flowchart of proposed methodology

position of the data in 3D space facilitating subsequent steps. The aligned point cloud is subjected to a second normal estimation stage to enable geometric classification into vertical and horizontal elements, as illustrated in Figure 3. After classification, a statistical outlier removal filter and a voxel downsampling is applied to clean each point cloud and eliminate spurious points.

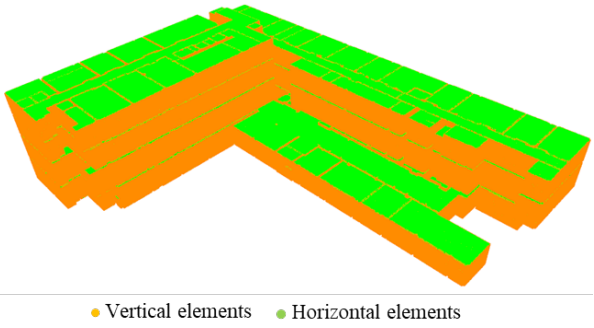

Figure 3. Point cloud classification.

Geometric Features

To automatically identify building storey levels, a height-based segmentation is performed using the vertical-point subset of the point cloud. Local minimum of a smoothed density function are used as cut elevations by two consecutive height intervals. After determining the set of level boundaries, each input point cloud class (e.g., vertical, horizontal) is segmented per level. On real point clouds, the quantity of noise can hinder the acquisition of entire contours of the existing rooms. On this work, the contour extraction for synthetic data is acquired from a z section of the vertical point cloud. Further ahead, on the Experimental analysis and discussion section, this extraction will be presented in more detail.

The point cloud contour extracted is given by:

$$\mathcal{P} = \{(x_k, y_k, z_k)\}_{k=1}^{N} \quad (1)$$

Where (x_k, y_k, z_k) represent the coordinate points of the point cloud contour then transformed into a 2D occupancy grid by discretizing the horizontal spatial domain into square cells of fixed resolution r. Each point projected onto the horizontal plane, and the grid cell c_{ij} is considered occupied (wall) if the number of projected points falling inside the cell (p_i) exceeds a predefined threshold τ:

$$c_{ij} = \begin{cases} 1, if\ p_{ij} \geq \tau \\ 0, otherwise \end{cases} \quad (2)$$

This procedure yields a binary wall mask that is robust to noise and suitable for image-based operations. These operations ensure that wall regions form coherent, topologically closed boundaries suitable for spatial reasoning. From the refined wall mask, a complementary free-space mask is obtained by logical inversion. To distinguish interior spaces from the exterior environment, a border-seeded flood fill is applied. This step guarantees that only enclosed regions bounded by walls are considered as candidate interior spaces. Therefore, a vectorization stage is applied to transform room masks into polygonal room boundaries (Figure 4), which can subsequently be extruded into 3D solids and IFCSpace.

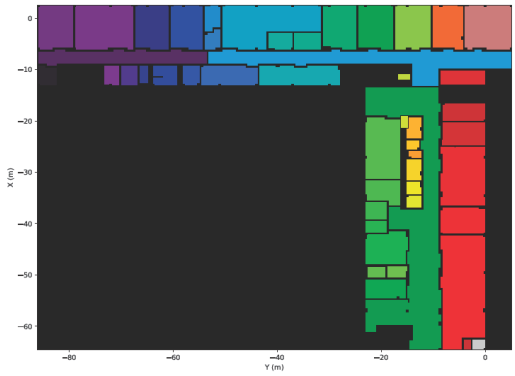

Figure 4. Room mask.

The binary regions are vectorized into metric polygons by enumerating boundary edges of occupied cells and colinear vertices are removed to yield simplified orthogonal loops. Ultimately, to mitigate corner gaps caused by discretization and later wall thickening, segments connected at junction endpoints are extended by half the nominal wall thickness, improving closure when generating IFCWall.

For level height, the RANSAC algorithm is applied on the horizontal point cloud to characterize the level. These geometric features are used to set the height of IFCSpace and to generate IFCSlabs.

IFCBuilding generation

The IFC generation was implemented using the ifcopenshell library. This stage instantiates a schema-compliant IFC4 spatial hierarchy (IfcProject–IfcSite–IfcBuilding–IfcBuildingStorey). For each storey, elements are positioned through hierarchical IfcLocalPlacement, ensuring consistent coordinate handling. The reconstructed 2D room boundaries are converted into IfcPolyline-based closed profiles and extruded along the +Z direction to form IfcSpace solids with a fixed height extracted from horizontal point cloud classification. Wall and slab elements are generated analogously by extruding closed profiles into IfcWall and IfcSlab solids; slabs are placed with a negative Z-offset so that their top surface coincides with the storey elevation, except on the first floor. As a result, a structured and information-rich IFC model is created, enabling BIM-based analysis, as can be observed in Figure 5.

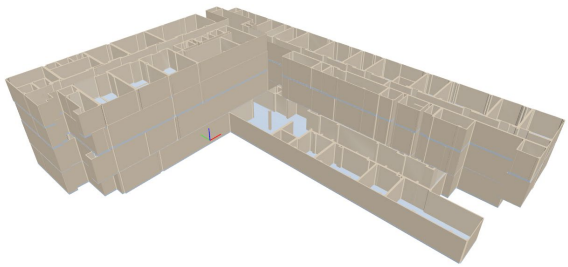

Figure 5. BIM model generated

Experimental analysis and discussion

This section presents the application of the proposed methodology to three public TLS datasets. The input point cloud, the resulting early design model and BIM model,

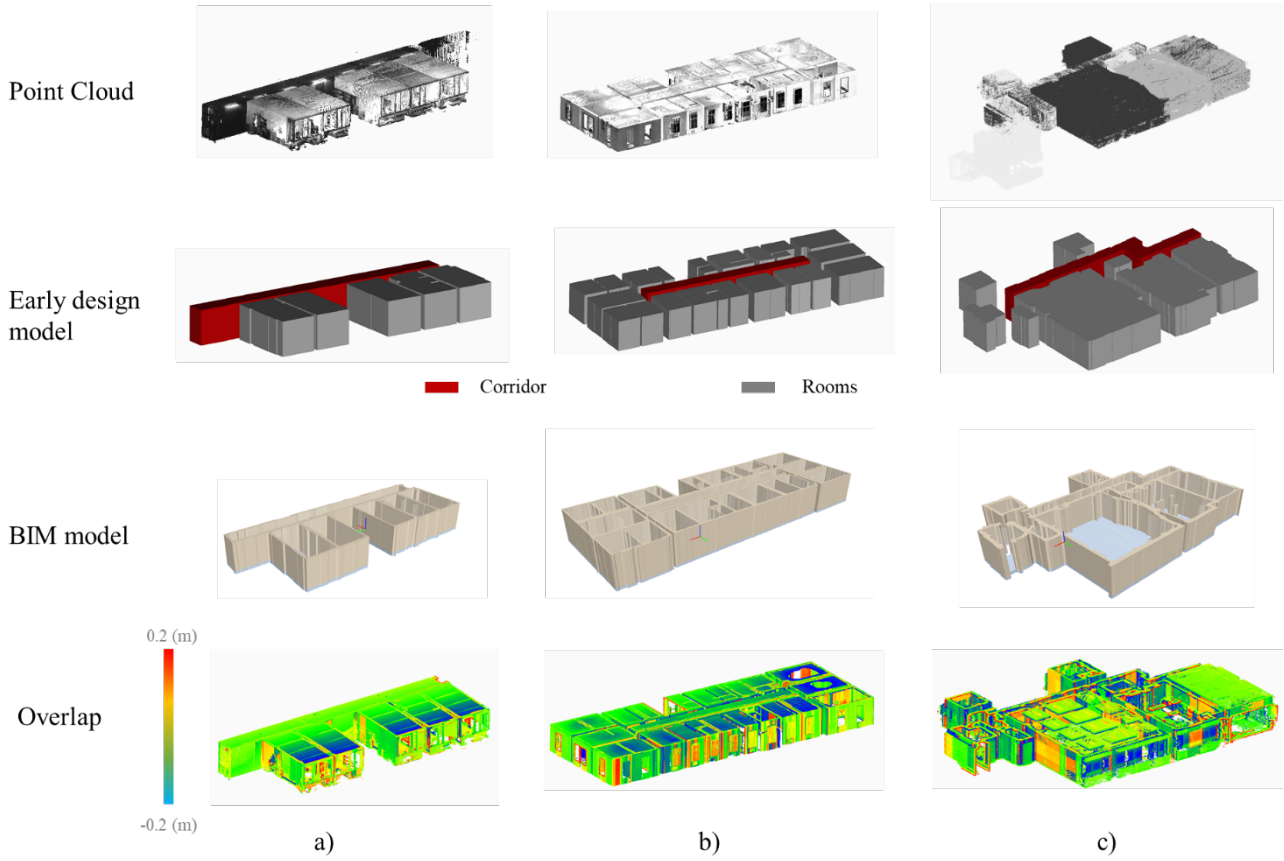

Figure 6. Experimental analysis of proposed methodology on real point clouds: a) University of Zurich (room3); b) Kladno railways station and c) University of Melbourne.

as well as the corresponding overlap results are shown in Figure 6.

For this type of data, the noise level of the point cloud has a significant impact on the contour extraction stage and consequently on the final result. To account for the diversity of building geometries, several trials were conducted to obtain contours that are both as clean and as complete as possible. In addition to vertical and horizontal surfaces, an inclined point cloud was extracted from the normal-based classification, comprising points whose unit normal vectors fall outside the predefined angular thresholds used to distinguish vertical and horizontal elements. This subset mainly represents transitional regions between horizontal and vertical surfaces and can reveal space-level separations.

Regarding the results obtained from the public datasets, the case studies of the University of Zurich (University of Zurich) (Figure 6a) and Kladno station (Urban, 2024) (Figure 6b) presents a good accuracy across most elements, achieving a mean distance of 0.059 m and 0.048 m, respectively. Nevertheless, variations in ceiling heights are visible. When the methodology was applied to a more complex dataset, such as the University of Melbourne case (Khoshelham et al., 2017) (Figure 6c), a reduction in performance was observed by a mean distance of 0.136 m. This dataset exhibits a higher noise level and includes a room that is not fully orthogonal, revealing limitations of the current approach. These results highlight the need for additional filtering of the extracted segments and for the generation of cleaner and smoother wall masks.

Contour extraction is therefore identified as the most critical stage of the entire process and remains the focus of ongoing research, with the objective of developing a method capable of handling a wider range of building typologies.

For the fire compartmentation evaluation, the early design model was manually modified to differentiate corridor spaces from rooms. This initial semantic distinction establishes the foundation for subsequent enrichment of the BIM model, particularly enabling the association of corridor-adjacent walls with fire-rated elements and supporting the definition of evacuation routes.

The proposed methodology ensures scalability and interoperability by transitioning from manual classification to a fully automated space classification framework, which builds on both property-based and relationship-based modeling strategies within the IFC schema.

At the property level, individual spaces (IfcSpace) may be enriched through dedicated property sets, such as Pset_SpaceCommon and Object Type, which explicitly encode whether a space is classified as a private room or a circulation area. This approach ensures compatibility with common BIM authoring and analysis tools while enabling straightforward querying and filtering operations. Complementarily, a higher-level semantic

grouping can be established through the use of IfcSpatialZone entities, allowing spaces to be aggregated into functional zones. This relationship-based structuring enhances the model's capacity to support fire safety analyses, including compartmentation logic, evacuation route modelling, and accessibility assessments, while preserving flexibility for multi-criteria classifications.

The transition towards automated classification is supported by a topology-driven strategy based on spatial adjacency. In this context, each space identified in the room mask (Figure 4) will be evaluated according to its connectivity with neighbouring spaces, derived from shared boundaries. Spaces exhibiting a number of adjacent connections above a predefined threshold will be interpreted as circulation elements (e.g., corridors or transitional zones), whereas spaces with limited connectivity are classified as enclosed functional units (e.g., rooms or offices). This graph-based interpretation of the spatial structure aligns with the inherent relational nature of the IFC schema and enables the derivation of higher-level semantic information from purely geometric and topological inputs. Furthermore, such an approach supports extensibility towards more advanced classification criteria, including geometric properties, accessibility patterns, or integration with external ontologies and classification systems.

Conclusions

The lack of architectural designs, detailed floor plans and 3D models for older buildings is a significant challenge in Portugal. To address this problem, this work presents a semi-automated scan-to-BIM methodology designed to support fire safety analysis in retrofitting projects.

The proposed methodology was first developed and described using a synthetic dataset and was subsequently validated on three different real-world point clouds from benchmark datasets. The results demonstrate the methodology's sensitivity when applied to noisy data, where the generated BIM models may contain irregularities. Nevertheless, validation across multiple datasets highlights the framework's primary advantage: its robustness and adaptability to diverse real-world conditions.

Conducted within the scope of the FireBIM project, this work provides a foundational contribution to fire safety analysis, specifically in assessing compartmentation within existing buildings. Furthermore, the resulting early-design model can be utilized to assist in planning fire safety evacuation routes, such as checking evacuation distances, width of exits and stairways, and determining the number of exits based on the capacity of the building's premises.

Future work will focus on developing more robust strategies for extracting accurate spatial contours from dense and noisy point clouds. This step is identified as critical to the entire workflow, as incomplete contours prevent the generation of successful BIM models. Moreover, an automated approach for BIM model enrichment will be incorporated, aimed at ensuring compliance with evacuation and compartmentation requirements. Additionally, the automated characterization of key building elements, such as stairs, doors, and openings, will be investigated to support connectivity modelling and fire safety analysis.

3D SEGMENTATION AGENT INTEGRATING 3D GAUSSIAN SPLATTING AND VISION-LANGUAGE MODELS FOR AS-BUILT ANALYSIS

Boyu Wang[1], Jun Ma[1], and Borja García de Soto [2]
[1]The University of Hong Kong, Hong Kong, China
[2]New York University Abu Dhabi (NYUAD), Abu Dhabi, United Arab Emirates

Abstract

The transition from raw as-built data to semantic object representations is a bottleneck in construction digitalization, currently hampered by manual dependencies and the "black-box" nature of existing point cloud segmentation networks. This paper introduces an autonomous self-correcting 3D segmentation agent tailored for construction environments, utilizing 3D Gaussian Splatting (3DGS) as the underlying representation and Vision Language Models (VLMs) as the reasoning core. Unlike static segmentation methods, our agent adopts a dynamic approach by performing active scene roaming. Through a closed-loop feedback mechanism, the VLM analyzes visual data, detects objects, and rigorously assesses the plausibility of segmentation results. The agent iteratively corrects its own errors until a high-fidelity, logically consistent segmentation is achieved. This method demonstrates superior interpretability and accuracy, enabling downstream applications such as as-built verification, progress tracking, and quantity takeoff. By bridging generative rendering with semantic reasoning, our approach provides a robust framework for automated 3D scene understanding.

Introduction

Construction automation is progressively evolving through four stages: data acquisition, semantic understanding, human-robot interaction, and fully autonomous construction. While the latter stages remain nascent, the industry has made significant strides in the first stage. Data acquisition has matured from manual logging to high-precision 3D laser scanning and, more recently, robust mobile LiDAR-visual Simultaneous Localization and Mapping (SLAM) systems. These technologies accurately capture the 3D geometry of construction sites. However, the resulting data remains unstructured. To enable automated tasks like as-built modeling and quality assessment, this raw geometric data must be transformed into structured, semantic representations.

Semantic 3D segmentation is the critical bridge for this transformation, yet it faces two significant barriers in construction contexts: 1) Generalization gaps**:** Conventional models trained on structured datasets (e.g., offices) often fail in dynamic, cluttered construction environments due to domain shifts. 2) Limited robustness and interpretability: "Black-box" deep learning models lack physical reasoning capabilities, often yielding results that are geometrically or topologically implausible.

To address these system-level challenges, we propose a 3D segmentation agent integrating 3D Gaussian Splatting (3DGS) and vision-language models (VLMs) inspired by the cognitive workflow of human engineers. Unlike end-to-end models, human experts adopt an iterative strategy: they first perform a rough identification, evaluate the result's plausibility (e.g., checking for completeness and topological connectivity), and actively manipulate their view including zooming in, rotating, or translating to resolve ambiguities before finalizing the segmentation.

Mimicking this paradigm, our framework, illustrated in Figure 1, integrates a 3DGS Rendering Engine with two core modules. Unlike 'black-box' neural networks that rely on implicit latent spaces, our approach achieves high interpretability by decomposing the segmentation task into an explicit, human-readable cognitive workflow. The Analysis Module utilizes VLM-based detection and topological reasoning to assess segmentation quality ("Plausibility Analysis"). If the result is unsatisfying or ambiguous, the system triggers the Operation Module. This module executes active visual manipulation such as multi-scale zooming, 3D rotation, and cropping to acquire clearer details, thereby achieving a robust, self-correcting understanding of the 3D scene.

Literature Review

Deep Learning-Based 3D Segmentation

Point cloud segmentation has evolved from manual processing to automated deep learning. Fully supervised methods, employing MLP, convolutional, or attention-based architectures, have been extensively applied across AEC scenarios ranging from Mechanical, Electrical, and Plumbing (MEP) systems to bridges (Wang et al., 2025). However, their reliance on massive, labor-intensive annotations severely limits scalability.

To mitigate data costs, weakly supervised and few-shot paradigms were developed, utilizing sparse labels or prototype alignment. Yet, these approaches often compromise accuracy and remain constrained to specific target domains.

Ultimately, these traditional methods share a critical limitation: they are "closed-set" systems. They lack the open-vocabulary reasoning required to interpret the diverse, unstructured elements found in dynamic construction sites without task-specific retraining. This bottleneck necessitates a paradigm shift toward large-scale foundation models, which liberate segmentation from fixed label sets and enable generalized, zero-shot 3D understanding.

Vision-Language Models (VLMs)

VLMs have revolutionized perception, shifting from closed-set tasks to open-vocabulary learning. While early models like CLIP (Radford et al., 2021) focused on global alignment, recent advancements like Grounding DINO (Liu et al., 2024) and SAM 3 (Carion et al., 2025) integrate semantic reasoning with precise localization. To extend this to 3D, researchers employ 2D-to-3D projection, mapping either segmentation masks or feature embeddings from multi-view images onto point clouds (Wang et al., 2024). These methods have shown promise in AEC applications ranging from indoor scanning to infrastructure inspection.

However, a significant bottleneck persists: VLMs remain inherently 2D-centric. They struggle with complex 3D construction environment, where single-view occlusion and background clutter hinder accurate detection. This limitation suggests a synergistic opportunity: leveraging 3DGS to render simplified, optimal viewpoints, thereby enabling VLMs to progressively analyze the environment and derive accurate segmentation results.

3D Gaussian Splatting (3DGS)

3D scene reconstruction has transitioned from discrete point clouds, which suffer from sparsity and artifacts, to continuous Neural Radiance Fields (NeRF) (Mildenhall et al., 2021). While NeRF achieves photorealism, its implicit nature incurs high computational costs. 3DGS bridges this gap by representing scenes with explicit, anisotropic 3D Gaussians (Kerbl et al., 2023).

Technically, 3DGS optimizes Gaussian parameters (position, opacity, covariance) via differentiable rasterization, projecting 3D ellipsoids into 2D image space for real-time rendering. Its adaptive density control dynamically densifies or prunes primitives to capture fine details efficiently. Subsequent advancements like Scaffold-GS (Lu et al., 2024) have further enhanced geometric consistency and surface alignment.

Despite these strides in visual fidelity, a critical gap remains: existing research prioritizes visual reproduction over structural interpretation. There is a distinct lack of methodologies leveraging 3DGS to semantically decompose and interpret complex civil engineering components, leaving this frontier largely unexplored.

Methodology

To address the challenges of segmenting complex 3D structures in cluttered environments, we propose a novel 3D segmentation agent. As illustrated in Figure 1, our framework establishes a dynamic synergy between the semantic reasoning capabilities of VLMs and the flexible rendering power of 3DGS. Unlike traditional static pipelines that process a fixed set of views, our agent mimics human visual inspection, treating 3D segmentation as an iterative, active perception process.

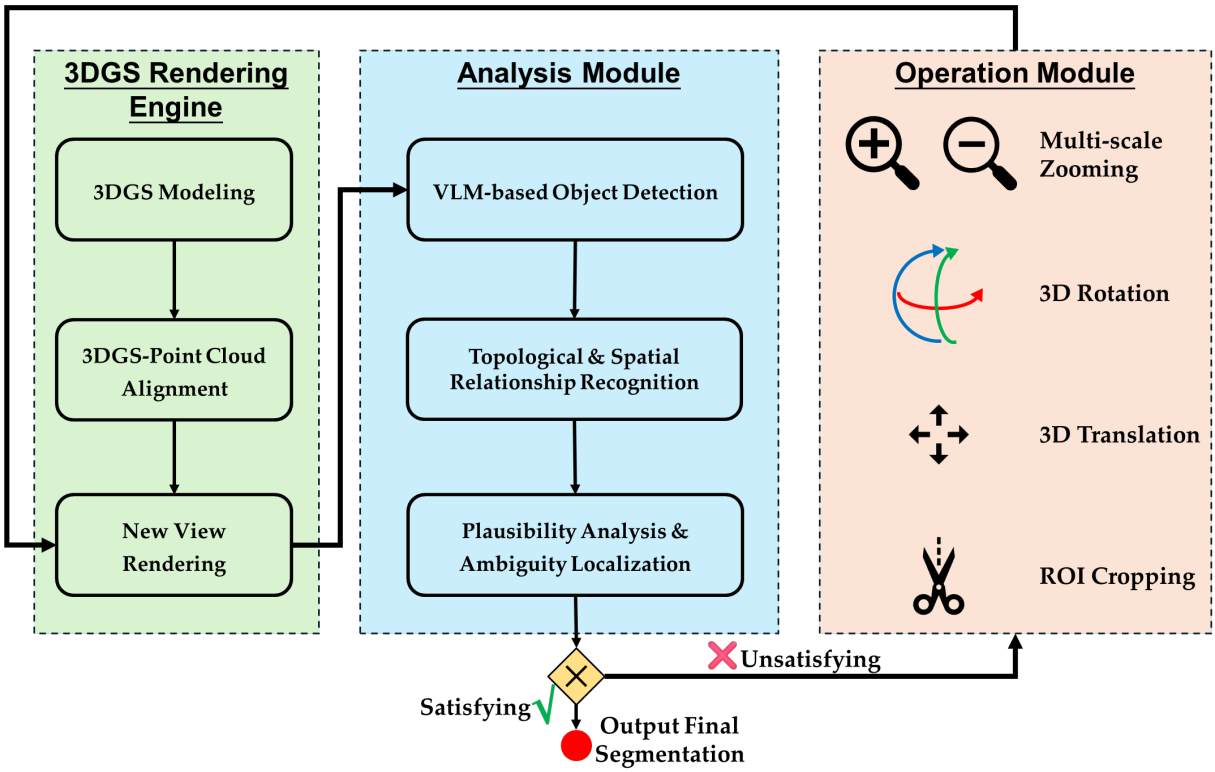

Figure 1: Overall framework of the proposed 3D segmentation agent system

The framework is structured around three interconnected components: the 3DGS Rendering Engine, the Analysis Module, and the Operation Module, forming a closed-loop active perception system:

- 3DGS Rendering Engine (Environment): This module constructs the scene via 3DGS Modeling and Point Cloud Alignment. It generates high-fidelity New View Renderings, providing the visual input necessary for semantic analysis.
- Analysis Module (Cognitive Core): Acting as the decision-maker, this module employs VLMs for object detection and topological relationship recognition. Crucially, it performs plausibility analysis to evaluate results. If the output is ambiguous, the system triggers the Operation Module.
- Operation Module (Active Control): To resolve identified ambiguities, this module executes targeted adjustments such as multi-scale zooming, 3D rotation, translation, or region of interest (ROI) cropping.

This cycle enables the agent to progressively refine its understanding of the scene until a high-confidence, topologically consistent segmentation is achieved. The following sections detail the implementation of these core components.

3DGS Rendering Engine

The 3DGS Rendering Engine acts as the bridge between the physical world and the agent's cognitive processes. Unlike traditional pipelines that rely solely on 2D images or sparse point clouds, our engine constructs a dual-representation environment that synchronizes photorealistic rendering with metric-accurate 3D geometry.

Data Acquisition and 3DGS Modeling: To capture complex as-built conditions, we utilize a handheld mobile scanning system integrating LiDAR and high-resolution RGB cameras. The system leverages Fast-LIVO2 (Zheng et al., 2024) for real-time SLAM, generating a dense point cloud with accurate global pose estimation. Simultaneously, we employ 3DGS to model the scene as a continuous radiance field. Initialized via sparse Structure-from-Motion (SfM) points, the scene is parameterized by volumetric 3D Gaussians, optimized iteratively to minimize photometric loss. This results in a representation that offers real-time, photorealistic rendering from arbitrary viewpoints, essential for the agent's active exploration.

Multi-modal Alignment and 2D-3D Projection: A critical feature of our engine is the rigorous alignment between the photorealistic 3DGS model and the metric-accurate SLAM point cloud. Since raw 3DGS reconstructions lack absolute scale, we register the two representations using a coarse-to-fine approach (anchor point estimation followed by Iterative Closest Point refinement). An example of 3DGS-Point Cloud alignment is shown in Figure 3.

This alignment establishes a deterministic mapping between the 2D rendered view and 3D space. By recording the extrinsic and intrinsic parameters of the 3DGS virtual camera for every rendered frame, we enable a precise pixel-to-point projection mechanism: Once the Analysis Module generates a 2D semantic mask, the engine could use the stored camera parameters to back-project mask pixels onto the aligned 3D point cloud. This mechanism allows the system to extract the exact spatial coordinates of semantic entities, effectively lifting 2D perception into 3D metric space for topological reasoning.

Analysis Module

The Analysis Module serves as the cognitive core of our agent, responsible for transforming raw visual data into a structured semantic understanding of the 3D environment. This process is divided into three progressive stages: VLM-based object detection, topological relationship recognition, plausibility analysis and ambiguous region identification.

VLM-based Object Detection and 3D Projection: To achieve robust segmentation without relying on pre-trained, domain-specific datasets, we adopt a "segment-then-recognize" strategy that integrates foundational 2D models with the reasoning power of Large VLMs.

The workflow begins with the 3DGS engine rendering an initial "initial look" image from a viewpoint as shown in the upper left corner of Figure 2. We utilize the Segment Anything Model (SAM) (Kirillov et al., 2023) to generate a set of high-quality, class-agnostic binary masks, where each mask corresponds to a distinct visual entity (e.g., a pipe segment, a wall patch) as shown in the upper right corner of Figure 2.

These binary masks, overlaid on the original RGB image, are fed into the VLM GPT-5.2. The VLM acts as a semantic parser, analyzing the visual context to assign specific semantic labels (e.g., "Water Pipe," "Concrete Wall," "Valve") to each mask ID as shown in the lower left corner of Figure 2. This step converts purely geometric segments into semantically meaningful objects.

To bridge the gap between 2D image space and 3D volumetric space, we perform a reverse projection. Using the known camera intrinsics and extrinsics from the 3DGS rendering process, each pixel within a 2D mask is back-projected to identify the corresponding 3D point clouds. This effectively "lifts" the 2D semantic labels onto the 3D point cloud, resulting in a semantically annotated 3D scene representation.

Topological and Spatial Relationship Recognition: Mere object detection is insufficient for complex engineering scenes; the agent must understand how objects interact. Once the 3D entities are labeled, the module extracts geometric primitives and infers spatial relationships.

The VLM analyzes these 2D visual features and 3D geometric features to construct a topological scene graph as shown in the lower right corner of Figure 2. This graph encodes connectivity and spatial adjacency, such as:

- Connectivity: Pipe 1 connects to Pipe 2 at Joint J1

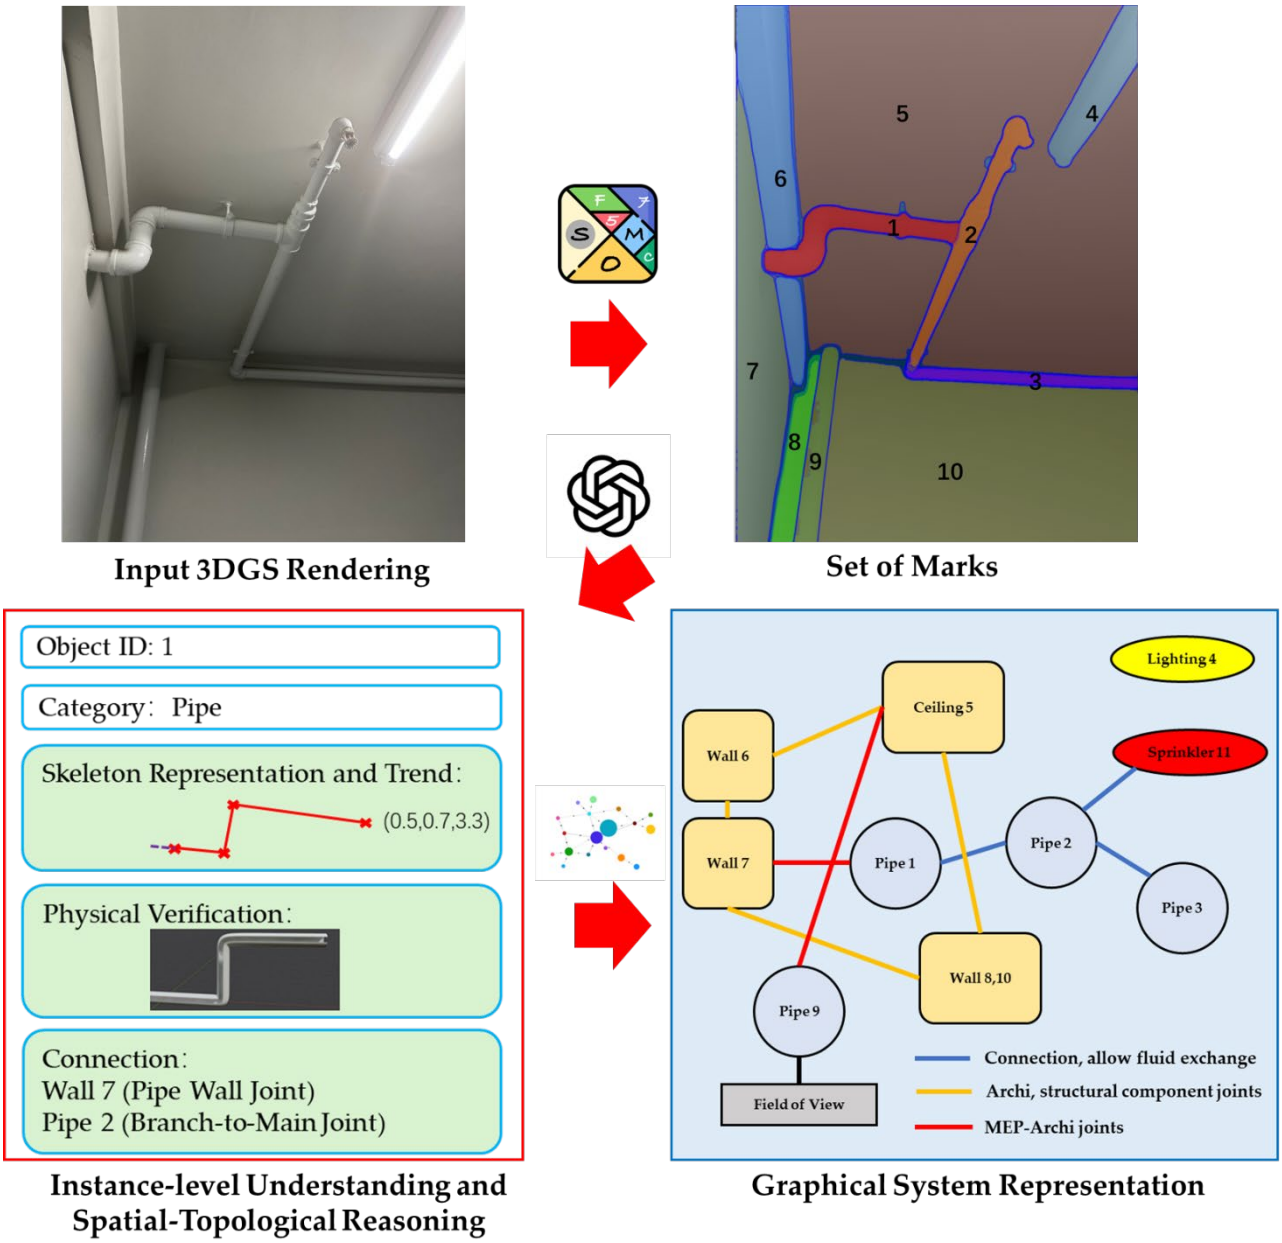

Figure 2: Analysis Module: VLM-based object detection and topological scene graph construction

- Attachment: Pipe 1 is mounted on Wall 7.
- Termination: Pipe 1 ends at coordinate (x, y, z)

Plausibility Analysis and Ambiguity Localization: With a structured scene graph established, the Analysis Module performs a "sanity check" based on physical priors. This is where the agent identifies ambiguities that require active investigation.

As illustrated in upper right corner of Figure 2, the initial segmentation successfully identifies the pipe network ("Pipe 1", "Pipe 2" and "Pipe 3") and the surrounding walls. Following this initial detection, the system evaluates the scene's topology using a hybrid verification mechanism that integrates geometric priors, structured prompting, and VLM-based visual judgment. Since the semantic labels and spatial coordinates (both 2D and 3D) of all detected components are known, the system first applies geometric priors (e.g., spatial proximity) to filter potential relationship candidates.

Applying this mechanism to the network, the topological analysis reveals a logical inconsistency regarding "Pipe 2". The system observes the skeleton of Pipe 2 and detects that it terminates abruptly in mid-air. To investigate this, a targeted logical verification chain is executed. For instance, during the Continuity Check, the system geometrically determines that "Pipe 1" is a viable candidate for connection. A targeted prompt then instructs the VLM to visually verify this specific connection within the 2D rendered image. Thus, while the verification logic is structurally constrained by geometric priors, the final determination relies on the VLM's visual reasoning. For the unattached end of Pipe 2, the VLM yields the following results:

- Continuity Check: Does the pipe connect to another segment? (Result: Negative)

- Boundary Check: Does the pipe extend outside the camera view? (Result: *Negative*)
- Structural Check: Does the pipe terminate into a wall surface? (Result: *Negative*)

According to established engineering priors, a water pipe cannot simply end in free space without a cap or a functional component. Consequently, the Analysis Module flags this region as having "Low Plausibility," hypothesizing that a small terminal device, likely a sprinkler head exists at this location but was missed due to the low resolution of the initial global view. This deduction seamlessly triggers the Operation Module, issuing a precise command: “Zoom in on the endpoint of Pipe 2 to verify the potential missing terminal component,” thereby initiating the active perception loop.

Crucially, this explicit, step-by-step verification chain provides a level of explainability absent in traditional end-to-end models. By structurally constraining the verification logic with geometric priors and outputting human-readable hypotheses (e.g., flagging a specific pipe termination as violating engineering norms), every decision made by the agent, from identifying an anomaly to actively moving the virtual camera, is fully traceable and transparent.

Operation Module

While the Analysis Module identifies what is missing or ambiguous, the Operation Module determines how to look closer. Acting as the agent's navigational controller, this module dynamically manipulates the virtual camera within the 3DGS environment to acquire supplementary views. The process is driven by a feedback loop that continues until the scene representation achieves both geometric high-fidelity and topological consistency. The Operation Module is triggered when the Analysis Module flags a region as "Ambiguous." To ensure rigorous execution, ambiguity is formally defined by two criteria: 1) Quantitative visual uncertainty, occurring when the SAM-predicted mask confidence score falls below 0.7 or the VLM semantic classification probability falls below 0.9; and 2) Qualitative topological inconsistency, occurring when a component fails the logical verification chain (e.g., a pipe exhibiting a "dangling edge" in the scene graph without connecting to a verified boundary or terminal). Upon detecting either condition, the Operation Module triggers a multi-scale zooming and rotation strategy.

- Focusing: For small or indistinct features (such as the potential sprinkler head identified in the last section), the module calculates a new camera pose that minimizes the distance to the target coordinate while maintaining the optical axis centered on the frame. This "zoom-in" operation increases the pixel density of the target, allowing the VLM to discern fine-grained details previously lost in the initial view.
- De-occlusion: If an object is suspected to be occluded, the module executes a 3D rotation around the target's centroid. By generating views from oblique angles, the system bypasses obstacles to reveal the hidden geometry.

Spatial Continuity and Boundary Extension: A common challenge in large-scale engineering scenes is that linear structures (like pipes or ducts) often extend beyond the current field of view (FoV).

- Truncation Detection: If a segmented mask touches the boundary of the rendered image frame, the system recognizes this as an incomplete observation.
- Trajectory Extension: The Operation Module computes the directional vector of the truncated object in 3D space. It then performs a 3D Translation (panning) along this vector, shifting the virtual camera to capture the subsequent segment of the structure. This ensures that long-span objects are tracked continuously across multiple frames rather than being fragmented into disjointed parts.

Active Perception Loop and Termination Criteria: The core mechanism of this module is an iterative Active Perception Loop. The system does not settle for a single pass; it continuously refines its understanding based on specific termination criteria. The loop cycles through Rendering Analysis Operation until the following three conditions are simultaneously met:

- Geometric Completeness: All segmented objects within the target block possess high-confidence mask scores (≥ 0.7), indicating clear boundaries and minimal visual noise.
- Topological Consistency: The scene graph is logically sound. There are strictly zero unexplained "dangling" edges; every segment must either connect to another component, terminate at a verified surface, or end with a recognized terminal device.
- Global Coverage: The union of all recognized entities fully occupies the spatial volume of the target block, ensuring the remaining uninspected void volume falls below a minimal threshold.

The loop iterates until all three conditions are simultaneously met, signifying convergence to a high-fidelity semantic model. To prevent infinite loops in cases of severe physical occlusion or missing scan data, the system enforces a maximum iteration limit (e.g., $N_{max} = 5$) per ambiguous target, after which the unresolved region is explicitly flagged for human review.

Experiment

To evaluate the effectiveness of the proposed pipeline, experiments were conducted on a real-world public toilet captured via mobile laser scanning. The evaluation focused on the object detection accuracy of architectural and functional components, assessed by comparing the predicted labels to manual annotations. The tested scene serves as a representative real-world case intended to validate the feasibility of the proposed pipeline, rather than to provide a comprehensive performance benchmark. Broader validation across multiple sites and building configurations is left for future work.

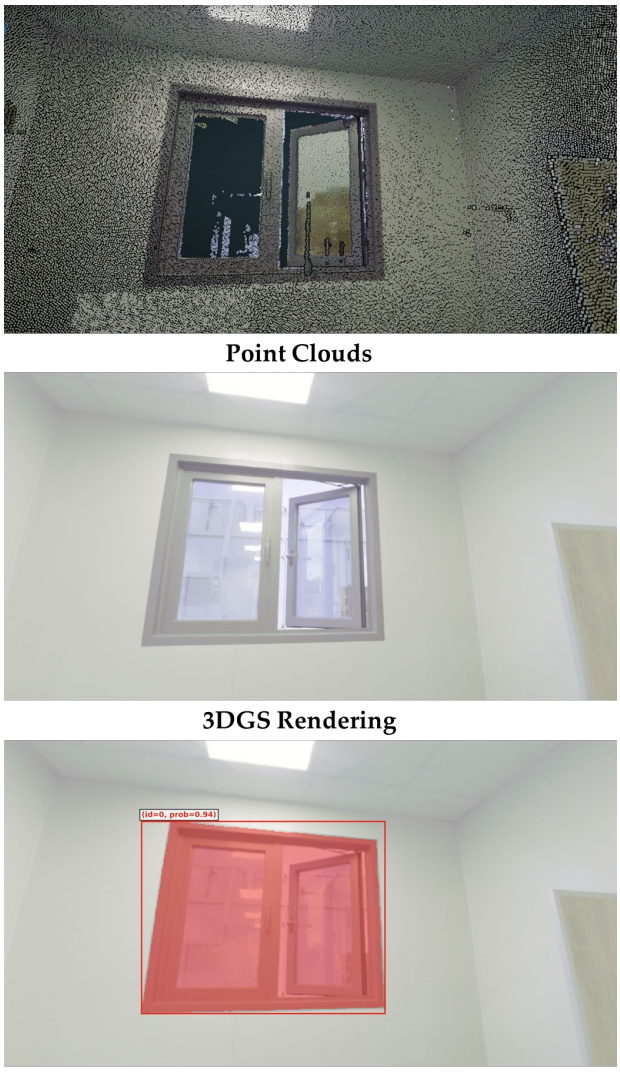

Figure 3: Alignment between 3DGS and point clouds from Rendering Engine and VLM-based object detection results in the experiment

Figure 3 shows a step-by-step breakdown of a specific detection instance (a window). The process relies on the precise alignment between the raw point cloud and the 3DGS model. The top row displays the raw point cloud view. It could be observed the laser scan data is sparse and noisy, lacking sufficient geometric definition for traditional shape-based detectors to reliably identify the object. The middle row shows the corresponding view rendered by the 3DGS. By leveraging the continuous volumetric representation, 3DGS effectively fills in the missing visual information, recovering the window frame structure and the reflective properties of the glass with photorealistic quality. The bottom row demonstrates the final detection result. The VLM performs inference on the rendered image. Because the visual features are clearly restored, the model successfully detects the target "window" with a high confidence score of 0.94, generating an accurate bounding box and segmentation mask. This example confirms that the proposed 3DGS rendering engine allows the system to overcome the sparsity inherent in point clouds, enabling accurate semantic recognition in complex scenarios.

Table 1: Results of public toilet component detection

Component Type	True Positive	False Positive	False Negative
Door	5	0	1
Window	4	0	0
Vent	5	0	0
Lighting	16	0	0
Urinal	2	0	0
Plate	11	0	0
Basin	6	0	0

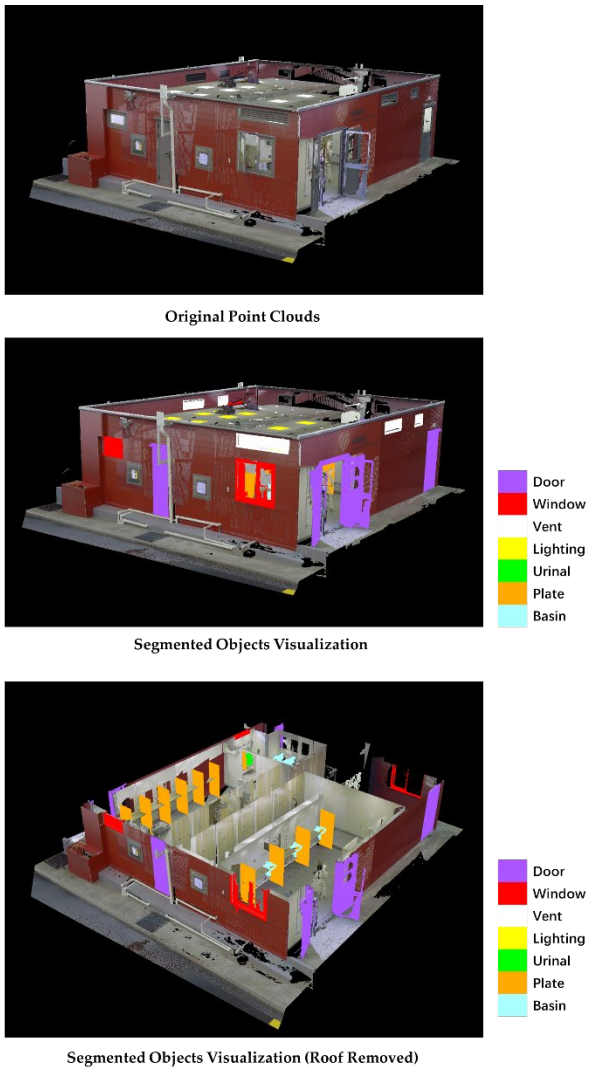

Figure 4: 3D segmentation results performed by the proposed agent

As shown in Table 1, A total of 50 components were annotated and used as ground truth. The results show that the proposed method achieves near-perfect precision

across almost all categories. Notably, repetitive functional elements such as Lights (16 instances), Partition Plates (11 instances), and Basins (6 instances) were detected with 100% precision and recall. The only detection error occurred in the Door category, where one instance was missing (5 out of 6 detected). This specific false negative was attributed to severe data incompleteness; the missing door was in a transition zone that was not fully covered by the scan path, resulting in a low-quality 3DGS for the VLM to form a valid semantic mask, even after the active operation module attempted to refine the view. However, the successful detection of most of the components confirms that the integration of 3DGS modeling and VLM-based segmentation enables high-quality detection with strong generalization across diverse indoor assets. The 3D segmentation results is shown in Figure 4.

Conclusions

This paper presents a novel 3D segmentation agent for as-built analysis by integrating 3DGS and VLMs. Through the synergy of a high-fidelity 3DGS rendering engine and an interactive operation module, the system dynamically adjusts observation perspectives via multi-scale zooming, 3D rotation, and translation. This active perception capability enables the analysis module to effectively perform VLM-based object detection, recognize complex topological and spatial relationships, and conduct plausibility analysis to localize and resolve ambiguities in the scene. Consequently, the system provides a highly interpretable and traceable decision-making process, successfully overcoming the 'black-box' limitations of conventional deep learning approaches.

Experimental results demonstrate the agent's robustness in interpreting complex as-built environments, achieving high accuracy in 3D segmentation and semantic reasoning. The approach successfully bridges the gap between geometric reconstruction and semantic understanding. However, some limitations remain, such as the automation level of the operation module is limited and the testing scenario is not complex enough. The efficiency of the proposed agent in large-scale scenes needs further validation. Furthermore, while our 3DGS-based re-rendering approach theoretically overcomes the limitations of standard 2D-to-3D projection methods, which rely on static raw images and struggle with physical occlusions, by enabling dynamic novel view synthesis, quantitative comparisons are currently absent. As part of our future work to expand this research into a comprehensive journal-length manuscript, we plan to conduct extensive quantitative ablation studies. These studies will systematically compare our active roaming framework against standard 2D-to-3D projection baselines to rigorously demonstrate the performance gains in segmentation accuracy and topological consistency. Overall, the proposed approach lays the foundation for intelligent as-built data analysis, providing a reliable and automated solution for as-built inspection and semantic enrichment.

AGENTIC AI – THE TRANSFORMATION OF DECISION-MAKING PROCESSES THROUGH ARTIFICAL INTELLIGENCE

Charlotte-Maria Esch[1], Marijana Srećković[2], and Josef Windsperger[1]
[1]University of Vienna, Vienna, Austria
[2]Vienna University of Technology, Vienna, Austria

Abstract

Agentic AI describes a new generation of AI that automates tasks, pursues goals independently, makes decisions and proactively interacts with its environment. This study - based on a qualitative exploratory research design with expert interviews - aims at understanding how the use of such systems affects internal decision-making logic and organizational structures in companies. Results show that Agentic AI changes decision-making processes. Decisions are being made by systems and humans, with humans mainly taking on supervisory or control functions. We provide a theoretical contribution to existing decision-making and organizational theories with practical recommendations for dealing with such autonomous AI systems.

Introduction

Traditional decision-making processes are reaching their limits due to the availability of large amounts of data, the increasing speed at which market changes occur, and the need to remain competitive in the global marketplace. The dynamic development of AI has the potential to fundamentally change the way companies operate in different industries (IT-P, 2024). In Architecture, Engineering and Construction (AEC), AI adoption is still very limited as reported in the global RICS survey (2025).

AI systems are often used in content generation, data analysis, and forecasting. However, research shows that increasingly powerful autonomous systems, e.g. Agentic AI (Stryker, 2024) are finding its way into practice. This technology goes beyond traditional AI systems in that it is capable of solving complex, multi-stage problems that have no fixed rules or predefined solutions. Agentic AI thus represents an advanced form of AI that can assume a supportive role, as well as act independently. This offers companies the opportunity to optimize decision-making processes and increase efficiency. The Harvard Business Review describes how these systems are transforming human-machine collaboration through their capabilities, for example in virtual nursing or AI-supported travel planning (Purdy, 2024), managing smart homes (Sepkota et al., 2026) or assisting in Urban Planning (Finn & Downie, 2025). Companies like PricewaterhouseCoopers (2024) emphasize the transformative influence of multimodal frameworks in which specialized AI agents work together to optimize efficiency and decision-making processes on an unprecedented scale. At the same time, research by Berkeley SCET highlights the opportunities and risks of these systems, in particular their adaptability to changing conditions and their ability to achieve specific goals autonomously (Ghose, 2024). Simultaneously, key questions arise regarding the area of application and the comprehensive effects, particularly with regard to transparency, accountability, and the delegation of decision-making powers to AI within the internal organization (Ghose, 2024; Purdy, 2024; Stryker, 2024).

In this context, it is becoming increasingly important to examine the organizational and strategic implications of Agentic AI. It is necessary to clarify in which business areas this technology can be used effectively, how it should be introduced, and what capabilities are required for its implementation. This raises the following research question: *"How is Agentic AI integrated into organizational systems to optimize decision-making processes, and what impact does this integration have on the internal structure?"* Hence, this scientific paper examines the effects of Agentic AI on decision-making processes and organizational structures in companies.

First, we examine the status-quo on Agentic AI and decision-making processes. Second, we conduct a qualitative study to explore the experts´ perspectives on AI integration and its implementation effects in organizational settings. This is followed by an analysis and discussion of the interview results, as well as theoretical and practical implications. Finally, we conclude with limitations of the study and related starting points for possible further research in this area.

Theoretical foundation

Decision-making processes in organizations

Research on organizational decision-making has evolved from idealized rational models to more realistic approaches that account for human and structural limitations. The classical rational model, grounded in the *homo economicus* assumption, posits fully informed decision-makers who maximize utility (Suchanek, 2021).

In practice, however, constraints such as incomplete information, time pressure, and bounded cognitive capacity prevail. Simon (1955) addressed these realities with the concept of bounded rationality, according to

which decision-makers seek satisfactory rather than optimal solutions. Complementary models highlight the roles of intuition, incrementalism, and uncertainty (Lindblom, 1959; Dane & Pratt, 2007; Cohen et al., 1972; Kahneman & Tversky, 1979).

Decision-making also varies by planning horizon. Operational decisions address short-term, routine matters, tactical decisions focus on medium-term resource allocation, and strategic decisions shape long-term organizational direction. Complexity and uncertainty increase with the decision level, influencing information needs and responsibility distribution (Chopra & Meindl, 2007; Misni & Lee, 2017).

Organizational structure and culture further shape decision processes. Bottom-up approaches, common in agile settings, emphasize decentralized and participatory decision-making, while top-down hierarchies concentrate authority. Group-based decisions, such as those in interdisciplinary AEC project teams, benefit from diverse perspectives but risk groupthink (Turner & Pratkanis, 1998).

This variety raises a central question: how should decision-making rights (DR) be distributed — centrally or decentrally? In modern organizations, DR are increasingly differentiated. Specific rights apply to codifiable processes, whereas residual rights remain in complex, uncertain situations. Sreckovic and Windsperger (2023) demonstrate, using blockchain-based organizations, that the degree of centralization depends largely on the codifiability of knowledge. The more a process can be formalized, the greater the potential for automation. Although derived from blockchain, this framework provides a valuable analogy for analyzing the impact of Agentic AI on organizational decision-making.

Limits of classic decision-making models

Modern decision-making faces increasing complexity, rapid market changes, and vast data volumes, exposing the limitations of traditional models (Davenport & Harris, 2007). Decisions are frequently made under conditions of incomplete information, time pressure, and cognitive constraints, which foster biases such as confirmation and overconfidence, as well as emotional misjudgments. Structural barriers—including information silos, lack of real-time data, and limited scalability—further restrict human decision-making capacity, particularly in dynamic environments (Berthet, 2021).

These constraints explain the growing importance of technology-based support systems. While business intelligence (BI) enables data-driven insights and real-time decision support (SAP, n.d.-b), Agentic AI goes further by independently analyzing situations, making decisions, adapting to change, and acting proactively (Stryker, 2024).

AI Agents and Agentic AI

Agentic AI is a key technology for automating complex tasks and enabling autonomous decision-making in dynamic, unpredictable environments (Finn & Downie, 2025). Unlike traditional AI systems that act reactively,

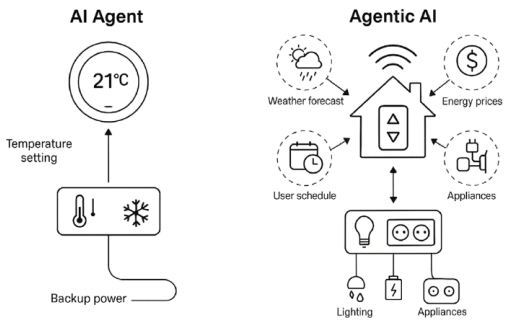

Figure 1: Comparative illustration of AI Agent vs. Agentic AI (Sapkota et al., 2026, p. 8)

agentic systems operate independently: they recognize goals, plan multi-step tasks, and orchestrate external tools or sub-agents to achieve outcomes (Stryker, 2024; Weiler. 2024). By combining the linguistic versatility of large language models with the structured precision of traditional programming, Agentic AI enables end-to-end automation of complex processes (Guan et al., 2024; Stryker, 2024; Finn & Downie, 2025). Rather than generating content on demand, these systems act proactively as goal-oriented collaborators, as illustrated in the smart home example (Figure 1).

The integration of Agentic AI into business processes shifts decision-making from passive suggestions to active, autonomous execution (Ismail, 2025; Fincken, 2024). While generative AI focuses on linguistic content, agentic systems introduce a new automation logic through strong reasoning, modular tool use, and goal pursuit, expanding their applicability across industries (Deslandes, 2025; Zhang, 2025). Key distinctions between AI paradigms are summarized in Table 1 (Sapkota et al., 2026).

Table 1: Key Differentiating Attributes of AI Agents, Agentic AI, and Generative Agents

Aspect	AI Agent	Agentic AI	Generative Agent
Primary Capability	Task execution	Autono-mous goal setting	Content generation
Planning Horizon	Single-step	Multi-step	N/A (content only)
Learning Mechanism	Rule-based or supervised	Reinforce-ment/meta-learning	Large-scale pretraining
Interaction Style	Reactive	Proactive	Creative
Evaluation Focus	Accuracy, latency	Engagement adaptability	Coherence, diversity

AI in AEC

The literature in the AEC domain shows that AI implementation is primarily focused on automated design generation, building performance optimization, system diagnostics enhancement, digital twin operations, and assistance in urban-scale planning, with the broader context of the built environment missing such as the building life-cycle (Lee et al., 2025; Khodabandelu &

Park, 2021; Piccialli et al., 2025). In their review of currently existing AI deployment limitations, Lee et al. (2025) mention: 1) predominant reliance on user-side prompt engineering (lack of a structured knowledge engineering framework); 2) missing comprehensive AI workflows and no knowledge integration with existing systems; 3) deficiencies in standardization and real-world validation (absence of in-depth real-world application resp. evaluations for benchmarking). Regarding collaborative integration and decision-making, Lee et al. (2025) argue that Agentic AI can enhance existing workflows and accelerate the transition toward Human-AI collaboration in the built environment.

The question remains here – how would these scalable integrations of AI work in the organizational setting and decision-making context? So far on the global level, the construction sector shows significant barriers to adopting and scaling AI use, including lack of skilled personnel; integration with existing systems – where companies strive to find flexible and transparent integration options from technology vendors, i.e. interoperable systems for AI integration with their current existing solutions, organizational structures and workflows; data quality and availability; and high implementation costs (RICS, 2025).

Methodology

Study design and sample

Agentic AI represents a novel and under-researched field, particularly regarding its organizational integration and implications. Given the absence of consolidated theoretical frameworks, a qualitative exploratory research design was adopted to generate new insights rather than test existing hypotheses (Corbin & Strauss, 2008).

Semi-structured expert interviews were selected as the data collection method, as they are well-suited for exploring complex, dynamic, and emerging topics and provide access to specialized expert knowledge (Patton, 2002; Saldaña, 2013). The interview guide was divided into five thematic blocks: (1) professional background of the interviewees and their points of contact with Agentic AI, (2) areas of application and potential of Agentic AI, (3) integration into internal company decision-making processes, (4) organizational and procedural implications, and (5) future prospects and integration recommendations. The guide was slightly adapted during the course of the survey in order to specifically address and further develop findings from previous interviews, such as the distinction between Agentic AI and Generative AI (Urquhart et al., 2010).

The interviewees were selected through criterion sampling, focusing exclusively on experts with direct experience in agent-based AI systems. The final sample comprised seven experts from the SAP corporate ecosystem, including SAP in-house specialists, implementation partners, and customer-side users already deploying Agentic AI productively. This diversity of roles — spanning technical, strategic, and innovation perspectives — enabled a multifaceted understanding of both technological and organizational aspects of Agentic AI integration. The focus on the SAP environment was deliberate, given the company's leading position in enterprise software and its substantial strategic investment in Agentic AI (Katanich, 2025; SAP, 2025). The ecosystem provides rich insights that are expected to be transferable to the AEC industry.

Data collection and analysis

The seven semi-structured interviews were conducted in German and English from June to July 2025, based on an interview guide that included open-ended questions.

The interview data was evaluated using the qualitative analysis software ATLAS.ti as part of a combined deductive-inductive process. The coding in ATLAS.ti yielded some insightful and interesting findings regarding the integration and impact of Agentic AI in decision-making processes. Table 2 shows a coding example.
Key topics were derived from the literature, systematically queried, and the corresponding responses were coded deductively. This was supplemented by an inductive approach, in which new categories and patterns, developed from the material, were identified and coded in summary form (Gioia et al., 2012, p. 10; Mayring & Fenzl, 2019, p. 641; Saldaña, 2013, p. 9).
Generated from ATLAS.ti, Table 3 provides an overview of all categories, including the corresponding number of codes, the assigned code group based on the structure of the interview guide, and the number of associated quotes. A total of 74 codes were applied to 325 quotes from seven

Table 2: Exemplary coding

Code group	Category	Code	Quote
Applications & Potential of Agentic AI	Current Applications	Variety of Agents	*"And we already have an agent in use, so to speak—this Classification Agent—which is currently helping in our call centers to structure customer inquiries. It essentially identifies the correct category for the inquiry so that the right agent can then work on the ticket. That was a big step forward. "* (Interviewee No. 2) *"It looks at your code, makes suggestions, writes code for you—whatever you want. Cursor is probably the agent I use the most. It basically executes code for you, writes code for you, tests the code for you, pushes it to GitHub into this external environment where you share the code with others, and also performs the operations you want there."* (Interviewee No. 7)
Effects of Integration	Structural Changes	Regulated Decision-Making & Decision Support	*"[Fully autonomous decision-making] will probably come eventually, but I don't see it happening right now; though I actually think it's quite good."* (No. 1) *"Yes and no—regulated decision-making, that is. It's not simply the system deciding a large part of our business plan, for example. It's about specific and limited decisions for specific environments."*(No. 7)

Table 3: Coding overview

Category	Nr. of Codes	Group / Document Group	Nr. of Quotations

interviews. Some quotes were assigned to multiple codes, as they address various aspects simultaneously. The coding was carried out in several cycles according to Saldaña (2013). In the first cycle, in-vivo coding (recording of direct quotes) and structured coding (thematic categorization based on the interview guide) were combined to capture both the interviewees' verbatim statements and the key thematic areas. Deductive coding was applied to, among others, "Agentic AI characteristics: Autonomous," "Structural changes: Centralization," or "Codifiability of processes," as these were specifically addressed in the interview guide. Additionally, categories with codes were developed inductively from the empirical material—for example, "Prerequisites for deployment: Cost-effectiveness over hype," "Structural Changes: Agents as Team Members," or "Long-Term Effects: Changed Work Methods & New Competency Requirements." In the second cycle, thematically related codes were bundled, abstracted, and merged into higher-level codes using *pattern coding*. This thematic grouping reduced the complexity of the analysis without losing depth of content. To avoid excessive differentiation through individual codes and the resulting high complexity of the analysis given an exceptionally large number of codes, thematically related codes were consolidated. For example, statements that were originally coded separately, such as "Test locally, then scaled centrally," "Test user groups," "Iterative approach," and "Trial & Error," were grouped into a single subcategory: "Test phase & scaling".

Discussion of results

This study provides answers to the research question of *how Agentic AI is integrated into corporate systems to optimize decision-making processes and what effects this integration has on the internal structure*.

The interview results show that Agentic AI is currently being implemented primarily as intelligent assistance that supports, accelerates, and partially automates decision-making processes—but without completely delegating control. Integration is taking place gradually and selectively, depending on the technological and organizational maturity of the company.

A common thread runs through the interviews: there is agreement on many aspects – in particular on the supporting role of Agentic AI, the importance of technical prerequisites such as data quality and system transparency, and the need for human control in the sense of a human-in-the-loop principle. At the same time, differing perspectives and uncertainties arise on key issues such as the codifiability of processes: some respondents consider it an indispensable prerequisite for the use of agents, while others see modern LLM-based architectures as sufficiently flexible to automate even semi-structured processes. The integration of Agentic AI is already having structural effects. New roles have been identified, such as agent architects and strategic AI managers, who do not perform operational tasks but instead coordinate the technology in a targeted manner. At the same time, Agentic AI is transforming traditional decision-making processes and contributing to the reorganization of workflows, for example, by automating repetitive tasks. Simultaneously, there is an apparent discrepancy between the way it is presented in publications and its actual implementation in practice.

All interviewees recognize the potential of Agentic AI, particularly with regard to efficiency gains, process improvements, and new forms of decision support. The central challenge is how and under what conditions it can be sustainably integrated into existing structures.

Organizational prerequisites and design factors

The successful integration of Agentic AI into corporate decision-making processes is not solely a question of technological feasibility- it strongly depends on organizational and infrastructural prerequisites. Many of those are not only conditions for meaningful
use, but offer concrete recommendations for action for successful and sustainable implementation. They are therefore consolidated in Table 4 as key success factors. To enhance practical utility, we augment each factor with concrete implementation examples drawn from the expert interviews and measurable success metrics.
Current market studies also illustrate that the use of Agentic AI often fails due to a lack of system transparency, fragmented IT landscapes, and inadequate infrastructure. Belcic and Stryker (2025) and Sj (2025)

Table 4 : Key Success Factors with Metrics

Success Factor	Description	Implementation Example (from interviews / practice)	Suggested Success Metrics
Economic efficiency over hype & Strategic selection	Focus on business value rather than technology trends; prioritize use cases	One SAP partner expert described starting with a procurement classification agent that flags non-compliant invoices before full automation (reducing manual review by ~40% in pilot). Similar to Coupa's autonomous procurement intelligence	ROI of agentic initiatives; cost savings vs. implementation effort; prioritized use-case coverage rate
System transparency & process clarity	Clear system landscape SAP workflows first and integrable, data-supported workflows	Interviewees emphasized mapping existing SAP workflows first (e.g., end-to-end procure-to-pay) beforeintroducing agents. DHL-style real-time logistics agents require interoperable date pipelines	Process mapping completeness score; quality index; system integration error rate
Technological & organizational implementation capabilities	Digital infrastructure foundation plus internal resources	Experts recommended pilot projects in logistics/supply chain using SAP Joule as a digital assistant before scaling to multi-agent orchestration	Infrastructure readiness score; training hours per employee; internal AI skill coverage
Governance & agent logic	Defined responsibilities, control structures, and comprehensible agent objectives	SAP customer-side expert described a multi-level approval workflow; agents handel routine procurement decisions up to €50k threshold, with automatic escalation to human "AI managers" above that	Agent goal alignment score; transparency/explainability index; governance policy adherence rate
Human control & monitoring	Human-in-the-loop structures with continuous oversight	All interviewees stresses "supervisory" roles; one example involved a quality-control agent in manufacturing that requests human input on edge cases (e.g., unusual material defects)	Human override rate (<15% target for codifiable processes); escalation frequency trend
Responsibility & Supervision /Change management & test phase	Iterative introduction with pilot phases and stakeholder participation	Experts advocated starting with 3-6 months pilots (e.g., ticket classification or invoice agent) followed by feedback loops and role definition workshops	Adoption rate; employee trust/satisfaction score (via pulse surveys); pilot-to-scale success rate

emphasize the need for robust, scalable architectures, while Noureen (2025) points out that despite a projected potential of over USD 450 billion, many companies do not have the technological maturity and organizational capability to implement it. These findings are consistent with the interviews conducted for this study, in which statements regarding the success factors "system transparency & process clarity" and "technological & organizational feasibility" was mentioned repeatedly. In addition, Shavit et al. (2023) provide concrete governance practices for the responsible use of Agentic AI. They emphasize the importance of transparent agent logic, automated monitoring, and limiting scope for action, thereby underscoring the relevance of the empirically derived factors "governance & agent logic" and "human control & monitoring".

Table 5 shows examples of areas of application and associated agent solutions that have already been discussed theoretically in this paper and have now been empirically confirmed (Capgemini, 2025; Dudley & DelMastro, 2025; Finn & Downie; Weiler, 2024).

Organizational transformation and decision-making rights

Agentic AI is currently understood primarily as a support system that structures, accelerates, and supplements decision-making processes, but not as an autonomous decision-maker. The experts surveyed describe a hybrid control model in which humans increasingly act as "AI managers" (Nicoud, 2025; Raskovich et al., 2024).
Responsibility remains deliberately with humans, especially in sensitive or strategic contexts, in contrast to simple and predominantly operational decisions, which can be automated to a greater extent. This tension between automation and control is consistent with the literature on human-in-the-loop principles and the emphasis placed by Shavit et al. (2023).

Table 5: Exemplary areas of application

Administration	Granola Note-taker, follow-up emails after meetings
Logistics & Supply Chain	Quality control agent, invoicing agent
E-commerce	Shopping agent
Marketing, Sales & Service / CX Area	Ticket Classification Agent, User Story Refinement Agent
Travel Industry	Booking Agent
Support	Code Generation / Cursor Pro / GitHub, Web Application, Security Agent
Wide range of applications	Digital Assistant Joule, Test Automation Agent
AEC	Autonomous calculations, code compliance check; proactive BIM model validation, clash resolution suggestions; risk-monitoring etc.

To move from current supporting roles toward more advanced hybrid decision-making, organizations can follow this practical pathway (derived from interviewee forward-looking statements and aligned with emerging industry roadmaps):

1. ***Pilot Stage (Awareness & Selective Automation)***: Focus on narrow, high-volume, codifiable tasks (e.g., invoice classification, routine scheduling). Emphasize data quality, transparency, and human oversight. The goal: Prove value and build internal trust.
2. ***Scaled Integration Stage (Hybrid Orchestration)***: Expand to multi-step processes involving sub-agents

(e.g., procurement agent coordinating with logistics and compliance agents). Introduce new roles such as agent architects and AI governance leads. Governance frameworks become central.

3. ***Optimized Autonomy Stage (Strategic Human-AI Collaboration)****:* Agents handle end-to-end operational decisions with minimal intervention in well-defined domains, while humans focus on strategic oversight, exception handling, and innovation. Continuous learning loops and ethical guardrails are fully embedded. This pathway helps companies progress gradually while mitigating risks such as loss of control or competence erosion.

The interviews also show that Agentic AI is increasingly seen as a team member rather than just a technical tool. Agents take on preparatory tasks, while final responsibility remains with humans—a division of roles that is also reflected in theory. At the same time, there is tension between decentralized use (in specialist areas) and centralized control through governance and monitoring (Accelirate, 2025; Nicoud, 2025). Efficiency and scalability can be ensured through central standards and control.

The codifiability framework also finds confirmation here. While standardized, codifiable decisions are increasingly being made automatically, residual decision-making rights in unclear, dynamic situations remain with human actors. In practice, therefore, Agentic AI is not used as a substitute, but as a cognitively complementary system (Sreckovic & Windsperger, 2023).

At the same time, organizational shifts are becoming apparent: new roles and skills are emerging, such as prompt designers, agent architects, and agent orchestrators; traditional process responsibilities are being replaced by cross-functional coordination and monitoring tasks. Successful integration of Agentic AI is not only a technical challenge, but an organizational transformation process – with clear responsibilities and new roles (Ismail, 2025; Nicoud, 2025).

Areas of tension and open questions

Despite the recognizable progress and potential associated with the use of Agentic AI, key areas of tension and unresolved issues remain. These relate not only to technological and organizational dimensions, but also to ethical, legal, and social aspects. A key area of tension is the discrepancy between public expectations and corporate reality. While media reports and specialist publications often outline the increasing dominance of autonomous, proactive agents, practical reports and the present study show that companies are currently still struggling with fundamental challenges: a lack of process standards, limited data quality, fragmented IT landscapes, and cultural reservations are hindering implementation (Belcic & Stryker, 2025; Dudley & DelMastro, 2025; Noureen, 2025). Another key area of tension concerns the relationship between autonomy and control. The more powerful Agentic AI becomes, the more pressing the question of legal, ethical, and operational frameworks becomes. Without clear accountability, comprehensible agent goals, and ethical guidelines, there is a risk of losing control—not only technically, but also socially (Weiler, 2024; Zhang, 2025). In addition, questions of efficiency versus competence development are gaining in importance. As agents increasingly take on routine tasks, junior roles in particular are coming under pressure. This is preventing learning and development opportunities, hence poses risk to the long-term retention of competence in organizations.

Furthermore, authors such as Ghose (2024) and Shavit et al. (2023), in line with the experts in this study, call for robust governance approaches not only at the corporate level, but also by social actors. In this context, governance refers to the entirety of institutional regulations, processes, and control mechanisms for the responsible design, control, and monitoring of technology use. This includes, e.g. legal minimum standards for transparency, data protection, the control of algorithmic biases, and the traceability of agentic decisions.

Finally, security risks should not be underestimated. Lack of traceability, potential for abuse, inadequate training, or hallucinations can have legal, technical, commercial, and social consequences. These risks, which were addressed in the interviews, are also confirmed in other articles (Ghose, 2024; Ramel, 2024).

New AEC Implications

Although the empirical findings are rooted in the SAP enterprise ecosystem, they carry relevant implications for the AEC industry, where AI adoption remains limited and fragmented (RICS, 2025; Lee et al., 2025). Construction projects are characterized by high uncertainty, fragmented workflows, data silos across design, procurement, and on-site execution, and stringent requirements for safety, compliance, and lifecycle performance. Agentic AI can address these challenges by enabling proactive, multi-step automation that goes beyond current reactive tools. For instance, agentic systems could autonomously validate BIM models in real time, detect and resolve clashes, monitor project risks through integration with digital twins and sensor data, and optimize resource allocation across supply chains while escalating complex or high-stakes decisions to human supervisors.

Drawing on the success factors, AEC organizations could begin with targeted pilots in codifiable areas such as automated code compliance checks or progress reporting, then progress toward hybrid orchestration involving coordinated agents for design optioneering, predictive scheduling, and sustainability assessments. The human-in-the-loop governance structures and phased transition pathway proposed here are particularly valuable in construction's risk-averse environment, where full autonomy must be balanced with accountability and regulatory compliance. As noted by Lee et al. (2025),

Agentic AI has strong potential to accelerate the shift toward true Human-AI collaboration in the built environment, yet success will depend on overcoming barriers such as poor data interoperability, skills gaps, and fragmented IT landscapes—precisely the organizational prerequisites emphasized in our findings. Future AEC-

specific applications could therefore benefit from adapting the codifiability framework and governance logic to the sector's unique project-based and multi-stakeholder context.

Limitations and further research

The results are based on a limited number of expert interviews with seven participants from the SAP corporate environment. This provided focused insight into the current practice and perception of Agentic AI, but limits the representativeness and generalizability of the results. In addition, all interview partners come from the Austrian/Germany/Switzerland region, which results in geographical homogeneity and limits the application to other cultural or economic contexts. Furthermore, the study is a snapshot of a dynamically developing field of research. Agentic AI is still in the pilot stage in many organizations, which is why numerous assessments are based on hypothetical assumptions or early experience. Rapid technological development can mean that individual findings become obsolete in a short period of time. Conceptual limitations are also apparent at the theoretical level. The analysis is primarily based on decision-making and organizational theory as well as the concept of codifiability. Other theoretical perspectives, such as ethical or legal approaches, were not systematically included. While this deliberate focus enables a targeted analysis of organizational decision-making processes, it also opens up space for future interdisciplinary research.

Despite methodological rigor, a certain degree of subjective interpretation is unavoidable when evaluating qualitative data. The subjectivity of the statements and potential distortions pose further methodological challenges. Future studies should specifically address these limitations. Quantitative studies with larger and more diverse samples could help to validate the patterns identified in this study and test their transferability to other contexts. There is also a need for further research in the form of longitudinal studies that examine changes in decision-making structures, role profiles, and governance systems over a longer period of time.

Conclusion

In the long term, the use of agentic AI will not only bring technological innovations, but also profound changes for organizations. This is not just a matter of more efficient processes, but of structural change. Working methods are changing, new roles are emerging, and the requirements for skills are shifting significantly—especially in the coordination and responsible control of intelligent agents. At the same time, the tension between technological progress, regulatory frameworks, and sustainable action remains. While autonomous agents appear as key decision-makers in some future scenarios, the question remains as to how much responsibility such systems can—and should—actually assume. The increasing pressure to innovate and rapid developments in the field of AI require companies not only to invest in technology, but also to develop a new understanding of leadership, trust, and responsibility, as well es AI Capabilities. These areas of tension mark central topics for future research and the governance of Agentic AI design.

NEURO-SYMBOLIC REINFORCEMENT LEARNING FOR MULTI-CATEGORY CONSTRUCTION RELATIONSHIP WITH REASONING AND SEQUENCE PLANNING

Akarsth Kumar Singh and Shang Hsien Heish
National Taiwan University, Taipei, TAIWAN

Abstract

Construction planning depends on tacit expertise that is rarely captured, causing recurring knowledge loss and weak standardization across projects. This paper presents a neuro-symbolic reinforcement learning framework for multi-category construction relationship reasoning that converts execution logic into explicit, domain-grounded constraints. It integrates synthetic WBS generation, LLM-based constrained reasoning, and Group Relative Policy Optimization (GRPO) with symbolic rewards to generate explainable relationship graphs at inference time. Results demonstrate stable learning, over 75% structural validity and reasoning quality across categories, bounded policy divergence, and reduced truncation, supporting more consistent, reusable, and auditable automated construction planning.

Introduction

Construction planning in practice is rarely a standardized or transferable process. Instead, it relies heavily on planners' tacit knowledge, informal judgment, and accumulated site experience. This knowledge is seldom codified. When a project concludes, the sequencing logic and coordination strategies developed during execution leave with the planner, while organizations retain only static schedules that record outcomes rather than the reasoning behind them (Koo et al., 2007). As a result, planning knowledge is repeatedly lost, forcing each project to relearn previously acquired lessons and contributing to persistent inefficiencies in construction delivery (Wu et al., 2010; Amer et al., 2023).

This limitation is compounded by the fact that construction execution is governed by a wide range of construction execution constraints that extend far beyond what is explicitly represented in formal schedules. These constraints encompass interdependent structural, temporal, resource, cross-discipline, quality, and safety considerations that are typically managed implicitly through informal coordination rather than codified planning artifacts. When such coordination fails, the consequences include rework, schedule delays, cost overruns, and safety risks. The persistent gap between documented plans and the constraints that must be coordinated on site remains a primary source of inefficiency in construction projects (Pfitzner et al., 2024; Soman and Molina-Solana, 2022). Capturing and reasoning over these interacting constraints simultaneously imposes a cognitive burden that exceeds the limits of manual planning processes, particularly for large-scale projects.

In this context, artificial intelligence becomes a necessary enabler rather than a mere productivity enhancement. While other industries have adopted AI-driven planning and coordination, construction planning remains largely manual and experience-dependent (Rashid and Louis, 2019). Recent advances in large language models and reinforcement learning offer an opportunity to formalize and automate the reasoning processes that planners currently apply implicitly. However, for AI to deliver meaningful value in construction, it must move beyond isolated automation of scheduling logic and instead reason explicitly across interacting execution constraints in an explainable and transferable manner. Such relationship modeling is also foundational for downstream applications, including 4D BIM simulation, automated project controls, and delay analysis.

Existing research has addressed individual aspects of this problem. Reinforcement learning has been applied to optimize resource-constrained sequencing (Yao et al., 2024; Kedir et al., 2022), natural language processing models have inferred scheduling dependencies from historical data (Amer et al., 2023), BIM-driven methods have automated schedule generation from geometric models (Faghihi et al., 2014; Gan, 2022), and knowledge graphs have been used to structure construction process information (Pfitzner et al., 2024; Shan et al., 2025). Large language models have further shown promise in compliance checking and construction knowledge extraction (Yang and Zhang, 2024; Zhang et al., 2025). Despite these advances, existing approaches remain fragmented, typically addressing only a limited subset of construction relationships in isolation. None provides a unified framework for reasoning jointly across the full spectrum of execution constraints.

Based on this gap, three core challenges must be addressed to enable practical and transferable AI-driven construction planning.

Challenge 1: Multi-category reasoning. Construction relationships span multiple interacting categories, including scheduling logic, structural and physical constraints, resource requirements, temporal constraints, cross-discipline coordination, quality and inspection requirements, and safety and permitting rules. These

categories are tightly coupled, as physical and regulatory constraints directly shape feasible sequencing and temporal dependencies. Effective reasoning therefore requires these relationships to be considered jointly rather than independently.

Challenge 2: Symbolic grounding. Construction relationships are governed by domain invariants derived from physical laws, material behavior, regulatory codes, and established construction methodologies. Predictions that violate load-path logic, omit mandatory inspections, or ignore curing requirements are not merely inaccurate but potentially unsafe. Learning-based models must therefore be grounded in explicit symbolic representations that enforce these constraints.

Challenge 3: Explainability and standardization. For AI-generated plans to be trusted, adopted, and reused across projects, each predicted relationship must be accompanied by a clear justification traceable to domain knowledge. Explicit reasoning enables standardization and knowledge transfer, directly addressing the chronic loss of planning knowledge observed in current practice.

To address these challenges, this research proposes a neuro-symbolic reinforcement learning framework for multi-category construction relationship reasoning. The framework integrates symbolic domain knowledge with learned reasoning policies through this research pipeline. First, a synthetic Work Breakdown Structure generation process produces structurally valid construction inputs at scale. Second, multi-category relationships are inferred using an ensemble of large language models constrained by formalized domain knowledge, generating reasoning-annotated dependency datasets across multiple execution constraint categories. Third, a 7B-parameter small language model is fine-tuned using Group Relative Policy Optimization with a composite reward function that encodes relationship correctness, directed acyclic graph validity, temporal plausibility, constraint compliance, and category coverage. Finally, the trained model generates explainable, multi-category relationship graphs for unseen inputs at inference time. Symbolic knowledge serves a dual role by grounding reasoning during data generation and providing verifiable reward signals during policy optimization.

The contributions are threefold. First, this research introduces a unified neuro-symbolic formulation for construction relationship reasoning, converting tacit planning knowledge into explicit, verifiable constraints rather than relying on symbolic rules or learning models alone. Second, it develops an LLM-driven data generation pipeline that produces reasoning-annotated construction relationship datasets with explicit justifications. Third, it provides a reproducible performance reference for multi-category dependency prediction using reinforcement learning with symbolic rewards, where LLM reasoning serves as the pre-optimization benchmark and supports explainable, standardized knowledge transfer across projects and organizations.

Related Work

AI for Construction Planning and Scheduling

Research on automated construction planning has progressed through several methodological paradigms. Early work emphasized constraint-based and rule-driven approaches using predefined methods, sequencing templates, and resource packages. For example, Wu et al. (2010) applied simulation and pattern-matching to generate schedules under explicit constraints, while Koo et al. (2007) formalized sequencing rationale through a constraint ontology for representing activity logic. Subsequent BIM-driven approaches leveraged geometric and structural information. Faghihi et al. (2014) employed genetic algorithms to derive structurally feasible sequences, and Gan (2022) introduced a graph-based model integrating IFC semantics and spatial topology for modular design generation. Despite their effectiveness, these methods typically address isolated relationship categories, such as scheduling or structural constraints, and depend on hand-coded rules that limit adaptability across projects.

Recent studies have shifted toward data-driven learning of construction sequencing. Amer et al. (2023) used transformer models to infer dependency constraints and generate lookahead plans, while Rashid and Louis (2019) demonstrated activity pattern recognition using deep learning with synthetic data. However, these approaches lack explicit symbolic grounding, failing to enforce domain invariants such as load transfer, curing constraints, and inspection requirements, thereby limiting reliability in safety-critical planning contexts.

Reinforcement Learning in Construction

Reinforcement learning has emerged as a promising paradigm for optimizing construction scheduling decisions under uncertainty and resource constraints. Yao et al. (2024) proposed a deep reinforcement learning framework with valid action sampling and graph convolutional feature extraction, achieving reduced project durations compared to heuristic baselines. Kedir et al. (2022) combined reinforcement learning with agent-based modeling and graph embeddings to optimize activity sequencing under constrained resources. Soman and Molina-Solana (2022) applied Q-learning with linked-data-based constraint checking to automate lookahead schedule generation, illustrating the potential of reinforcement learning as a decision support tool for short-term planning. More recently, Yang et al. (2026) introduced the Construction Markov Decision Process framework, employing multi-agent proximal policy optimization to simulate crew-level decision-making across multiple construction stages with spatial dynamics.

Despite these advances, reinforcement learning applications in construction have largely focused on optimizing scheduling objectives such as project duration or resource utilization within narrowly scoped problem formulations. Symbolic domain knowledge is typically applied as hard constraints or pre-processing checks rather than being embedded directly into the reward

structure. As a result, these models neither reason across multiple categories of construction relationships nor provide explicit, explainable justifications for predicted dependencies, limiting their usefulness for knowledge transfer and practitioner adoption.

Knowledge Graphs, Ontologies, and Semantic Reasoning in Construction

Knowledge representation through ontologies and knowledge graphs has a long-standing role in construction informatics. Pauwels et al. (2017) enhanced the ifcOWL ontology with optimized geometric representations to improve semantic BIM data exchange. Zhang and El-Gohary (2017) integrated semantic NLP with logical reasoning for automated building code compliance and later extended this work using transformer-based models to align IFC entities and regulatory concepts within a knowledge-graph-enhanced classification framework Zhang and El-Gohary (2023). Ding et al. (2016) proposed an ontology-based framework for construction risk knowledge management, enabling semantic inference of risk interdependence in BIM environments. Collinge et al. (2022) developed a BIM-based safety ontology to support prevention-through-design by structuring tacit and explicit knowledge. More recently, Pfitzner et al. (2024) constructed knowledge graphs from continuous site image data, linking detected objects to spatiotemporal metrics for progress monitoring.

These studies demonstrate the value of structured knowledge representations for specific domains such as safety, compliance, risk management, and progress tracking. However, most knowledge graph–based systems remain static or query-driven and are not integrated with learning-based policy optimization. Moreover, they are typically domain-specific and do not provide a unified representation that jointly captures scheduling, structural, resource, temporal, cross-discipline, quality, and safety relationships required for automated construction planning.

Large Language Models and Neuro-Symbolic Approaches in AEC

Large language models have recently been introduced to address knowledge-intensive tasks in the AEC domain. Yang and Zhang (2024) demonstrated prompt-based automation of building code information transformation, achieving high precision with limited training data. Zhang et al. (2025) proposed a JSON-based agent schema for LLM-driven building energy analysis, enabling reusable agent workflows. Shan et al. (2025) applied LLMs with in-context learning to automate knowledge graph construction for building health resilience using multi-modal data. More broadly, Pan et al. (2023) highlighted the potential of integrating LLMs, which encode parametric knowledge, with knowledge graphs, which represent explicit symbolic knowledge, to overcome limitations inherent in either paradigm alone.

Despite these promising developments, current LLM applications in construction remain predominantly zero-shot or few-shot and rely heavily on prompt engineering rather than systematic learning. Generated outputs are rarely validated against domain knowledge, often lack consistency across relationship categories, and provide no guarantees of physical or regulatory correctness. Furthermore, no prior work combines LLM-based symbolic reasoning for dataset generation with reinforcement learning–based policy optimization for construction dependency prediction. The framework proposed in this study addresses this gap through a neuro-symbolic pipeline in which formalized domain knowledge grounds LLM reasoning during data generation and simultaneously serves as a verifiable constraint signal during reinforcement learning optimization The reasoning-annotated outputs generated by the LLM during data construction serve as the reference against which the RL-trained model is evaluated, implicitly establishing prompted LLM reasoning as the performance reference point that policy optimization is designed to exceed.

Problem Formulation

Given a Work Breakdown Structure (WBS) instance

$$W = \{h, p, l, O, T\}$$

where h denotes the construction head (discipline), p the work package, l the location (building, floor, or zone), O=$\{o1,\ldots,om\}$a set of structural or MEP objects, and T=$\{t1,\ldots,tn\}$ a set of construction tasks without explicit dependencies, the objective is to infer a multi-category construction relationship graph

$$G = \{(r_i, c_i, l_i, e_i)\}_{i=1}^{|G|}$$

Each relationship tuple consists of:

- ri=$(from,to,link_type,lag)$, a directed dependency between two tasks or objects with an associated precedence type (FS, SS, FF, SF) and lag duration;
- $ci \in C$, the relationship category (scheduling, structural, resource, temporal, cross-discipline, quality, or safety);
- li, a natural-language justification traceable to domain knowledge;
- $ei \in [0,1]$, a confidence score.

Figure 1 illustrates a sample multi-category relationship graph for a column construction WBS scope, where nodes represent tasks and directed edges encode relationship tuples across structural, quality, temporal, and scheduling categories with associated confidence scores.

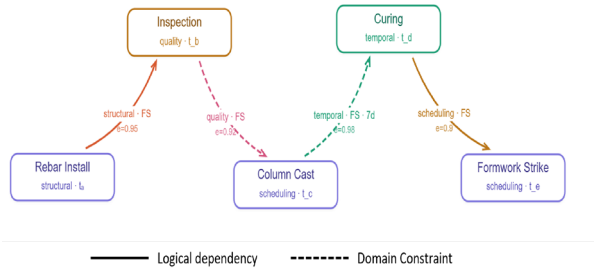

Figure 1: Example multi-category construction relationship graph G inferred from a column construction WBS instance

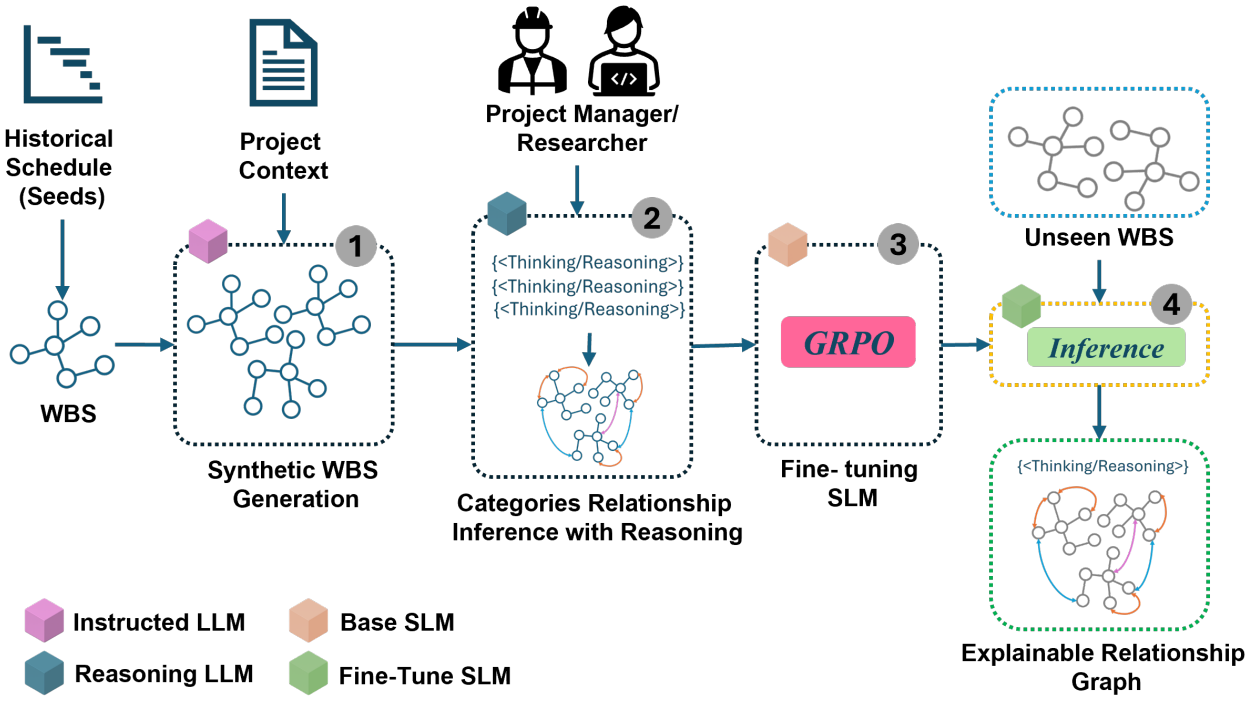

Figure 2: Overview of Framework

The predicted graph G must satisfy three validity conditions:

(1) graph validity, such that scheduling relationships form a directed acyclic graph;

(2) physical feasibility, ensuring compliance with gravity-driven load transfer and construction logic; and

(3) domain compliance, meaning all applicable construction constraints are respected.

Methodology

The proposed methodology integrates synthetic data generation, domain-constrained reasoning, and reinforcement learning to enable multi-category construction relationship inference. As illustrated in Figure 2, the framework begins with the generation of diverse Work Breakdown Structure representations reflecting realistic construction contexts without explicit dependency information. Construction relationships are then inferred category-by-category using large language model reasoning grounded in explicit domain constraints, generating directed edges between task nodes with accompanying explanatory traces. These outputs train a small language model through reinforcement learning, where symbolic constraints are embedded directly into the optimization objective as verifiable reward signals. During inference, the trained model generates explainable construction relationship graphs validated for scheduling acyclicity and physical compliance before being finalized across all execution categories.

Domain Knowledge Representation

Construction knowledge that is typically implicit in planners' experience is formalized as a set of verifiable domain constraints expressed as predicates over the relationship graph G — for example, $\text{supports}(o_i, o_j) \rightarrow \text{precedes}(\text{task}(o_i), \text{task}(o_j))$ for structural load transfer, or $\text{requires_inspection}(t_i) \rightarrow \text{precedes}(\text{inspection}(t_i), t_j)$ for safety compliance. These constraints encode principles derived from structural mechanics, material behavior, construction methodology, trade coordination practice, and regulatory requirements. Each constraint maps to one or more relationship categories and can be automatically evaluated against a predicted graph, enabling both dataset validation and reward computation without manual annotation.

Synthetic WBS Generation

Labeled multi-category construction data is scarce due to proprietary schedules and inconsistent documentation practices. To address this, synthetic WBS instances are generated using template-based augmentation grounded in real project schedules. Recurring WBS patterns are first extracted from reinforced-concrete building projects, capturing typical relationships among construction heads, work packages, locations, objects, and tasks. These patterns are then provided to an instruct-tuned LLM, which generates diverse yet domain-consistent WBS instances by varying contextual attributes such as floor levels, object types, and task labels. Each generated WBS is normalized into a unified schema containing tasks and objects but no explicit dependencies, ensuring that all relationships must be inferred by the model.

Multi-Category Relationship Inference via LLM Reasoning

Each synthetic WBS instance is processed by a reasoning-oriented large language model to infer construction relationships across scheduling, structural, resource, temporal, cross-discipline, quality, and safety categories. Inference is performed in a category-aware manner, reasoning over one category at a time while maintaining

global context consistency. The model receives structured WBS inputs with category-specific domain knowledge to generate structured relationship outputs while verifying assumptions. Category-specific schemas define representations such as precedence and lag (scheduling), load-transfer logic (structural), and clearance or inspection requirements (quality and safety). For each category, the model outputs relationships with justifications and confidence scores. Outputs are validated for logical and structural consistency and aggregated into a unified multi-category graph, retaining reasoning traces to support learning of reasoning quality alongside output correctness.

Reinforcement Learning with Symbolic Rewards

The small language model is fine-tuned using Group Relative Policy Optimization (GRPO) to learn construction relationship reasoning policies. For each WBS input, eight candidate relationship graphs (K=8) are sampled and ranked relative to one another using a symbolic, multi-component reward function (weights reported in the Experiments section), and policy updates reinforce higher-quality reasoning trajectories.

$$R(G) = \alpha_1 R_{correct} + \alpha_2 R_{format} + \alpha_3 R_{structure} + \alpha_4 R_{constraint} + \alpha_5 R_{reason}$$

$R_{correct}$ evaluates semantic agreement with reference relationship graphs generated during data construction.

R_{format} enforces strict adherence to the required output schema.

$R_{structure}$ validates category-specific structural properties, such as acyclic scheduling graphs and physically feasible dependencies.

$R_{constraint}$ verifies consistency with construction domain knowledge relevant to each relationship category.

R_{reason} rewards clear, internally consistent reasoning traces accompanying each prediction.

Each reward component is independently scaled to [0,1] prior to weighted aggregation, and GRPO advantages are computed as each candidate's reward minus the group mean, normalized by group standard deviation across the K=8 sampled graphs. This formulation allows multiple valid solutions while penalizing infeasible or poorly justified outputs. By embedding symbolic validation directly into the reward, the model internalizes domain-consistent reasoning rather than relying on post-hoc filtering. This design directly targets the known limitations of zero-shot LLM reasoning, inconsistency across relationship categories and lack of guaranteed domain compliance, as mentioned in the Related Work section.

Inference and Explainable Outputs

At inference time, a WBS instance is provided to the fine-tuned SLM, which generates a multi-category relationship graph with concise natural-language justifications for each dependency, reflecting the domain principles that motivate relationships and enabling transparency and interpretability. Since each WBS instance is processed independently, multiple instances can be inferred in parallel, enabling full project-scale schedule generation with inference time scaling linearly with the number of instances. Automated post-processing verifies scheduling acyclicity, structural feasibility, and domain compliance, flagging rather than discarding violations to preserve explainability. The final output can be directly consumed by scheduling software, BIM-based 4D simulation tools, or project control systems, and because each dependency includes a traceable justification, the generated plans are inherently transferable across planners and projects, directly addressing the knowledge loss problem identified in the Introduction.

Experiments

Dataset Construction

The experimental dataset was constructed using the proposed Stage 1 and Stage 2 pipelines, with a real-world residential construction schedule as the seed source. The project includes 28 Work Breakdown Structure (WBS) instances comprising 125 activities across substructure, superstructure, and finishing works. To enhance structural diversity and generalization, these WBS patterns were extended into synthetic variants representing multiple structural systems, including masonry, reinforced concrete, composite, precast, steel, and timber structures, specifically to mitigate the residential sequencing and coordination bias introduced by the single-project seed source. The final dataset contains 619 unique construction tasks spanning disciplines, locations, and object types. Using the Stage 2 reasoning pipeline, multi-category relationships were inferred for each task across seven execution categories, yielding 4,333 relationship annotations. The dataset was designed to maintain balanced representation across categories, preventing bias during training.

Reinforcement Learning Fine-Tuning

The policy model was initialized from Qwen3-4B-Base and fine-tuned using Group Relative Policy Optimization (GRPO). For each WBS input, eight candidate relationship graphs were sampled per training step and ranked using a symbolic, multi-component reward function. The reward combined output correctness (40%), format compliance (15%), output structure validity (25%), rule application consistency (10%), and reasoning quality (10%), ensuring balanced supervision across semantic accuracy, structural validity, and explanatory coherence. Training was conducted for five epochs with a batch size of 8 and a learning rate of 1×10^{-4}, using a cosine learning-rate scheduler with warm-up to improve training stability. All experiments were performed on a workstation equipped with an NVIDIA RTX 6000 Ada GPU (48 GB VRAM); the 4B-parameter model is additionally compatible with deployment on GPUs with 24 GB VRAM using standard quantization, broadening accessibility beyond high-end research hardware.

Results and Discussion

Training-Time Analysis (GRPO Optimization Dynamics)

Training results indicate that the proposed neuro-symbolic GRPO framework converges in a stable and

controlled manner. As shown in Figure 3, improvements in total reward are primarily driven by sustained gains in output correctness and rule-consistent reasoning, indicating that the policy progressively learns semantically valid construction relationships rather than merely satisfying structural or formatting constraints. Rule application improves steadily throughout training, confirming increasing internalization of symbolic domain knowledge, while format compliance and structural validity saturate early and function mainly as stabilizing constraints.

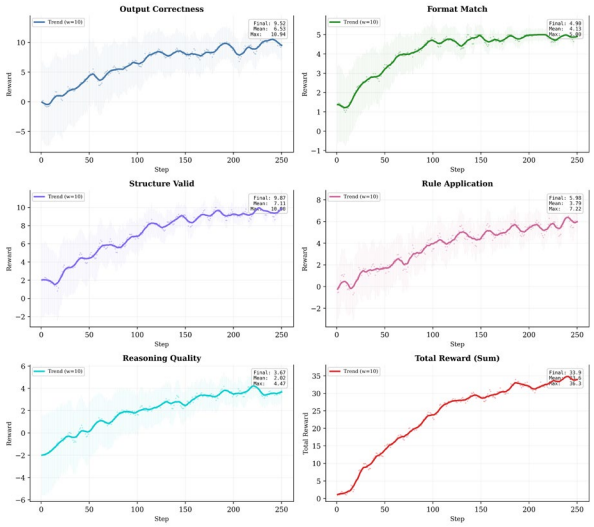

Figure 3: Evolution of GRPO reward components during training

Completion-length behavior further explains the improved optimization dynamics. As shown in Figure 4, increasing the maximum completion length reduces truncation, with the mean length stabilizing at approximately 1,370 tokens per WBS instance and an average inference time of 25–30 seconds per instance on the described hardware, indicating a predictable and bounded cost suitable for practical planning workflows. The truncation ratio decreases to 13.5%, preventing partial reasoning traces from corrupting reward computation and enabling more reliable evaluation of correctness and reasoning-related rewards.

Policy stability during GRPO optimization is supported by the KL divergence profile shown in Figure 5. After an initial adjustment phase, divergence remains bounded around a mean of approximately 0.22, with no upward drift over the training horizon, indicating controlled policy updates and regulated exploration. Overall, these results demonstrate reliable reward optimization,

Figure 4: Completion length and truncation behavior

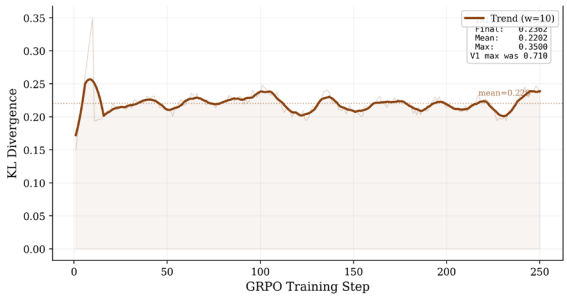

Figure 5: KL divergence during GRPO optimization

mitigation of truncation-induced noise, and stable learning dynamics, providing a robust foundation for inference-time evaluation on unseen construction planning instances.

Inference-Time Performance and Category-wise Analysis

Inference-time evaluation on 100 unseen WBS instances demonstrates that the trained model generalizes consistently across all reward components. As shown in Figure 6, the distributions of output correctness, structural validity, and format compliance are strongly concentrated near their upper bounds, indicating stable and reliable prediction behavior. Reasoning quality also exhibits a tight distribution around high scores, confirming that the model maintains coherent explanatory traces beyond training data. Rule application shows greater variance, reflecting the inherent difficulty of enforcing complex, context-dependent construction constraints during inference.

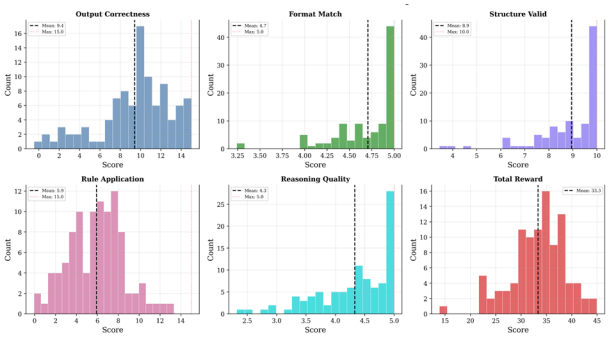

Figure 6: Inference-time reward distribution

A category-wise breakdown of inference rewards further highlights the multi-category robustness of the proposed framework. As illustrated in Figure 7, structural validity, format compliance, and reasoning quality consistently exceed the 75% performance threshold across all construction categories, including scheduling, structural, temporal, cross-discipline, quality, and safety. Output correctness varies more across categories, with lower scores observed for resource and cross-discipline reasoning, which require more implicit coordination knowledge. Nevertheless, safety and quality categories achieve the highest overall performance, reflecting the effectiveness of symbolic constraints in regulating critical execution logic. Overall, these results confirm that the

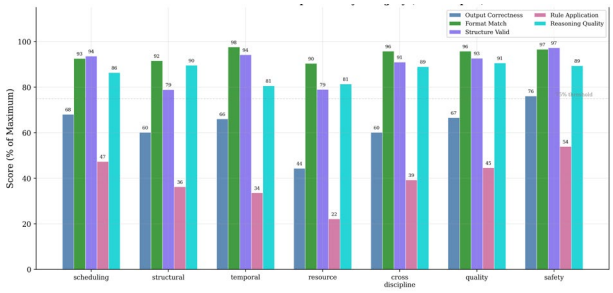

Figure 7: Category-wise inference performance

proposed neuro-symbolic GRPO framework produces explainable, structurally valid, and category-consistent construction relationship graphs at inference time, supporting its suitability for deployment in practical construction planning and downstream project control applications.

Inference and Interpretability

Figure 8 shows an example of inference output for a foundation excavation task. From a dependency-free WBS input, the model generates coherent multi-category relationships, including scheduling precedence, temporal constraints, resource requirements, cross-discipline coordination, and safety considerations. The inferred relationships are context-aware, category-consistent, and aligned with practical construction logic. Non-applicable categories are omitted, indicating controlled reasoning rather than template-based generation. This example highlights the model's ability to produce interpretable and deployment-ready construction relationship graphs at inference time.

Conclusions

This study presented a neuro-symbolic reinforcement learning framework for multi-category construction relationship reasoning, addressing key limitations in planning practice, namely the loss of tacit knowledge and the absence of standardized, explainable representations of execution constraints. Unlike prior approaches focused on isolated scheduling logic or post-hoc validation, the framework embeds symbolic domain knowledge into both data generation and policy optimization, enabling planning-time reasoning across interacting constraints.

Construction relationship inference is formulated as a structured graph prediction problem spanning scheduling, structural, temporal, resource, cross-discipline, quality, and safety categories. To mitigate limited labeled data, a synthetic Work Breakdown Structure generation pipeline is combined with reasoning-guided annotation using large language models constrained by domain knowledge. A small language model is subsequently fine-tuned using Group Relative Policy Optimization with a composite symbolic reward enforcing structural validity, temporal plausibility, constraint compliance, and reasoning quality, shifting learning from output memorization to transferable reasoning policies.

Experimental results indicate stable training dynamics, characterized by controlled policy updates, reduced truncation effects, and consistent reward convergence. Inference on unseen WBS inputs demonstrates robust generalization across all relationship categories, producing structurally valid and explainable dependency graphs. Performance is strong in structural and safety-critical relationships, while higher variability in resource and cross-discipline reasoning reflects the complexity of implicit coordination tasks. Each predicted relationship includes an explicit justification traceable to domain knowledge, supporting transparency and planner trust.

System Prompt

```
Analyze the construction task and identify scheduling relationships.

Output format: Array of scheduling_relationships with:
- from_task, to_task: Task names
- link_type: FS (Finish-to-Start), SS (Start-to-Start), FF (Finish-to-Finish), SF (Start-to-Finish)
- lag_days: Numeric lag in days
- reason: Justification citing relevant domain rules
- is_driving: Boolean indicating if this is on critical path
- total_float: Float days available

Output your analysis in this format:
<start_working_out>
[Your reasoning about the task, mentioning relevant domain rules]
<end_working_out>

<OUTPUT>
[JSON array of scheduling relationships]
</OUTPUT>
```

Inference Input (User Prompt)

```
Country: India, Project Type: Residential Building, Structure Type: RCC Frame, Work Package: Sub Structure (STRUCTURAL), Location: Foundation Area, Object: Foundation Footings, Task: Excavation Work

Analyze this task from a SCHEDULING perspective.
```

Model Reasoning (Intermediate)

```
<start_working_out>
Excavation work is a critical foundation activity and cannot begin until soil conditions and access safety are confirmed.
Per R-007 and R-010, temporary works such as shoring must be completed before excavation starts.
Soil assessment directly governs excavation feasibility and is therefore a driving predecessor.
Once excavation is underway, some verification activities such as subgrade testing can proceed in parallel in completed zones, forming a Start-to-Start relationship.
However, foundation formwork requires a short stabilization period after excavation completion, consistent with R-001 and R-009, introducing a Finish-to-Start dependency with lag.
Only preparatory and formwork-start dependencies are critical; intermediate testing activities retain float.
<end_working_out>
```

Final Output (Scheduling Relationships)

```
<OUTPUT>
[{ "from_task": "Soil Condition Assessment", "to_task": "Excavation Work","link_type": "FS","lag_days": 0, "reason": "Soil bearing capacity and type must be verified prior to excavation to ensure design compliance and safety.", "is_driving": true, "total_float": 0 },
 { "from_task": "Temporary Works Completion", "to_task": "Excavation Work", "link_type": "FS", "lag_days": 0, "reason": "Shoring and temporary stabilization systems must be in place before excavation to prevent collapse and allow safe access.", "is_driving": true, "total_float": 0 },
 { "from_task": "Excavation Work", "to_task": "Subgrade Compaction Testing", "link_type": "SS", "lag_days": 0, "reason": "Compaction and density testing can start in completed zones while excavation continues elsewhere.", "is_driving": false, "total_float": 2 },

</OUTPUT>
```

Figure 8: Inference Output Showing Explainable Multi-Category Construction Relationships

The study is based on a residential project dataset augmented with synthetic WBS generation, enabling scalable training but introducing bias toward residential construction logic. Although methodologically general, the learned policy may not transfer directly to other typologies, such as suspension bridges, tunnels, or petrochemical plants, where execution constraints differ significantly and the domain constraint layer must be adapted to project-specific physics, regulations, and construction methods. Future work will extend the constraint framework to additional project types, incorporate typology-specific constraints and uncertainty-aware reasoning, and validate on diverse real-world datasets to assess cross-domain transferability. Overall, this work demonstrates a practical pathway toward

explainable and transferable AI-driven construction planning that respects the domain-specific nature of construction knowledge while enabling reuse across projects and organizations.

FROM BUILDING PERMIT REVIEW COMMENTS TO COMMENT-BASED PROCESS INDICATORS: AN ESTBERT-BASED CLASSIFICATION WORKFLOW

Pille-Riin Peet[1], Ergo Pikas[2], and Aime Ruus[1]
[1] Tartu College School of Engineering, Tallinn University of Technology, Puiestee 78, 51008, Tartu, Estonia
[2] Building Lifecycle Research Group, Department of Civil Engineering and Architecture, Tallinn University of Technology, Ehitajate tee 5, 19086, Tallinn, Estonia

Abstract

Current building permit evaluation methods use broad metrics like duration and interviews, lacking detail and objectivity for targeted improvements. This paper introduces a workflow to convert unstructured reviewer comments into process indicators using EstBERT, a taxonomy, and supervised multi-label classification. Comments are categorized by issue type and domain, then combined into indicators of rework reasons, inconsistency, and transparency. On a validation set of 365 comments, the classifier scores micro-F1 of 0.470 and macro-F1 of 0.395. Results indicate reviewer comments can reliably support baseline assessment and inform targeted interventions across applications, municipalities, and work types.

Introduction

The building permit process and related procedures are a critical regulatory step in the delivery of construction projects (Hagedorn et al., 2025). However, it is often described as lacking transparency and predictability, with interpretive subjectivity and inconsistencies stemming from the volume and fragmentation of regulations, which lengthen the process and increase construction project costs (Peet et al., 2025). The process is complex, involving numerous stakeholders and disciplinary domains, and its implementation varies across jurisdictions due to differences in administrative practices, values, legal frameworks, and institutional structures (Fauth et al., 2024).

Given this complexity, commonly used metrics, such as total processing time and activity counts (e.g., review rounds and number of remarks), are insufficient because they describe outcomes without providing insight into why rework and iterations occur. On the other hand, effectiveness is frequently assessed through interviews and stakeholder surveys that capture concepts such as transparency, robustness, and citizen-friendliness. These perception-based assessments can be influenced by role-dependent and reporting biases, limiting their suitability as objective baselines. Emerging quantitative approaches, such as stakeholder management analysis metrics (Motahar et al., 2025), provide complementary insights into coordination and communication structures. However, they do not offer scalable, content-level evidence on the issues that cause review iterations in individual cases. In other words, current methods do not adequately support the diagnosis of process problems in a way that is sufficiently scalable and objective to enable benchmarking and monitoring of improvements.

Building permit process activity logs include unstructured comments that capture what reviewers found missing, unclear, inconsistent, or non-compliant, thereby providing direct evidence of why iterations occur. This paper examines whether building permit reviewer comments can be classified into a structured two-layer taxonomy with sufficient reliability to support the development of comment-based process indicators. More specifically, the study evaluates whether an Estonian-language transformer model (EstBERT) (Tanvir et al., 2021) can support multi-label classification of reviewer comments by issue type and disciplinary domain in a way that is useful for baseline assessment and intervention monitoring. The aim is to complement qualitative analyses with scalable indicators that reveal content-level reasons for rework requests across applications, municipalities, and work types. Rather than treating classification as an end in itself, this study uses it as an intermediate step in a broader workflow for transforming unstructured reviewer comments into structured evidence for process diagnosis.

Thus, the main contributions of this study are as follows:

- a workflow for deriving comment-based process indicators from unstructured building permit activity logs;
- a two-layer taxonomy for structuring permit review comments by issue type and disciplinary domain;
- an EstBERT-based multi-label classification pipeline that enables scalable application of this taxonomy to permit review comments.

This paper is structured as follows. The Methodology section describes the data source and the main workflow. In Data Preprocessing, we describe how the data were cleaned, how multi-item remarks were split, and how anonymization was implemented. Comment Classification covers the taxonomy, labeling strategy, and the EstBERT-based multi-label classification method. Deriving Metrics defines comment-based indicators and evaluation measures. The Results section describes the main findings, and the Discussion section discusses the implications, limitations, and possible directions for future research.

Methodology

The building permit process activity logs are from the Estonian Building Registry (EBR). EBR is a database designed to store, provide, and disclose information on planned, under-construction, and existing buildings, as well as related procedures. It is a nationwide environment used for all formal communication between the applicant and the reviewers during the building permit process. For this study, five municipalities representing a range of municipal sizes and annual application volumes (see Table 1) were selected. The building permit activity logs query was submitted to the EBR analyst for all applications in the five selected municipalities that ended in 2025 and started after 01.06.2022 (this date was selected because, in May 2022, EBR underwent a major update affecting all available services and related data).

Table 1: Selected municipalities by population size and annual application volume

	Size of the Municipality (inhabitants as of 2025)	Building permit and building notification applications in a year
A	< 5000	< 500
B	5000 – 10 000	< 500
C	10 000 – 20 000	< 500
D	20 000 – 50 000	500 – 1000
E	> 50 000	> 1000

Types of work planned in the building:

1. Renovation of a building
2. Building construction
3. Building extension
4. Demolition of a building
5. Replacement of part of a building with an equivalent

Table 2: Count of applications by municipality and work type

	A	B	C	D	E
1	0	24	47	111	1029
2	28	105	18	436	632
3	2	13	5	62	176
4	1	2	3	30	93
5	0	0	3	14	52

The dataset was exported as a .csv file containing administrative fields and process names, with column names in Estonian. To improve readability, we use English labels for these fields throughout the paper, while retaining the original column names in an accompanying data dictionary for reproducibility. This paper includes only the subset of fields used for preprocessing, model training, and indicator derivation. Additional fields present in the exports are documented but not used.

The proposed workflow uses reviewer comments as a source of structured evidence on the causes of rework in building permit review. To enable this, comments are classified using a two-layer label system and then aggregated into municipality- and work-type-level comment-based process indicators. Because reviewer comments are unstandardized and vary substantially in style, length, and specificity, the workflow combines rule-based preprocessing with supervised classification. Comment texts were tokenized using the tartuNLP/EstBERT checkpoint, accessed via the Hugging Face model hub and the Transformers library. EstBERT generated (Tanvir et al., 2021) contextual word embeddings were then used to train a multi-label logistic regression classifier using scikit-learn (Pedregosa et al., 2012). All preprocessing, classification, and indicator computation scripts are available on GitHub (https://github.com/pillepidu/EBR-comment-classification.git).

Data preprocessing

Before analysis, the raw building permit activity logs (91,056 rows) were cleaned to ensure data quality and relevance. The dataset was first filtered to include only document types classified as building permit applications ('Ehitusloa taotlus') and building notifications ('Ehitusteatis'), as these were the focus of the analysis. Rows where the comment goal ('eesmark') was marked as internal purpose ('EESMARK_SISEMINE') were removed, as these comments were deemed irrelevant for external classification. Furthermore, any rows with entirely empty values across the comment ('kommentaar'), reason ('pohjus'), and comment goal fields were excluded, as these likely represented system entries without meaningful information. To facilitate chronological analysis and ensure uniform representation, date columns such as application start ('algus'), application end ('lopp'), and date of entry ('tehtud_kp') were converted into pandas `datetime` objects (dd/mm/yyyy), and missing dates are kept as null values. The personal identification code ('isikukood') and registration code ('reg_kood') columns were converted into binary indicators, showing whether each column has a value or not.

The raw comment ('kommentaar') fields contained embedded HTML syntax, which is extraneous for NLP tasks and could introduce noise. To address this, HTML syntax was systematically removed using the `BeautifulSoup` library. Regular expressions were used to identify additional image tags and replace various image tag formats, such as `<img src="data:image/...">` (base64-encoded images) and `<img src="//:0">` (other image references), with the standardized placeholder `[pilt]`. This approach preserved the semantic information that an image was present in the original comment while removing lengthy and irrelevant character sequences.

In the 34,250 rows of activity logs, some of the comments didn't have a value, and many comments were a list of multiple comments, either bulleted (e.g., using '·') or numbered (e.g., '1. Text', '1) Text'). To enable granular analysis and accurate classification, rows with empty comments were filtered out. Comments that were lists were split into individual comment entries. The splitting logic specifically targeted patterns indicative of valid list items: a number followed by a period or parenthesis, and then an uppercase letter (marking the start of a new sentence). This allowed differentiation from legal references, which often contain numbers but lack the specific pattern indicating the start of a sentence. Each identified list item was then treated as a separate row, with all other metadata fields duplicated from the original entry. This resulted in 19,585 unique rows. The classifier was trained and evaluated on these split comment items. Indicator calculations then aggregate predicted labels over all comment items associated with the same application ID (and, where relevant, review round), treating a label as present if it occurs at least once within the group.

To protect personal data and comply with privacy regulations, a three-step anonymization process was applied to the comment fields. In the first two steps, regular expressions were used to anonymize email addresses and phone numbers. Standard email address patterns (e.g., `example@domain.ee`) were identified and replaced with the placeholder `[e-mail]`. Phone numbers that comply with Estonian regulations (*Eesti Numeratsiooniplaan–Riigi Teataja*, 2018) were detected and replaced with `[telefoni number]`. To prevent misclassification of regulation references, numbers containing a slash or preceded by 'nr.', 'nr', or 'nr.' were excluded from this anonymization. The third step was the anonymization of persons' names using the EstNLTK `NerTagger` (Laur et al., 2020), which assigned the 'PER' (person) tag to identify personal names. Once identified, these names were replaced with a sequence of 'X' characters of equal length (e.g., 'Kalle Kask' became 'Xxxxx Xxxx'). This method ensured that personal identifiers were obscured while preserving the textual structure.

Comment classification

To capture the content and context of building permit review comments beyond general procedural status labels, we developed a two-layer label system in which the primary labels refer to the type of problem raised in the comment, and the second layer, the domain tag, describes the disciplinary context. The initial list of categories was developed based on an existing legal analysis of the requirements for construction projects in Estonia (Sorainen & TalTech, 2024). Because reviewer comments often contain multiple requests or refer to closely related problems, the label system was designed as a multi-label scheme in which a single comment may receive multiple primary labels and multiple domain tags. Some category boundaries are necessarily adjacent, particularly between comments about missing information, inconsistency, incorrect content, and requests for clarification. To reduce ambiguity, short decision rules were used during manual labeling. However, some overlap remained and is treated as an inherent characteristic of the comment data rather than as a purely technical modeling issue.

To train a multi-label classifier, we first extracted a subset of 2048 unique preprocessed comments for manual labeling. The subset of comments was randomly selected; to ensure an even distribution across municipalities and application types, we ensured that there were 200 unique comments for each municipality and application type. If there weren't enough of them, then all of them were chosen for the manual training set.

During the manual labeling phase, the label set was refined to better reflect recurring patterns in the reviewers' comments. The manually labeled subset was divided into a training set of 1682 labeled comments and a validation set of 365 labeled comments. The training set was used to train the initial classifier, which was applied to automatically label the remaining comments.

Primary Labels:

P1. Missing Documentation or Information
Required documents, parameters, information, or attachments are missing and must be provided.

P2. Incorrect or Error
There is an incorrect value, detail, or error in the submitted content.

P3. Inconsistent
Two submitted documents contradict one another (e.g., an explanatory document and a site plan).

P4. Non-Compliance with Regulations
Comment states non-compliance with law/regulation/standard (often with legal reference).

P5. Non-Compliance with Design Requirements or Detail plans or General Plans
Conflict with the detailed plan, general plans, or design conditions. Often explicitly stated.

P6. Unclear or Needs Clarification
Information exists but is ambiguous. The reviewer requests clarification or justification.

P7. Format or Presentation (e.g., missing or wrong signatures)

P8. Process or status (e.g., EBR form or procedural issues, formal Statements of approval or refusal without explanation)
Remarks regarding EBR forms or workflow issues rather than technical content.

P9. Requirements for stakeholder approval
Requires consent or approval from another authority or party (e.g., neighbors, utility service providers, Environmental agencies).

P10. No Issues
Explicit statement that there are no remarks.

Domain Labels:

D1. Fire Safety
D2. Heritage
D3. Site
D4. Utilities

D5. Administrative or Procedural
D6. Environmental
D7. Waste Management
D8. Energy efficiency

EstNLTK (Laur et al., 2020) was used to preprocess Estonian-language comment texts before automatic classification. Each comment was sentence-segmented and tokenized into word tokens. For tokenization, each comment text was converted into an EstNLTK `Text` object and tokenized using the `words` layer. For sentence segmentation, the same `Text` object was annotated with the `sentence` layer to provide sentence boundaries for downstream NLP processing. Each comment was then tokenized using EstBERT (Tanvir et al., 2021) based embeddings, a transformer-based language model trained on Estonian text. Contextual embeddings were generated using EstNLTK `BertTagger`, which assigns a BERT embedding to each token in the comment text after annotating the text with the `words` and `sentences` layers. Token-level embeddings were then aggregated into a single fixed-length vector per comment by calculating the arithmetic mean across all token embeddings (mean pooling). This comment-level tokenization supports downstream similarity-based analysis while allowing comments to be associated with multiple issue categories in subsequent steps, even when a single comment contains multiple distinct issues.

Deriving metrics

Following model training, the final classifier was applied to the complete preprocessed dataset to assign primary labels and domain tags to each reviewer comment. These predicted labels were then added to the activity logs and aggregated into comment-based process indicators for rework, inconsistency (e.g., review rounds and recurring issue types), and procedural transparency (e.g., the presence of explicit legal references). The indicators were calculated for the full dataset and also by municipality and intended construction work type. For multi-label outputs, each assigned label was counted once when calculating category frequencies. For application-level metrics (e.g., whether an application contains issues about missing information or documentation), a category is counted as present if it occurred in at least one comment associated with that application.

Model performance was evaluated using the validation set of 365 manually labeled comments (20% of the labeled dataset). Because the task is multi-label and the label distribution is imbalanced, the primary evaluation metrics are micro- and macro-averaged precision, recall, and F1 score, together with per-label precision, recall, and F1 for the primary labels. For completeness, we also report label-cell accuracy as a supplementary metric. For each label ℓ, we compute true positives (TPℓ), false positives (FPℓ), and false negatives (FNℓ) from binary predictions. Macro-averaged precision, recall, and F1 were calculated by averaging the per-label scores, giving equal weight to each label. Micro-averaged precision, recall, and F1 are calculated by first summing TPℓ, FPℓ, and FNℓ across all labels, and then computing precision, recall, and F1-score, with label weights proportional to their frequency. Additionally, we conducted a qualitative error analysis by reviewing misclassified samples to identify the causes of systemic failures (e.g., overlapping category boundaries, multi-problem comments not fully separated during preprocessing, and domain-specific phrasing).

In addition to the predicted labels, each comment was tagged for the presence of an explicit legal reference (has_legal_reference: True/False) using regular expression pattern matching for citation markers and keywords commonly used in Estonian, such as "§", "EhS", "määrus", "standard", "juhend", "seadus", and "nõuded". This flag was used to quantify the proportion of comments that provide explicit legal justification, both overall and by municipality.

Table 3 summarizes the comment-based process indicators used in the quantitative analysis.

Table 3: Overview of metrics derived from EBR activity logs

Theme	Question	Analysis and derived metrics
Inconsistencies and subjectivity	How many applications require multiple review rounds?	Calculates R=max('ringi_nr') per application. Reports the percentage of applications where R > 1 overall, by municipality, and work type.
	What are the most common reasons for revision requests?	Identifies comments, both primary and domain tags. Reports the most common labels overall, by municipality, and work type.
Procedural transparency and a generally worded legal framework	How many comments contain an explicit reference to any legal document, standard, or guide as justification for the comment?	Identifies comments where `has_legal_reference`=True. Reports the percentage of comments with legal references overall, by municipality, and by work type.
Inconsistency and procedural transparency	How often do requirements shift across review rounds within the same application?	Tracks both the primary and domain tags per application that first appear when the review round > 1. Reports the percentage of applications with late-appearing labels, the most common late-appearing labels overall, and how many times they occur.

Results

Classification performance

Table 4 summarizes overall performance using micro- and macro-averaged precision, recall, and F1, reported separately for the primary labels (P1–P10), the domain labels (D1–D8), and all labels combined. Label-cell accuracy is also reported as a supplementary metric across the validation set.

Overall, domain labels (D1–D8) are predicted more reliably than primary labels (P1–P10), with higher label-cell accuracy (0.893 vs 0.778) and macro-F1 (0.437 vs 0.362). The gap between micro and macro scores indicates uneven performance across labels, with labels with less training data lowering the macro-averaged results. Table 5 reports per-label performance for the primary labels. Performance varies substantially across labels, with the highest F1 observed for "Process or status" (P8, F1 = 0.662) and the lowest for "No issues" (P10, F1 = 0.143).

Table 4: Overall performance of the classifier

	Primary labels (P1-P10)	Domain labels (D1-D8)	All labels (primary + domain)
Micro Precision	0.332	0.395	0.351
Micro Recall	0.689	0.761	0.712
Micro F1	0.448	0.520	0.470
Macro Precision	0.274	0.349	0.307
Macro Recall	0.620	0.638	0.628
Macro F1	0.362	0.437	0.395
Accuracy	0.778	0.893	0.829

Table 5: Performance for primary labels (P1-P10). P1 - Missing Documentation or Information, P2 - Incorrect or Error, P3 – Inconsistent, P4 - Non-Compliance with Regulations, P5 - Non-Compliance with Design Requirements or Detail plans or General Plans, P6 - Unclear or Needs Clarification, P7 - Format or Presentation, P8 - Process or status, P9 - Requirements for stakeholder approval, P10 - No Issues

	Precision	Recall	F1
P1	0.437	0.874	0.582
P2	0.126	0.621	0.209
P3	0.358	0.763	0.487
P4	0.125	0.438	0.194
P5	0.136	0.75	0.231
P6	0.363	0.589	0.449
P7	0.194	0.619	0.295
P8	0.62	0.71	0.662
P9	0.247	0.686	0.364
P10	0.133	0.154	0.143

Additionally, we conducted a qualitative error analysis by manually reviewing misclassified validation samples (false positives and false negatives) to identify recurring causes of systematic failures. Two main problems were detected. First, overlapping category boundaries led to confusion between similar labels, especially when a comment could belong to more than one primary category. Second, the splitting preprocessing function failed to capture multiple requests or issues in a single text. The model tended to either assign only a subset of the relevant labels (false negatives) or add an additional label triggered by a specific phrase (false positives). This helps explain the uneven per-label performance and highlights that both label-definition clarity and data-preparation exceptions are key drivers of systematic misclassification.

Frequency and reasons for rework

Table 6 reports the share of applications that required multiple review rounds (R > 1) by municipality (marked A-E as described in Methodology) and intended work type (marked 1-5 as described in Methodology). Across the full dataset (N = 2,804 applications), 1,498 applications (53.4%) required more than one review round, with an average of 2.10 rounds per application.

Table 6: Percentage of applications that require multiple review rounds by municipality and work type (%)

	A	B	C	D	E
1	0.0	41.7	38.3	43.2	50.4
2	25.0	31.4	61.1	46.8	72.2
3	50.0	38.5	20.0	54.8	63.6
4	0.0	0.0	33.3	30.0	62.4
5	0.0	0.0	33.3	85.7	25.0

Table 7 summarizes the most common issue types driving revision requests, broken down by municipality and work type. Across all municipalities and work types, the classifier assigned 51,051 primary labels in total (each label counted once per comment). The three most frequent issue types were "Missing Documentation or Information" (P1, 9,573), "Unclear or Needs Clarification" (P6, 8,519), and "Incorrect or Error" (P2, 7,711). This indicates that rework mainly results from incomplete submission documentation, unclear information, and specific errors in the submitted documents.

Table 7: Most common reasons for revision requests by municipality and work type (Top 3, P - Primary label). P1 - Missing Documentation or Information, P2 - Incorrect or Error, P3 – Inconsistent, P4 - Non-Compliance with Regulations, P5 - Non-Compliance with Design Requirements or Detail plans or General Plans, P6 - Unclear or Needs Clarification, P7 - Format or Presentation, P8 - Process or status, P9 - Requirements for stakeholder approval, P10 - No Issues

	Top3	A	B	C	D	E
1	1	-	P1	P1	P1	P1
	2	-	P2	P6	P2	P2
	3	-	P6	P2	P8	P6
2	1	P6	P1	P1	P8	P1
	2	P8	P8	P2	P1	P6
	3	P1	P9	P6	P6	P2
3	1	P1	P2	P1	P1	P1
	2	P9	P1	P2	P6	P6
	3	P8	P4	P6	P2	P2
4	1	P2	P1	P8	P8	P6
	2	P6	P6	P1	P6	P1
	3	-	P8	P2	P1	P2
5	1	-	-	P1	P1	P8
	2	-	-	P3	P8	P1
	3	-	-	P2	P3	P3

Table 8 summarizes the most common issue domains driving revision requests by municipality and work type. Across all municipalities and work types, the classifier assigned 20,481 domain labels. The three most frequent were “Administrative or Procedural” (D5, 5,790), “Site” (D3, 5,094), and “Waste Management” (D7, 2,622). This shows that revision requests are influenced not only by technical compliance issues but also by procedural requirements and site-specific factors.

Table 8: Most common reasons for revision requests by municipality and work type (Top 3, D - Domain label). D1 - Fire Safety, D2 - Heritage, D3 - Site, D4 - Utilities, D5 - Administrative or Procedural, D6 - Environmental, D7 - Waste Management, D8 - Energy efficiency

	Top3	A	B	C	D	E
1	1	-	D1	D5	D5	D5
	2	-	D5	D2	D1	D3
	3	-	D7	D3	D3	D7
2	1	D5	D5	D5	D5	D3
	2	D3	D3	D3	D3	D5
	3	D1	D1	D7	D7	D7
3	1	D3	D1	D5	D5	D5
	2	D5	D5	D1	D1	D3
	3	-	D3	D7	D2	D7
4	1	-	D7	D5	D5	D5
	2	-	D5	D3	D3	D3
	3	-	-	D2	D7	D7
5	1	-	-	D5	D5	D5
	2	-	-	-	D3	D3
	3	-	-	-	D7	D1

Taken together, Tables 7 and 8 demonstrate that the primary drivers for revision requests are not limited to a single technical discipline. Instead, they combine issues related to submission completeness, information clarity and correctness, administrative procedures, and site-specific requirements. This supports the value of comment-based process indicators, as they offer a more nuanced understanding of the causes of rework than high-level process metrics alone.

Transparency of the rework requests

Table 9 reports the share of comments that explicitly reference a legal document, standard, or guide. Overall, 26.9% of comments contained explicit legal references. Variations in referencing practices across municipalities and work types indicate differences in how reviewers justify remarks and the transparency of the written feedback.

Table 9: Percentage of comments that contain an explicit reference to any legal document, standard, or guide as justification for the comment by municipality and work type (%)

	A	B	C	D	E
1	0.0	28.8	38.0	32.8	32.2
2	38.7	36.2	48.6	34.9	20.4
3	0.0	27.9	16.7	24.0	31.5
4	0.0	50.0	0.0	29.8	28.4
5	0.0	0.0	20.0	39.4	44.5

Table 10 reports the share of applications in which issue types or domain tags first appear after the first review round (“late-appearing labels”). Overall, 4.7% of applications had late-appearing labels, suggesting that most issues are identified early, but that a subset of cases experience shifting requirements across rounds. The five most frequent late-appearing labels were “Process or status” (P8, 436 times), “Inconsistent” (P3, 416), “Administrative or Procedural” (D5, 414), “Requirements for stakeholder approval” (P9, 356), and “Unclear or Needs Clarification” (P6, 350).

Table 10: Percentage of applications with late-appearing labels by municipality and work type (%)

	A	B	C	D	E
1	0.0	12.5	19.6	2.8	4.2
2	25.0	10.6	27.8	5.8	2.5
3	0.0	23.1	0.0	0.0	0.6
4	0.0	0.0	33.3	6.7	2.3
5	0.0	0.0	33.3	14.3	0.0

Discussion

This study shows that unstructured building permit review comments can be structured into categories and aggregated into comment-based process indicators that complement both qualitative assessments (e.g., perceived transparency) and high-level quantitative measures (e.g., total application duration). The results indicate substantial variation in review rounds (Table 6), the types of issues raised in revision requests (Tables 7–8), and the use of explicit legal references in comments (Table 9). Taken together, these indicators provide a more diagnostic view of the permitting processes by showing not only how much rework occurs, but also what kinds of issues drive it and how review practices differ across jurisdictions and work types.

The proposed indicators should be interpreted as signs of process characteristics rather than direct measures of performance quality or administrative performance. For example, a higher number of comments or legal references may reflect a thorough and transparent review rather than inefficiency. Conversely, fewer comments could indicate either efficient early-stage collaboration between the applicant and the reviewer or limited feedback from the reviewer. Additional review rounds may result from project complexity, applicant experience, or local administrative practices. For this reason, comparison across municipalities or work types should be interpreted in context and, where possible, alongside qualitative analysis.

The evaluation conducted in this study is based on activity logs from the Estonian Building Registry (EBR) and on an Estonian-language transformer model, EstBERT. The taxonomy was developed through analysis of Estonian law, and the label definitions reflect local regulations and administrative practices. Applying the workflow in other contexts would therefore require adaptations, including revising the label set, collecting new annotated data, and retraining or adjusting the language model for the target language and document style. Nevertheless, the core workflow - preprocessing comments, multi-label categorization, and aggregation into comment-based process indicators - remains reusable across contexts.

Manual labeling may introduce bias, particularly when performed by a single labeler. Certain categories, such as "Missing Documentation or Information," "Unclear or Needs clarification," "Incorrect or Error," and "Inconsistent," are semantically adjacent and may therefore be interpreted differently across labelers. Short definitions and decision rules were used to reduce ambiguity, but future research should involve multiple labelers and report inter-labeler agreement. This would strengthen the reliability of label assignments, clarify category boundaries, and improve the interpretability of both the classification results and the indicators derived from them.

The activity logs show variation in municipal reviewing practices. Some municipalities provide brief comments, whereas others use long lists or aggregate multiple review requests into a single entry. The splitting method used in this paper extracts list items but fails to separate multiple issues expressed within a single sentence, or may incorrectly split text that resembles a list. These preprocessing problems can affect both classification performance and resulting indicators. Future improvements should therefore focus on more robust sentence-level splitting, improved list detection, and targeted handling of complex comment structures identified through error analysis.

The classification approach used in this study relies on EstBERT-based embeddings with mean pooling and logistic regression, providing a transparent and locally executable baseline for privacy-sensitive administrative text. However, this approach may overlook fine-grained contextual cues within longer or more complex comments and may perform weakly on rare or semantically adjacent labels. This is reflected in the gap between the micro- and macro-averaged results, reinforcing the need for cautious interpretation of category-level outputs. A promising direction for future research is to extend the workflow toward a more explainable AI setting in which the classification-based approach presented in this paper is complemented by an LLM-based method applied in parallel. In such a setup, the structured classifier would support auditable category assignments, while the LLM-based component could help interpret more complex or ambiguous comments, for example, by directing low-confidence predictions to LLM-based classification, decomposing multi-issue comments before labeling, or generating post hoc justifications for human review. Potential improvements, therefore, include threshold tuning, alternative aggregation strategies, stronger handling of long comments, and comparative or parallel evaluation against more recent language-model-based approaches, where privacy and deployment constraints permit.

Conclusions

This study demonstrates that reviewer comments in building permit activity logs can be structured into comment-based process indicators that make recurring causes of rework and review practices visible at scale. In contrast to high-level process measures such as total duration or number of review rounds, these indicators provide more specific evidence about the content of revision requests and the issues that drive iterative review.

Their main value lies in supporting baseline assessment, cross-case comparison, and the identification of dominant issue patterns across municipalities and work types. The three-stage workflow, consisting of preprocessing, classification, and indicator aggregation, is transferable to other jurisdictions by replacing the target-language transformer and the locally derived taxonomy and training set, while the indicator definitions remain unchanged.

The proposed workflow can support future building permit process improvement efforts by helping identify dominant issue categories, such as missing documentation, unclear submissions, or procedural bottlenecks within each jurisdiction. This helps inform improvement efforts, such as clearer reviewer templates, better applicant guidance, or the addition of a pre-consultation phase. Future research should evaluate how such interventions affect specific comment-based indicators over time and should further strengthen the workflow through improved preprocessing, stronger annotation procedures, and comparative or parallel model evaluation.

STRUCTURED INNOVATION IN CONSTRUCTION VALUE ENGINEERING THROUGH LLM-ASSISTED TRIZ REASONING

Fuhao Zu[1] and Linghui Xie[2]
[1]Chongqing University, Shapingba District, Chongqing, China
[2]The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong, China

Abstract

This study proposes an integrated framework that enhances idea generation in construction VE by leveraging LLMs to facilitate the application of TRIZ. The framework systematically incorporates project-specific contextual information into an LLM-driven TRIZ reasoning process. It enables context-aware abstraction of technical contradictions, retrieval of relevant inventive principles, and generation of solution ideas. By bridging TRIZ-based structured ideation with VE context, this approach supports more relevant and feasible creativity without requiring deep TRIZ expertise, demonstrating the feasibility of integrating LLM-assisted TRIZ reasoning into VE workflows.

Introduction

Value Engineering (VE) has been widely adopted in the construction industry as a structured method to maximize project functional value while minimizing cost and resource use (Chen et al., 2022). In current VE practice, the idea generation phase has been criticized for relying on unstructured brainstorming, limited reuse of innovation knowledge, and inconsistent solution quality, ultimately constraining the overall effectiveness of VE implementation (Park et al., 2017).

TRIZ (the Theory of Inventive Problem Solving) provides a systematic framework that introduces structured reasoning to enhance the creativity and consistency of generated alternatives during VE execution (Mao et al., 2009). Developed through the systematic analysis of over 200,000 invention patents, TRIZ aims to uncover repeatable patterns in resolving technical problems through innovation (Sheu et al., 2020). Its core tools include the Contradiction Matrix, the 40 Inventive Principles, the Separation Principles, and a series of Standard Solutions, all designed to guide engineers in reformulating specific problems into generalized structures that can be resolved through heuristic reasoning (Kalevi & Ellen R., 2007). This structured logic makes the TRIZ conceptually well aligned with the tasks during VE execution, particularly in developing alternative ideas. TRIZ has, therefore, been introduced into VE frameworks to support more systematic idea generation and reduce reliance on unguided brainstorming (Mao et al., 2009; Wu et al., 2020; Zhang et al., 2009). However, the integration of TRIZ into practical VE applications remains limited. One of the major challenges lies in the high level of abstraction embedded in TRIZ guidance tools, such as the contradiction matrix and inventive principles (Spreafico, 2022). Though conceptually powerful, these tools are typically presented in a condensed and domain-agnostic format, requiring both deep familiarity with TRIZ logic and advanced abstraction skills for effective use (Chen et al., 2024). These requirements are rarely met in typical VE teams. As a result, the cognitive effort required to map project-specific problems to usable TRIZ models has hindered its broader adoption in construction-related VE practice (Jiang et al., 2025).

Recent advancements in large language models (LLMs) offer promising avenues for addressing the cognitive and expertise-related barriers that limit the practical application of TRIZ. These models, exemplified by GPT-4 (OpenAI, 2023), DeepSeek (DeepSeek-AI, 2025), and similar architectures, exhibit strong capabilities in multi-step reasoning, analogical mapping, pattern recognition, and natural language generation. These competencies are well aligned with the analytical demands of TRIZ reasoning. In particular, LLMs can assist in abstracting technical contradictions, retrieving relevant inventive principles, and articulating generalized solution paths (Chen et al., 2024), thereby acting as intelligent assistants in the TRIZ reasoning process (Lee et al., 2024). Previous efforts have explored the integration of LLMs into TRIZ-based workflows. Relevant studies and prototype systems demonstrate that LLMs can automatically map problem statements to TRIZ contradiction models (Guarino et al., 2022), query inventive principles from pre-structured knowledge bases (Lee et al., 2024), and generate exploratory solution ideas (Chen et al., 2024; Jiang et al., 2025). These findings suggest that LLMs can reduce the reliance on expert-level TRIZ knowledge and make structured ideation more accessible.

However, while the feasibility of LLM-driven TRIZ reasoning has been preliminarily demonstrated, its application in the VE context remains underdeveloped. This is particularly significant given that prior attempts to integrate TRIZ into VE have struggled with practical adoption due to the abstract and domain-agnostic nature of TRIZ tools, which require considerable expertise to interpret and apply (Wu et al., 2020). With their capacity for abstraction, analogical reasoning, and guided knowledge retrieval, LLMs offer a viable solution to this

challenge by assisting non-expert users in applying TRIZ. Moreover, current work regarding LLM-assisted TRIZ remains largely confined to generic problem-solving scenarios, with limited consideration of domain-specific constraints (Lee et al., 2024). Existing approaches, such as AutoTRIZ and TRIZ-GPT, primarily focus on mapping problem descriptions to TRIZ models and generating solution ideas, but typically treat the input as standalone problem statements without systematically incorporating structured domain-specific information. Unlike general design settings, VE is inherently embedded in rich project-specific contexts (Gunduz et al., 2022). Before idea generation, VE involves extensive information gathering, including clearly defined objectives, requirements, constraints, and functional decompositions, among other things (Zu & Zhang, 2025). These are central to evaluating the feasibility and value of the proposed ideas. In contrast, this study explicitly integrates such VE-derived contextual information into the TRIZ reasoning process, enabling context-aware abstraction and idea generation aligned with project-specific constraints and value considerations.

Based on this, this study proposes an integrated framework that embeds project-specific contextual information, generated through the structured VE workshop, into LLM-driven TRIZ reasoning, to support the idea generation phase of VE practice. VE inherently clarifies project context through its early-stage activities, such as information gathering and function-cost analysis, providing a foundation for following idea generation (Zu & Zhang, 2025). By systematically incorporating this contextual information into the LLM-driven TRIZ reasoning process, the proposed framework aims to enhance the relevance and feasibility of the generated ideas while preserving the inventive rigor of TRIZ. In doing so, the framework bridges the gap between TRIZ-based systematic ideation and VE-oriented contextual understanding, offering a novel, LLM-powered approach tailored to the creativity phase of VE. This approach enables project teams to access structured innovation support without requiring in-depth TRIZ expertise, providing a context-aware pathway toward effective, value-driven VE practices in construction projects.

Methodology

This section presents the proposed methodology to integrate LLMs into the TRIZ reasoning in the context of construction VE. It aims to enhance the idea generation phase by combining TRIZ innovation strategies with the intelligent reasoning capabilities of LLMs.

Framework overview

As shown in Figure 1, the framework builds upon the traditional VE process, replacing the commonly used brainstorming approach with a structured, LLM-assisted TRIZ reasoning pipeline. In this way, it leverages the systematic innovation logic of TRIZ while addressing the expertise barrier that has historically limited its adoption in construction projects.

The process begins with the information and function analysis phases of VE, where project-specific information is collected, including project context (objectives, stakeholder priorities, and constraints, denoted as C) and functions with value improvement potential (denoted as F). This information serves as the foundation for defining the specific engineering challenge to be improved. Next, LLMs are engaged through prompt engineering techniques, leveraging few-shot examples and structured templates, to abstract the specific challenge into a formal TRIZ contradiction model. This abstraction translates domain-specific challenges into standardized TRIZ contradictions consistent with TRIZ theory. The contradiction model is then used to query the TRIZ matrix, producing a set of relevant inventive principles through structured retrieval. Finally, LLMs recontextualize these general TRIZ strategies into domain-specific, actionable alternatives. In this step, context-aware prompt engineering combined with a two-step process enables the LLM to fuse the retrieved TRIZ principles with detailed project context and functional descriptions. This ensures that the generated alternatives are inventive, feasible, targeted, and aligned with the project requirements, constraints, and stakeholder objectives. Through this, the framework not only addresses the expertise barriers in TRIZ application but also provides a scalable pathway for integrating AI-driven structured reasoning into VE practice.

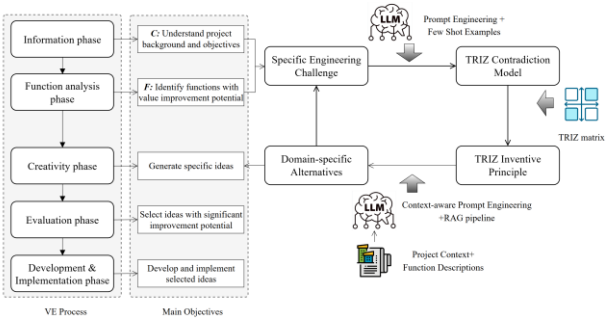

Figure 1: Framework of context-aware TRIZ reasoning supported by LLMs for VE

LLM-Assisted abstraction of TRIZ contradictions

The first critical step in the proposed framework is to abstract engineering challenges into TRIZ contradiction models, bridging contextualized VE information with systematic TRIZ problem-solving tools. The objective is to identify pairs of engineering parameters representing the desired improvement and the accompanying negative trade-off, which define the row and column of the TRIZ contradiction matrix. Traditionally, this abstraction relies heavily on expert judgment, requiring practitioners to interpret specific challenges through the 39 standardized TRIZ parameters. In the proposed framework, this task is performed by LLMs guided through prompt engineering and few-shot learning techniques.

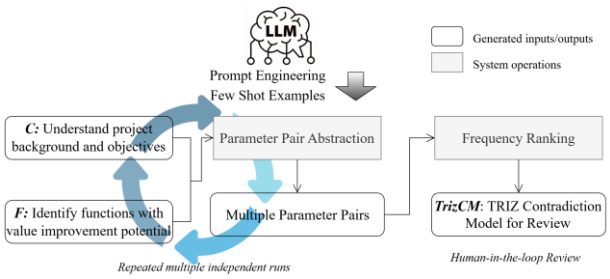

Figure 2: LLM-assisted abstraction and human-in-the-loop review of TRIZ contradictions

As depicted in Figure 2, to enhance LLM performance in TRIZ abstraction, the model is provided with carefully designed prompts and few-shot examples demonstrating how similar challenges have been mapped to TRIZ parameters. This enables the LLM to derive logical mappings from the input context, i.e., descriptions of project objectives and functional improvement targets, to appropriate technical contradictions. For example, the model may infer that enhancing structural durability at the cost of increased material use corresponds to a contradiction between "strength" and "production expense." Recognizing that complex design challenges often admit multiple perspectives, the framework incorporates multiple independent reasoning cycles to explore this diversity. In each cycle, the LLM generates distinct improving-worsening parameter pairs, offering alternative interpretations of the current challenge. The generated pairs are aggregated, and the most frequent are identified as the outputs of this phase. To ensure transparency and alignment with the project context, the framework incorporates Human-in-the-loop Review. As depicted in Figure 2, the ranked outputs are presented to VE teams for validation or adjustment based on domain knowledge, practical feasibility, and stakeholder priorities. In this step, users are expected to assess whether the identified contradiction pairs accurately capture the core design trade-offs and remain relevant to the specific project context. When discrepancies arise, they are resolved through discussion within the VE team, following standard workshop practices, and the selected pairs are refined accordingly.

This approach balances automation and flexibility. While the LLM handles the complexity of abstraction, human oversight preserves contextual appropriateness and critical judgment, with users evaluating the relevance of contradiction pairs, resolving disagreements through structured discussion, and refining selections to improve their contextual suitability for subsequent reasoning. The number of parameter pairs per cycle and the number of cycles are configurable, allowing adaptation to specific VE workflows or project complexity.

TRIZ principle mapping and recontextualization

The core objective of this stage is to transform the TRIZ contradiction model into domain-specific alternative ideas that align with VE objectives. This stage ensures that the systematic innovation strategies of TRIZ are effectively translated into practical design proposals that are inventive and also feasible within the specific context of construction projects. The process consists of two integrated components: (1) retrieval of inventive principles from the TRIZ matrix and (2) context-aware recontextualization of these principles through LLM-supported reasoning, as depicted in Figure 3.

In the retrieval phase, the framework employs a rule-based procedure grounded in TRIZ theory. Since the improving and worsening parameters of the TRIZ contradiction model have been identified, they map deterministically to inventive principles via the TRIZ matrix. This ensures that for any given contradiction, the inventive principles retrieved are traceable to historically validated solutions for similar technical conflicts, preserving methodological rigor. In the generation phase, the framework employs LLMs enhanced with context-aware prompt engineering to adapt the abstract inventive principles to the specific project environment. The model receives three types of input: (i) the retrieved inventive principles, (ii) the project objectives and constraints, and (iii) the functional improvement targets. These inputs are synthesized through carefully designed prompts that introduce the TRIZ strategies while embedding key elements of the project context, as well as functional descriptions, into the reasoning process. While the inventive principles retrieved for each contradiction pair are defined by the TRIZ matrix, the number and diversity of recontextualized ideas generated per principle can be configured according to project complexity or preferences. In this study, for demonstration purposes, five alternative ideas are generated for each inventive principle, providing project teams with a manageable yet diverse set of options for evaluation and selection. This ensures that the generation phase remains flexible and adaptable to different VE contexts.

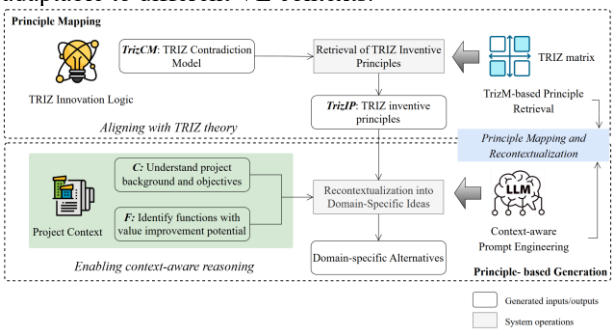

Figure 3: Two-step TRIZ reasoning and contextualized alternative generation

This framework integrates TRIZ-based retrieval with LLM-assisted recontextualization to systematically support the creativity phase of VE. By building directly on the outputs of the information and function analysis phases, it enables automated idea generation that aligns seamlessly with the VE workflow and reduces reliance on traditional brainstorming methods. At the same time, the framework ensures that the generated ideas are rooted in the structured logic of TRIZ and adapted to the specific goals, constraints, and functional requirements of the project, thereby enhancing their relevance, feasibility, and value for subsequent evaluation and decision-making. This offers a structured, scalable alternative to the

conventional creativity phase in the VE workshop, supporting more consistent, rigorous idea generation.

Demonstration

This part presents the development of the proposed prototype and demonstrates its functional workflow through a representative case study.

Prototype development

To demonstrate the feasibility of the proposed LLM-assisted TRIZ reasoning framework for construction VE, a prototype system is developed. The platform integrates LLMs, TRIZ theory, and human-in-the-loop validation to support automated, context-aware idea generation that aligns with the standard VE workflow.

As depicted in Figure 4, the system comprises four main components: (1) a user interface module implemented using Python Tkinter for structured input collection, human-in-the-loop review, and result visualization; (2) an LLM-assisted abstraction module for mapping project context and functional requirements to TRIZ parameter pairs; (3) a TRIZ knowledge base module that stores the 39 standard TRIZ parameters, the contradiction matrix, and inventive principles in structured JSON format; and (4) a context-aware idea generation module that implements the two-step process, combining principle retrieval with LLM-based recontextualization.

In the parameter pair abstraction phase, the system invokes ChatGPT-4o via Azure OpenAI to identify improving and worsening parameters from the user-provided project context and functional improvement targets. The prompt design for this phase follows a template-based structure. 39 TRIZ parameters and their definitions are embedded statically within the prompt, together with the designed few-shot examples relevant to the construction domain (e.g., balancing size v.s. performance, or durability v.s. maintainability). This structured design provides information for understanding and replicating the core prompting logic, although full prompt templates are not included due to space constraints. The project-specific inputs are inserted into this static template at runtime. This design ensures that the LLM reasons consistently within a defined framework while accounting for variations in project descriptions. To enable the LLM to generate multiple reasonable interpretations of the problem for frequency aggregation, the temperature is set to a moderate level (0.5-0.7). The system performs multiple independent abstraction cycles, aggregates the resulting parameter pairs, and ranks them by frequency for human validation, thereby enhancing robustness against individual model variances. In this study, five reasoning cycles were conducted, each generating three parameter pairs. The frequency of each contradiction pair was calculated based on its occurrence across the five cycles, and the two highest-ranked pairs were provided for subsequent analysis. When ties occurred, final selection was determined through human review based on project context.

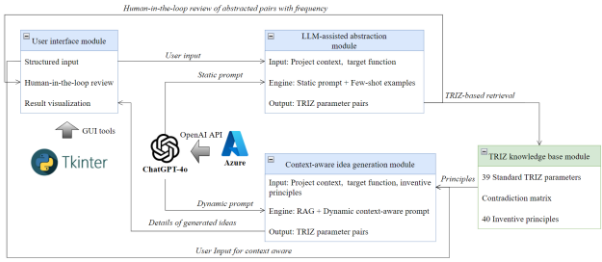

Figure 4: Architecture of the developed prototype

From a deployment perspective, multiple LLM calls introduce additional cost and latency, which are controlled in this prototype by limiting the number of reasoning cycles to 5 and outputs per cycle to 3. Each cycle completes within a few seconds, resulting in an overall response time suitable for interactive VE use. Potential failure modes include incorrect contradiction mapping and inconsistent or unsupported reasoning. To mitigate these risks, the system constrains the LLM using a fixed prompt structure embedding the 39 TRIZ parameters, incorporates domain-specific few-shot examples to guide mapping consistency, and applies frequency-based aggregation to filter unstable outputs across cycles. These measures complement the human-in-the-loop validation by reducing the likelihood of erroneous candidates being presented to users.

In the TRIZ strategy retrieval and idea generation phase, the recognized parameter pairs are used to query the stored contradiction matrix (in JSON format) to retrieve the associated inventive principles. The LLM is then engaged to generate domain-specific alternative ideas based on the retrieved principles and project context. The prompts for this phase are dynamically constructed in real time, designed to synthesize the inventive principles, project objectives, functional targets, and key constraints. The LLM is explicitly instructed in these prompts to reason how each inventive principle can be adapted to the specific project conditions and to articulate the rationale behind each generated idea, enabling context-aware reasoning that tailors idea generation to the unique conditions of the project. To encourage creative and diverse idea generation, the temperature is increased to a high level (0.8-1.0) at this stage. This configuration supports the generation of innovative alternatives that remain traceable to TRIZ theory and adapted to the specific realities of the VE project.

This architecture demonstrates the technical feasibility of embedding LLM reasoning and TRIZ logic into the VE process to systematically enhance the creativity phase, providing a system foundation for functional demonstration and evaluation in subsequent sections.

Functional demonstration

To verify the functionality and practical feasibility of the developed prototype, a demonstration was conducted using a representative case study aligned with typical VE applications in construction projects. The case focuses on enhancing passenger throughput in an urban transportation hub during peak periods, while minimizing energy consumption and space utilization.

Abstraction of TRIZ contradictions

The first step of the prototype corresponds to the information and function analysis phases of VE. As shown in Figure 5, the user provides structured inputs describing the project context and functional improvement target. These inputs are derived from typical VE artifacts, where the project context summarizes key constraints, stakeholder requirements, and system characteristics, while the functional improvement target reflects the prioritized functions identified through function analysis and function-cost evaluation. The project context specifies the development of a large-scale urban transportation hub designed to accommodate high passenger volumes while ensuring safety, comfort, and compliance with environmental and cost constraints. The functional improvement target focuses on increasing passenger throughput during peak periods with minimal energy consumption and space usage.

Once the input is submitted, the system engages the LLM-assisted abstraction module to identify potential contradiction pairs. ChatGPT-4o (via Azure OpenAI) is invoked multiple times, with each reasoning cycle leveraging a static prompt that embeds the 39 TRIZ parameters, their definitions, and domain-relevant few-shot examples. The project-specific input is dynamically inserted into this template at runtime. To promote diverse interpretations of the problem, the temperature is set to a moderate value of 0.5 in the demonstrated case. The system executes five independent abstraction cycles, with each cycle generating three candidate contradiction pairs. The resulting pairs from all cycles are aggregated, and their frequency distribution is computed.

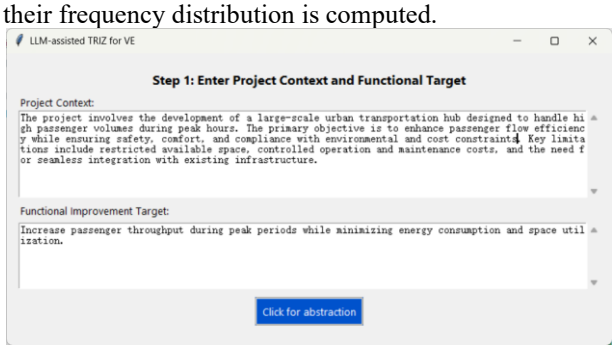

Figure 5: Interface for specifying project context and functional improvement target

As shown in Figure 6, the system visualizes the top-ranked pairs in a bar chart along with textual explanations of their origins. At this point, a human-in-the-loop review is conducted. The user examines the generated contradictions and their contextual explanations, and selects two pairs for further analysis. This interactive step ensures alignment of the automated abstraction results with domain knowledge and project-specific priorities, enhancing the transparency and adaptability of the process.

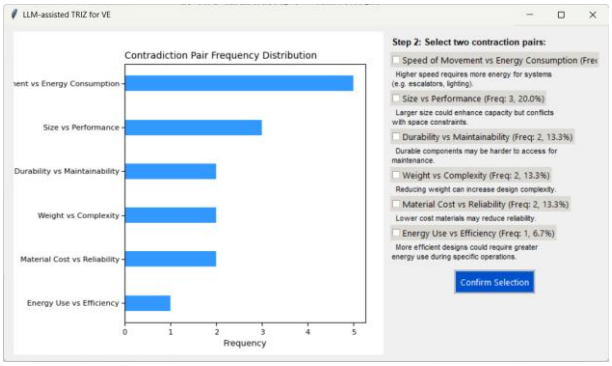

Figure 6: Interface for human-in-the-loop review.

Retrieval of TRIZ principles

After the user confirms their selection, i.e., Speed of Movement vs Energy Consumption and Size vs Performance, the system queries the embedded TRIZ contradiction matrix to retrieve the associated inventive principles. The context-aware idea generation module then dynamically constructs prompts combining the retrieved inventive principles, project objectives, functional targets, and key constraints. The LLM is explicitly instructed within these prompts to reason how each inventive principle can be adapted to the specific project conditions and to articulate the rationale for each proposed idea. The temperature is raised to a higher range, 1.0 in this case, to foster creativity and encourage diverse solution pathways.

Context-aware idea generation

As illustrated in Figure 7, the system generates multiple domain-specific alternative ideas for each inventive principle. Each idea is accompanied by a clear rationale demonstrating how the principle is contextualized within the specific VE problem. For example, under the Preliminary Action principle, the system suggests deploying smart signage that activates before peak periods to proactively guide passenger flow, thus reducing reactive energy demand. Under Mechanics Substitution, proposals such as AR-based wayfinding and virtual queuing are generated, offering innovative alternatives that minimize reliance on physical infrastructure. These generated ideas, together with their reasoning logic, form structured and traceable outputs that can seamlessly feed into the subsequent VE evaluation phase, where design alternatives are assessed for value contribution, feasibility, and alignment with stakeholder objectives. The human-in-the-loop review at this stage further supports the collaborative refinement and selection of the most promising alternatives.

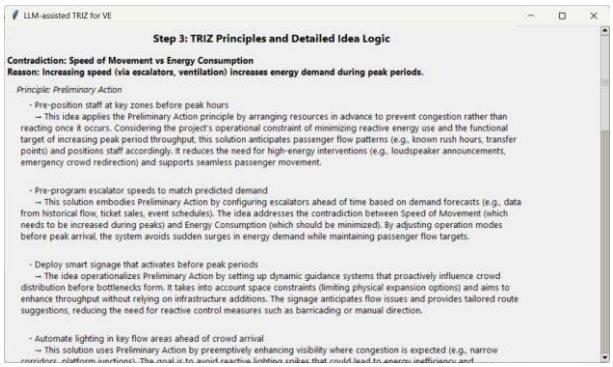

Figure 7: Interface for context-aware TRIZ idea generation with principle-specific rationales

Conclusions

This study presents a framework for integrating LLM-assisted TRIZ reasoning into construction VE. The results demonstrate its feasibility in supporting structured, context-aware, and traceable idea generation during the creativity phase. Its main contributions can be summarized in three dimensions. From a methodological perspective, the proposed framework demonstrates how LLMs can function as structured reasoning assistants, guiding the mapping of project-specific challenges to standardized TRIZ contradictions and supporting context-aware generation of alternative ideas. This advances the theoretical foundation for enhancing the creativity phase in VE by combining AI reasoning with established innovation models. From a technical standpoint, the prototype demonstrates the feasibility of the proposed framework. It supports TRIZ-inspired reasoning in identifying contradictions and generating alternative ideas. These ideas span both technological solutions and operational considerations, such as space optimization and energy efficiency. The inclusion of clear, traceable reasoning chains linking the identification of contradictions, the retrieval of principles, and the rationale for solutions supports subsequent evaluation and decision-making in VE phases. Finally, in terms of practical relevance, this study highlights how LLM-assisted innovation reasoning can be embedded within real-world VE workflows. The tool can serve as a supportive aid in group discussions, providing structured suggestions and reasoning cues that participants can iteratively review and refine. The integration of human-in-the-loop ensures that automation is balanced with expert oversight, making the system adaptable to collaborative and time-constrained workshop settings across varied project contexts.

Despite these contributions, there remain limitations. Specifically, the prototype is developed as a standalone tool and has not yet been integrated into a comprehensive VE management platform. It focuses on demonstrating methodological feasibility and does not include a systematic evaluation of the quality of generated ideas. Future work will incorporate user studies and expert-based comparisons with conventional brainstorming and expert-led TRIZ processes. In addition, the mapping of project-specific challenges to TRIZ parameters relies on LLM-based reasoning, which may introduce inconsistencies across contexts and therefore requires human validation; improving the reliability of this process remains an important direction for future work.

FORECASTING MACHINE WORKING TIMES IN OFF-SITE CONSTRUCTION: A MACHINE LEARNING BENCHMARK FOR SUPPORTING PRODUCTION PLANNING

Andrea Sbaragli[1], Xiang Xie[2], John Hedley [2] and Mohamad Kassem[2]
[1]School of Architecture, Technology and Engineering, University of Brighton, Brighton, BN2 4AT, UK
[2]Department of Engineering, Newcastle University, Newcastle, NE1 7RU, UK

Abstract

Off-site construction relocates building processes to controlled manufacturing environments, enhancing productivity but increasing the risk of cost overruns due to the non-repetitive nature of module fabrication. This work presents a machine learning benchmark for a cyber-physical system that digitises manufacturing operations by capturing machine working times alongside design and production features. The benchmark spans tree-based and support vector regressors, with the best-performing model embedded in an industrial dashboard for data-driven scheduling. Validated in a UK steel frame manufacturer across eight months of production data, Random Forest achieved 10.84% median absolute percentage error on 420 frames, enhancing production planning and scheduling.

Introduction

Off-site manufacturing has increasingly been adopted within construction by drawing on industrial production and assembly systems methodologies. Approaches such as prefabrication and modular construction involve manufacturing building components in controlled factory environments before transporting them to the site for installation (Fan et al., 2024). Although this paradigm shift improves project planning, overall productivity, and delivery time, several threats may disrupt production cycles (Mehdipoor and Iordanova, 2021). Construction projects present a wide range of variability, arising from geographical conditions, budgetary constraints, intended building functions, and client personalisation. These drivers may lead to design–production misalignment and prevent manufacturing standardisation. Delays and inaccuracies in translating Building Information Models (BIM) into manufacturing processes can generate bottlenecks (e.g., reworks) that negatively impact profit margins and expose projects to penalties arising from missed deadlines (Jowett et al., 2024). These environments require an expanded digital footprint to enable continuous monitoring of industrial Key Performance Indicators (KPIs) and to support their control within desired efficiency levels (Saif et al., 2024). The fourth industrial revolution vastly digitised and automated manufacturing environments, exploiting several enabling technologies. While robotics and automation have progressively replaced human involvement in repetitive and hazardous tasks, workers continue to play a pivotal role in manufacturing value creation, performing operations where automation remains either technically unfeasible or economically unviable. Yet monitoring the human factor poses particularly significant challenges. Unlike machine processes, human behaviour is inherently variable, shaped by cognitive states, fatigue, skill levels, and environmental conditions, making it difficult to model and standardise. Compounding this, human-related data are often noisy, context-dependent, and subject to rapid fluctuations, further hindering reliable and continuous assessment (Sbaragli and Nardello, 2025). Several cyber-physical systems (CPS) have been developed to support decision-making in industrial processes by leveraging multiple architectural layers. Acquisition layers enable the automated collection of data from shop-floor resources, while cyber layers process these data streams and apply machine learning algorithms to compute Key Performance Indicators (KPIs) (Thiede et al., 2016; Alsakka et al., 2024). Before model deployment, various algorithmic structures and configurations are systematically benchmarked to identify the most performing solution for the specific use case (Sbaragli and Nardello, 2025; Albanese et al., 2022). These industrial metrics are subsequently integrated into dashboards that automate key tasks for manufacturing stakeholders and enhance the operational visibility of industrial processes (Thiede et al., 2016). Among the various industrial applications, CPS have been extensively investigated to support production planning and scheduling (Brunelli et al., 2019). In this context, product-related industrial and design features are used as inputs to machine learning models to predict manufacturing processing times (Çakıt and Dağdeviren, 2023). Despite providing a robust foundation for improving production planning and scheduling operations, these data-driven applications suffer from two main limitations. First, these methodologies offer proof-of-concept solutions, where acquisition layer designs are not discussed, affecting successful deployments in production environments (Çakıt and Dağdeviren, 2023; Masoumi and Bond, 2025). Second, the evaluation of cyber layers and related machine learning models is often constrained to a limited set of indicators, resulting in incomplete evaluations and discussion of their weaknesses (Masoumi and Bond, 2025; Çakıt and Dağdeviren, 2023). Based on these limitations, this work proposes a CPS to support production planning in human-

centric off-site construction environments, with the core contribution being the systematic benchmarking of different machine learning regression models to accurately forecast semi-automated machine working times. The remainder of this work is organised as follows. A literature review of studies on forecasting resources' working time in production environments is presented. This is followed by the presentation of our developed CPS, its evaluation, and the discussion of findings. The last Section ends this work by outlining the conclusions and further research opportunities.

Literature Review

Production planning involves the systematic forecasting, coordination, and scheduling of activities, resources, and materials required to execute manufacturing processes efficiently (Göppert et al., 2024). Traditionally, operations research models, such as multi-objective programming and metaheuristic algorithms, have been extensively applied to support these decisions by iteratively identifying suboptimal industrial configurations (Demartini et al., 2021). For instance, Auer et al. (2021) proposes a heuristic to minimise production throughput time under constraints such as resource capacities and set-up times. However, these approaches often rely on static parameters (e.g., standard cycle times), which limit their effectiveness in dynamic manufacturing environments. In this context, machine learning-powered CPS approaches are increasingly adopted to enhance the robustness and responsiveness of scheduling decisions. Recent advances demonstrate the effectiveness of supervised, unsupervised, and reinforcement learning techniques in forecasting key operational variables, such as machine utilisation and processing times (Göppert et al., 2024). By enabling data-driven and adaptive decision-making, machine learning methods effectively complement the limitations of traditional optimisation approaches. For instance, Çakıt and Dağdeviren (2023) designs a CPS benchmarking machine and deep learning models to predict cycle times of bus manufacturing operations. The trained dataset consists of several features, including the number of sub-assemblies, welding operations, and metal forming processes. The k-nearest neighbor emerges as the most performing classifier with a Root Mean Squared Error (RMSE) equal to 1.48, granting superior visibility into manufacturing operations before scheduling jobs into the shop floor. Despite these promising results, this methodology has some notable limitations. The acquisition layer does not discuss how the dataset features are automatically gathered and thus fed into computational models. Furthermore, some dataset features, such as environmental conditions (products' complexity and ergonomics patterns), are highly subjective as they depend on evaluators' perception as well as workers' experience and physiology. The algorithms' validation does not discuss percentage errors between actual and predicted working times, and falls short in validating the methodology with a production sequence. This analysis is pivotal to discussing how potential under- or overestimation may affect production environments and the related stakeholders' activity. Similarly, Masoumi and Bond (2025) validates an approach to optimizing and estimating the lead time of wooden furniture. The dataset maps chair products as a function of design (e.g., leg shapes) and industrial (e.g., machine configurations) features. Neural networks and tree-based regressors validate the CPS performances, showing a Mean Absolute Percentage Error (MAPE) equal to 1.63%. Despite the excellent performance in forecasting production times, this approach suffers from two main limitations. First, the authors do not discuss the design of the acquisition layer, limiting the deployment into manufacturing environments. Second, the investigation targets fully automated environments, neglecting the pivotal role that workers play in production environments. In particular, the intrinsic entropy of the human factor during task execution may challenge the learning capabilities and thus the classification and regression performances of cyber layers (Sbaragli et al., 2025). Besides traditional manufacturing industries, production planning digital systems have been leveraged in off-site construction environments to better schedule building phases and collaborate with project stakeholders (e.g., site installation). Aghajamali et al. (2022) proposes a CPS to estimate fitting and welding stations' working times in a Canadian construction specialist business. Dataset features relate to each resource involved in the productive value-creation. While fitting station targets the amount of bolted and cut parts, the welding process relies on the product's linear length. These datastreams are fed into a linear regressor and a fully connected neural network to estimate industrial resources cycle times. Despite the neural network's superior performance, the discussion solely evaluates the Mean Squared Error (MSE), falling short in outlining percentage errors between actual and predicted working times. Moreover, authors do not investigate the aggregate errors in a test production sequence in order to identify how potential overestimation may affect the sequential operations of other stakeholders. Data-driven approaches have also been developed to predict construction wall frames production cycle times (Alsakka et al., 2024). In particular, an acquisition layer digitizes the shop floor by leveraging MES and BIM datastreams and Internet of Things sensors such as cameras. This information is fed into neural networks and simulation models to predict working times in real-time. This CPS is validated with a run sequence of 25 assembly frames, showing an underestimation of 22 minutes compared to the actual cycle time. This approach massively outperforms a baseline model that relies on frames' linear meters. However, the sensors' cost, along with their potential occlusions, may limit the applicability of this human-centric solution in other off-site use cases. In summary, the reviewed CPS studies provide valuable methodologies and actionable metrics to support production planning. However, their applicability to off-site construction environments can be further enhanced from two key perspectives.

- **Acquisition layers design and ownership cost:** (Çakıt and Dağdeviren, 2023; Masoumi and Bond, 2025) do not address the design of acquisition layers for automated production data collection. Such functionality is essential for deploying production-ready CPS, as it enables the continuous integration of shop-floor data into algorithms to derive actionable metrics. Furthermore, acquisition systems should be cost-effective to facilitate their adoption in real-world operating environments (Alsakka et al., 2024).
- **Performance benchmarking & evaluation:** the benchmark of machine learning regressors is often based on a limited set of metrics, failing to highlight strengths and limitations in predicting work times. Also, these data-driven approaches are required to investigate how models' predictions affect manufacturing run sequence, potentially affecting other businesses' operations (e.g., site installation) (Masoumi and Bond, 2025; Çakıt and Dağdeviren, 2023).

Building on this discussion, this paper proposes a machine learning-powered CPS to address the identified limitations. The system comprises three interconnected components. First, an acquisition layer consisting of two cloud-based Extract, Transform, Load (ETL) pipelines automates the collection of real-time production data and product design workflows through a cost-effective approach. Second, a cyber layer pre-processes the collected data streams via feature extraction techniques and systematically benchmarks five machine learning regression models to forecast machine working times, including operators' manual material handling activities. Third, a web-based dashboard streamlines production scheduling by automatically dispatching selected frames to stand-alone machines and notifying manufacturing decision-makers via email with predicted working times, while providing key metrics to monitor operations and support integration with other business functions. The CPS is validated in a job shop of a UK-based off-site construction company that manufactures 16 steel frame types. The dataset contains more than 2000 frames manufactured during the first eight months of 2025. Among the benchmarked regressors, the Random Forest achieves the best performance, with a Median Absolute Percentage Error of 10.84% and a percentage residual error of 0.02% on a production order of 420 frames.

Cyber physical system

The digital system is developed to support decision-makers in monitoring and planning fast-paced human-centric off-site production environments. To meet these complementary goals, the CPS consists of four conceptual entities (Fig.1). The first layer targets any human-centric construction environment in which workers execute production cycles by interacting with a diverse set of resources, including machines and assembly stations. An acquisition layer digitizes process execution in these fast-paced, non-standardized settings, replacing reliance on plant managers' experience and lean methodologies. While products' design features and machine working times are acquired using cloud-based ETL pipelines, the Scanning App is an in-house built MES that records product and worker-dependent manufacturing events. These data streams, after specific pre-processing computations, are fed into the third system's entity, the cyber-physical layer. In this regard, machine learning regressors and time-driven algorithms forecast products' working times and derive industrial KPIs. These metrics flow in a dashboard, divided into four different areas. While the first three monitors manufacturing outputs and efficiencies of resources leveraging data coming from the MES (see Fig.1), the planning area presents an interactive user interface to support manufacturing stakeholders in scheduling production run sequences on the shop floor. This preliminary work investigates the feasibility of supporting production planning through the integration of machine learning algorithms within a cyber-physical system. The core contribution lies in benchmarking different regression models for predicting machine working times and in presenting the functionalities of the dashboard's planning area to support run sequence scheduling. The remaining CPS components, such as the MES, are beyond the scope of this paper and are therefore not discussed in further detail.

Acquisition Layer

The acquisition layer runs two parallel ETL pipelines to gather design data streams and machine working time from the shop floor (see Fig. 2). Starting with the first, the structural team publishes the modeled frames on Asite, where any stakeholder may track the product workflow. Any product is uniquely identified by an assembly reference and two supplementary files. While the PDF shows the assembly drawing useful to assist the shop floor task executions, the spreadsheet lists the coil parameters, stud length, and their machine-specific operations (e.g., dimples, notches, swages, etc.) along with a 3D frame position. Each frame also carries a design status, such as On Hold or Approved IFC, along with a revision identifier. A Databricks recursive pipeline (see green lines in Fig.2) continuously accesses all frames regardless of their design status, storing stud identifiers and required machine operations into a cloud database table. As a result, when a frame transitions from On Hold to Approved IFC, the corresponding database records are updated rather than newly created. Therefore, each frame and revision generates multiple entries, one per manufactured stud, with the assembly reference and stud identifier forming the composite primary key. The pipeline runs three times per day to ensure that any revision or status change is promptly reflected in the database. Only the latest revision of frames with an Approved IFC design status can be scheduled for production. Once the production is scheduled and running, the stand-alone machine processes frame-specific spreadsheets and records studs working times in TXT logs. The machine is network-connected and exposed to a static IP address that facilitates the data retrieval of the second pipeline (see blue

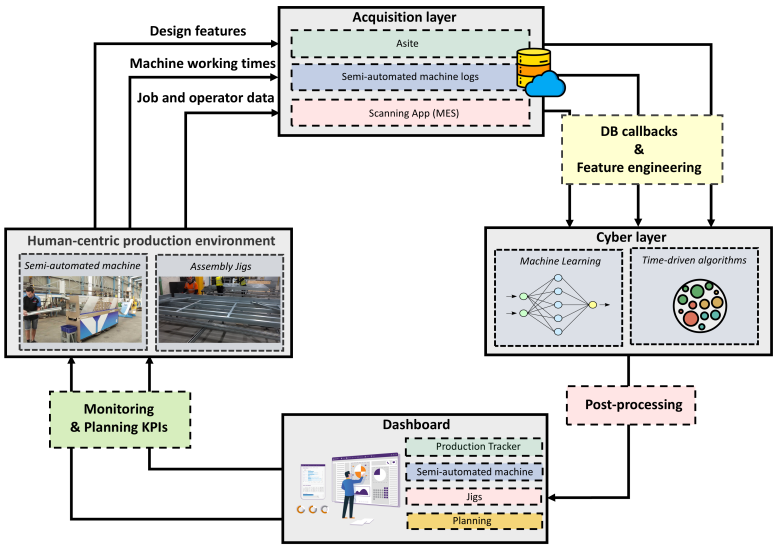

Figure 1: Cyber-physical system to monitor and plan human-centric offsite construction environments

lines in Fig.2). Production data are stored in a separate table but share the same composite primary key of the design flow. The machine pipeline time resolution is equal to 5 minutes, enabling future close-to-real-time shop floor operations monitoring.

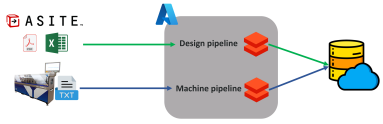

Figure 2: Acquisition Layer data flow

Cyber Layer - Machine Learning

Acquired datastreams are retrieved using database callbacks and subsequently joined on the shared composite primary key. Multiple machine learning models, commonly applied in industrial applications, are then trained on the aggregated dataset to forecast steel frames production times based on design features (Sbaragli et al., 2025). The dataset was partitioned into training and testing subsets using an 80%-20% split, and model performance was evaluated using 5-fold cross-validation. Models' hyperparameters are sub-optimized through the grid search algorithm. The following bullet point lists the evaluated models:

- **Baseline:** this model assumes a direct and linear relationship between frames' length and machine work time, as investigated by Alsakka et al. (2024). The training defines a coefficient as $minutes/millimeter$ that is used to infer process times in the test set.
- **Linear Regressor (LR):** a parametric model that assumes a linear mapping between predictors and the target variable. As LR requires no hyperparameter tuning, it represents a computationally efficient baseline against which to compare more flexible models (Aghajamali et al., 2022).
- **Support Random Vector (SVR):** this kernel-based method fits a regression function within an error tolerance. Its predictive behavior is governed by several parameters. While the regularization parameter C controls the trade-off between model complexity and tolerance to errors, the kernel coefficient γ determines the influence of individual training samples. Finally, the insensitive loss margin ϵ defines the tolerance zone around predictions where no penalty is applied (Çakıt and Dağdeviren, 2023).
- **Random Forest (RF):** an ensemble approach that develops multiple decision trees on bootstrapped samples and aggregates their predictions to reduce variance. Performance depends on parameters such as the number of trees, node-splitting thresholds, and feature selection strategy (Sbaragli et al., 2025).
- **Light Gradient Boosting Machine (Light GMB):** this boosting-based ensemble regressor builds trees sequentially, where each iteration corrects the residuals of the previous one. Key parameters include the number of boosting rounds, learning rate, boosting type (e.g., GBDT or DART), and the learning objective set for regression (Masoumi and Bond, 2025).

After having trained and tested these classifiers, the most performing model is used to support manufacturing engineers in production planning and scheduling. While the comparison benchmark of models is discussed in the Results Section, the following subsection outlines the benefit of leveraging this data-driven CPS in off-site manufacturing environments.

Dashboard - Planning Area

Building on the discussed cyber-layer capabilities for predicting machine work times, this final subsection discusses the dashboard's planning area. The frontend presents an interactive table that reflects the design workflow captured by the ETL pipeline. As shown in Fig. 3, the table maps assembly references (e.g., ARef) against key attributes including project, coil configuration, frame length

(e.g., Len), and the number of screws to be fitted in the jig area. Since an assembly reference may go through multiple design revisions, the table displays only the latest revision for each, ensuring that engineers always work with the most up-to-date information. Each assembly entry also displays its current design status and scheduled production day. Manufacturing engineers can schedule a frame to the shop floor only when two conditions are met: i) the structural manager has set the design status to Approved IFC in Asite, and ii) the frame has not yet been assigned to a production date (i.e., the field is null in Fig.3). To support efficient navigation of large datasets, a filter button allows users to narrow the table view by attributes such as project, design status, and coil configuration. Once the desired eligible items have been selected for scheduling, the user clicks the Schedule Selected button, which triggers two back-end operations. First, the machine files for the selected frames are transferred via the File Transfer Protocol to a designated folder on the stand-alone machine, which the shop floor operator can then open and automatically load. Second, a spreadsheet summarising the expected production times and linear coil consumption for each configuration is automatically emailed to the relevant production stakeholders, such as manufacturing engineers and the production director. By automating both file transfer and the manual development of run sequences, the dashboard significantly reduces the non-value-added administrative burden on engineers, ultimately driving meaningful productivity enhancements across the production workflow.

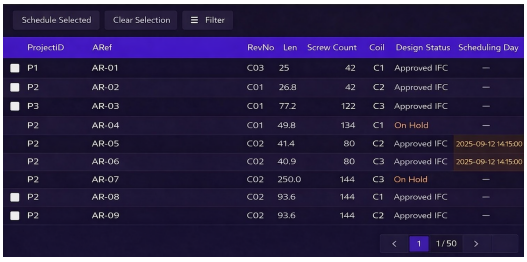

Figure 3: Interactive web-based application to support production scheduling

This novel data-driven methodology provides the business a key opportunity to strengthen its operational value creation. Indeed, the manufacturing team has greater operations visibility that enables better coordination and collaboration with other business areas:

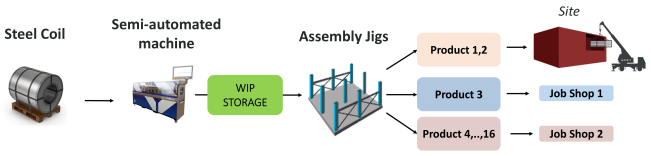
- **Purchasing & Accounting:** the known a priori coil configurations consumption facilitates a just-in-time approach that minimizes stock occupancy and avoids cost overruns in low-rotating or project-specific material. At the same time, project cash flows, such as labor and material costs, are seamlessly integrated.
- **Site:** forecasted due dates of run sheets enable a data-driven definition of frames shipping windows, avoiding project delays and related penalties for missed deadlines.

Results

This section validates the CPS by feeding structural frames' design features into machine learning models to forecast semi-automated resource working times, as captured by the ETL pipeline. Notably, these times encompass material handling activities, which may challenge regressors' learning capabilities. Before discussing the performance of the benchmarked regressors, the following subsection discusses 1) the off-site use case manufacturing operations and 2) the obtained dataset by collecting 8 months of steel frame structural production.

Off-site use case: structural steel frame production

The discussed CPS is tested and validated in a UK-based off-site construction specialist. The monitored human-centric job shop manufactures several steel frame products involving different resources. Fig.4 outlines the off-site manufacturing operations, starting from the steel coil, which is distinguished by different configurations of depth and width (e.g., C1, C2, etc.). Once structural frames are modeled and set to Approved IFC, they are released into the shop floor by using the discussed interactive web-based dashboard. The manufacturing process is then carried out by a semi-automated machine, in which a skilled operator loads the machine file before execution and moves sequentially processed studs into work-in-progress (WIP) storage units. A jolly worker may join the process to facilitate the material handling of studs up to 6.4 meters long. Based on the final product's complexity, a structural steel frame may consist of up to 74 studs. Each processed stud is distinguished by a set of design features (e.g., dimples, swages, notches, length, weight, etc.) that affect the machine's working cycle times. However, ETL-captured working time logs, whose resolution and structure are dictated by the machine output rather than experimental design, also include material handling events. This may challenge machine learning regressors due to the intrinsic process variability (e.g., differences in stud size) and variability in human commitment and experience (Sbaragli and Nardello, 2025). The construction job shop follows a one-piece flow approach in normal operating conditions, and thus, WIP units are moved next to the available or less saturated assembly jig. Four jigs assemble steel frame products in parallel, leveraging up to 4 skilled operators each. Based on the designed assembly drawings, manual operations require stud fittings and screwing operations, as well as potential reworks to address some modelling and/or machine errors. Completed frames are classified into 16 products and thus follow separate production flows (see Fig.4). While Product IDs 1 and 2 are sent to the construction site for their installation, the remaining ones represent WIP modules for other in-plant job shops.
Based on this discussion on manufacturing operations, the following subsection details the acquired datasets from the semi-automated machine.



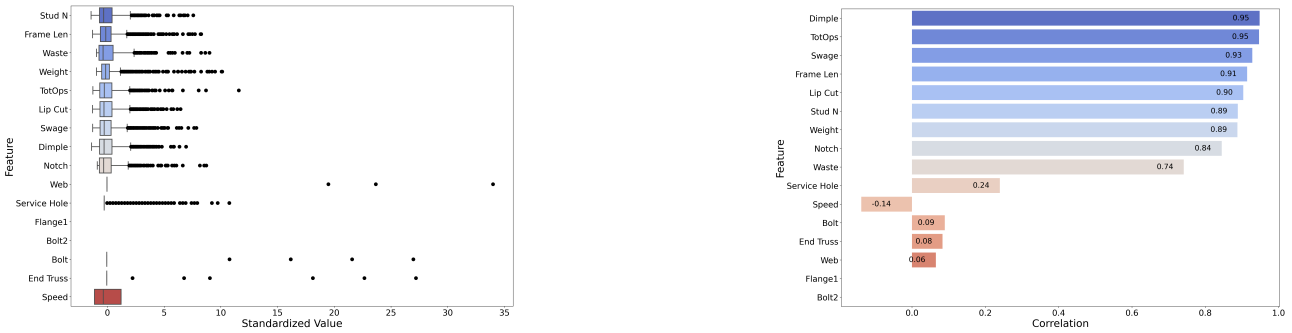


Figure 4: Human-centric production environment

Dataset

To validate the proposed methodology in forecasting machine processing times, 8 production months in 2025 (e.g., from January to August) are retrieved from the resource-specific database involving 5 construction projects across the United Kingdom. The stud-based dataset comprises 26500 samples, with individual work times ranging from 2 to 71.8 seconds. The average process time and standard deviation are equal to 20.4 and 14.2 seconds, respectively. This low-level dataset is grouped by assembly reference to achieve a frame-based representation, where one ARef may group 6 to 74 studs based on the final product complexity and application. This aggregation is implemented for two main aspects. First, the studs' working times are highly exposed to the intrinsic uncertainty of the human factor during task executions. The dedicated operator often pauses the machine to perform audit checks and move manufactured items into WIP storage units. Despite being cyclic, these events have high degrees of entropy, affecting the studs' working times and limiting the learning capabilities of any machine learning model. Second, frames might be assembled only if all studs are processed and stored in a specific location (see Fig. 4). The new compressed dataset includes 2099 steel frames having working times ranging from 0.2 to 26.4 minutes. The average process time and standard deviation are equal to 4.3 and 2.9 minutes, respectively. Once the machine dataset is compressed, a separate callback downloads and post-processes data from the design database table. Similarly to the machine dataset, frame features are obtained by summing or counting the studs descriptors while grouping on the ARef field. These frames' features include the total amount of required manufacturing operations (e.g., Lip Cut, Notch, Web, Service Hole, etc.), the aggregate dimensions (e.g., length and weight), and the count of grouped studs. Finally, the two datasets are joined together on ARef, the common and unique column. Fig. 5 (a) outlines the entire set of frame features, where waste and speed represent steel scrap and machine velocity in manufacturing a given product. It is worth noting that Stud N and TotOps represent the total amount of studs and machine operations on every frame, respectively. The remaining structural features are not detailed further due to the company non non-disclosure agreement. The job shop's production output is very customized to meet the customer and construction requirements of different healthcare projects. Fig.5 (a) streamlines features relative variability and distribution patterns through z-scores. The 16 different variables have standardized values ranging from 0 to approximately 35 and might be divided into different sub-groups. Structural information (e.g., Lip Cut, Swage, Dimple, Notch, etc.), dimensions (e.g., Weight and Frame Len), and Waste present compact distributions with upper quartiles below the standardized unit 5. However, many outlier reiterates the uniqueness of structural modules within projects. Less-exploited design specifications, such as Web, Bolt, and Service Hole, present very narrow distribution close to zero but with several distinct outliers at higher values. Flange1 and Bolt2 are not represented in this dataset. Finally, the Speed has no whiskers, underlying machine velocities equal to 20%, 50%, and 70% of the maximum. This set of features is ranked to reduce computational load and simplify the learning process for machine learning models. The data distributions are non-Gaussian, may lack linear relationships with machine work time, and include many outliers. Therefore, the Spearman correlation is applied to evaluate the strength and direction of monotonic associations. Fig. 5 (b) ranks the pair-wise correlation between each feature and the machine work time. It is worth noting that the Speed correlation captures a weak inverse relationship with the processing time. Feature selection employed a correlation threshold of 0.7 to minimize dimensionality for machine learning models. Therefore, the subsequent performance benchmark discussion excludes all descriptors with correlations below this cutoff, from Service Hole to Bolt2.

Working times prediction: algorithms' performance benchmarking

The structural dataset has been validated using the five different regressors discussed in the cyber layer subsection. The training process involves five-fold cross-validation and grid-search hyperparameter optimisation. Regressors are benchmarked using Training Time (TrTime), Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), Mean Absolute Percentage Error (MAPE), and Coefficient of Determination (R^2), which provide standard error and goodness-of-fit measures, alongside Median Absolute Error (MdAE) and Median Absolute Percentage Error (MdAPE) as robust, scale-independent alternatives less sensitive to outliers. Tab.1 benchmarks the performance of the algorithms to forecast the semi-automated machine work times by having as input the features discussed in the previous section. The baseline approach that leverages frame length delivers the weakest performance. The high error levels (e.g., RMSE = 1.19, MAE = 0.78, MAPE = 19.09%) and a relatively low coefficient of determination (e.g., R^2 = 0.84) reflect the model's inability to capture the underlying data patterns and relationships. LR substantially improves these metrics, achieving the highest R^2 and competitive error values. RMSE and MAE are equal to 0.72 and 0.51, respectively. However, LR's percentage-based metrics (e.g., MAPE = 14.51%, MdAPE = 11.36%) remain higher compared to tree-based methods, suggesting reduced robustness when predicted working times are

(a) Z-score features distribution

(b) Spearman Correlation

Figure 5: Dataset features distribution and ranking

Table 1: Performance comparison of regression models.

Regressor	TrTime [sec]	RMSE	MAE	MAPE	MdAE	MdAPE	R^2
Baseline	NA	1.19	0.78	19.09%	0.50	17.81%	0.84
LR	NA	0.72	0.51	14.51%	0.37	11.36%	0.94
SVR	8.2	0.88	0.55	17.26%	0.39	12.39%	0.92
RF	**44.0**	**0.85**	**0.52**	**13.79%**	**0.33**	**10.84%**	**0.92**
Light GBM	14.8	0.85	0.55	16.02%	0.37	11.92%	0.92

(a) Absolute Residuals

(b) Relative Residuals

Figure 6: Aggregate model performances on the test set

assessed relative to actual values. SVR performs moderately well, even though the RMSE of 0.88 and MAPE equal to 17.26% indicate less stability compared to LR and RF models. Light GBM achieves comparable performance to SVR (e.g., RMSE = 0.85 and MAE = 0.55), but MAPE and MdAPE equal to 16.02% and 11.92% show limitations in effective generalization. Within this benchmark, the RF regressor demonstrates the most balanced and robust performance metrics. Despite a training time equal to 44 seconds and slightly higher exposure to outliers compared to LR (e.g., RMSE = 0.85), RF yields the lowest MAPE (13.79%) and MdAPE (10.84%), indicating that its predictions are not only accurate but also less sensitive to variations in scale. The performance benchmark is further expanded by investigating how models' performances affect the run sequence of the test set (e.g., 420 frames). In this regard, Fig. 6 depicts the aggregate absolute and relative residuals after having summed the actual machine working times and the ones predicted by each algorithm. RF is the only model to achieve an aggregate absolute residual close to zero (0.45 minutes), whereas LR, SVR, and LightGBM display absolute and relative deviations ranging from 6.05 to 8.20 minutes and from 0.34% to 0.46%, respectively. The baseline remains the worst regressors, accounting for an underestimation of 179.23 minutes and 9.94%.

Operational implications

These results confirm that the RF regressor provides the most reliable and operationally robust performance among the tested models (Tab. 1 and Fig. 6). Crucially, the dashboard workflow automates production scheduling by generating optimised run sequences directly from the web application, eliminating the need for engineers to interact with multiple company software systems (e.g., Asite), manually download files, or transfer machine files to the stand-alone resource. Preliminary investigations on run sequences ranging from 20 to 30 structural frames demonstrate a 75% reduction in planning time. At the same time, machine learning-based predictions enhances visibility into manufacturing operations, allowing stakeholders to better anticipate workloads and coordinate downstream processes. By integrating this capability across departments, the system supports tighter alignment across

key functions. For planning, it enables more realistic deadline scheduling against production constraints. For purchasing, it facilitates just-in-time material deliveries and reduces stock occupancy. For finance, it provides advance visibility into material consumption, supporting improved cost forecasting and budget control.

Conclusions & Further Research

Off-site construction environments tend to suffer from cost overruns and constantly delayed deadlines due to poor operations management and a lack of standardization across projects. Therefore, construction factories are required to leverage Industry 4.0 enabling technologies to support production planning and achieve a more reliable operations visibility. This work proposes a machine-learning-powered CPS that supports manufacturing stakeholders in forecasting machine cycle times and automating run sequences on the shop floor. While two ETL pipelines acquire design features and machine work times, the cyber layer benchmarks 5 different algorithms, establishing the RF as the most performing model to forecast frame production times. This tree-based regressor is embedded in an interactive web-based dashboard, enabling manufacturing stakeholders to forecast production times before scheduling run sequences into the shop floor. This CPS has been validated in a UK-based steel frame job shop production using 8 months of data in 2025. Further research should validate this methodology in the jigs area and use metaheuristic algorithms to optimise production scheduling given a set of constraints.

Acknowledgments

This work has been supported by Innovate UK under the Knowledge Partnership Program with grant number 10099000.

EMERGING BUSINESS-MODEL ARCHETYPES OF A SMART MOBILE FACTORY FOR CONSTRUCTION 4.0

Alexander N. Walzer[1], Irfan Čustović[2], Konrad Graser[1] and Daniel M. Hall[2]
[1] Zurich University of Applied Sciences, Winterthur, Switzerland

Delft University of Technology, The Netherlands

Abstract

Smart Mobile Factories (SMFs) bring prefabrication to the construction site, enabling just-in-time delivery, shorter haulage distances and lower carbon emissions. Although integrated digital twins and modular factory designs have demonstrated the technical feasibility of SMFs in construction, their value-creation mechanisms for operators and clients remain unclear. Adapting the Business-Model Canvas to SMFs, we identify four emerging archetypes. Two case vignettes illustrate the transition from a low-tech, asset-centric to a high-tech, data-centric service model. Finally, we propose a mapping that relates organizational digital maturity to suitable SMF business-model archetypes, which allows to indicate a possible path toward profitable and sustainable adoption.

Introduction

Construction activities account for roughly 6% of European gross domestic product, a percentage that has steadily declined in the past two decades (UNECE, 2025), trailing manufacturing in terms of productivity, schedule reliability, and environmental performance (Hamza et al., 2019). Off-site prefabrication has long been held as a strategy for increasing productivity, but the approach is still suffering from the spatial and temporal disconnect between off-site prefabrication plants and on-site assembly zones. Transporting large components over long distances inflates fuel consumption and forces projects to maintain excess on-site inventory, a phenomenon often called the just-in-time delivery paradox (Johansson et al., 2024). Smart Mobile Factories (e.g., Figure 1) have emerged as technological response to these limitations, reintroducing production flexibility into the construction context through mobility (Matt, Rauch & Dallasega, 2015).

Moreover, recent research suggests that mobile factories can introduce a new level of efficiency and flexibility into construction projects by relocating production closer to the point of use (Wagner et al., 2020; Nahmad Vazquez, Garivani & Dackiw, 2024). Beyond just differentiated in logistics, SMFs are typically conceived as highly digitalized production systems, embedding sensors, data integration, and automated control within a controlled, yet relocatable environment (Ibid.).

This setting facilitates process monitoring and data-driven coordination that is difficult to achieve in conventional, exposed, and constantly changing construction sites. The combination of mobility and digital control therefore distinguishes SMFs operationally and in terms of their data generation and decision-making potential.

Figure 1: Smart Mobile Factory for Infrastructure (SMF4INFRA, 2025)

Despite increasing conceptual maturity and pilot applications, the economic rationale for SMFs remains weakly articulated. Existing research has largely focused on technical configurations and productivity gains, with limited attention to value capture, revenue generation, and risk allocation (Matt, Rauch & Dallasega, 2015). At the same time, insights from servitization and Industry 4.0 research highlight the potential of digital technologies to enable service- and performance-based business models, but these are primarily derived from stationary manufacturing contexts and insufficiently address the mobility, project-based organization, and site-specific constraints of construction (Grubic, 2014; Frank et al., 2019). This gap is rather critical, as digitalization requires coordinated business model alignment across multiple actors (Kohtamäki et al., 2019), and the high upfront investment associated with SMFs amplifies financial risk perceptions when revenue logic is unclear (European Commission, 2025; Walzer et al., 2024b). Consequently, the relationship between organizational digital maturity and viable, scalable business models of SMFs remains poorly understood and is the center of this study.

State of the Art

Smart Mobile Factories

A mobile factory is defined as a distributed production facility composed of reconfigurable and mobile production systems that can adapt capacity and functionality to site conditions (Dallasega et al., 2024).

By physically relocating prefabrication activities to the construction site, these factories challenge the traditional separation between manufacturing and assembly. Producing closer to the site reduces transportation distances and delivers clear environmental and economic advantages (Ma et al., 2025). This proximity also supports more responsive production planning, reducing storage requirements and buffer inventories that remain a persistent source of inefficiency in construction logistics (Matt, Rauch & Dallasega, 2015). Moreover, the relocatable nature of mobile factories allows prefabrication benefits to be extended to remote or otherwise difficult project locations. From a sustainability perspective, SMFs contribute to lower transportation-related emissions, improved resource efficiency, and reduced waste, while enabling the use of energy-efficient production technologies (Matt, Rauch & Dallasega, 2015).Smartness in SMFs is achieved through the integration of advanced digital technologies that connect factory operations with site-level management systems (Čustović et al., 2023b). These systems provide a digital representation of processes, materials, and equipment, enabling more transparent and coordinated production control. Over time, accumulated production data supports performance benchmarking and improves the prediction of system behavior under varying conditions (Thelen et al., 2022). Recent empirical studies show that IoT sensor networks enhance quality monitoring in mobile factory settings (Tripathi et al., 2025). In addition, digital twin (DT) approaches allow production plans to be adjusted dynamically in response to uncertainty (Čustović et al., 2025) and support informed decisions regarding factory relocation, considering schedule, cost, and environmental impacts (Cao et al., 2024; Ma et al., 2025). These developments position SMFs as data-intensive systems at the intersection of Construction 4.0 and service-oriented manufacturing (Jäkel et al., 2024; Karmakar & Delhi, 2021; Sawhney et al., 2020).

Business Model Aspects of Smart Mobile Factories

Despite technological progress, the business model implications of SMFs remain weakly developed. The majority of SMF-related studies frame these systems primarily as technical solutions, emphasizing automation, system design, and efficiency gains (Matt, Rauch & Dallasega, 2015). As a result, commercially critical issues such as pricing mechanisms, asset and data ownership, lifecycle cost allocation, and inter-organizational governance are rarely examined in depth. This narrow focus limits understanding of how technical performance translates into economic value across project networks. By contrast, the servitization and Industry 4.0 literature studies the role of digital capabilities in enabling outcome-based services and collaborative value creation (Grubic, 2014; Frank et al., 2019; Čustović et al., 2023a). Yet, these models typically assume stable production environments and long-term customer relationships, assumptions that do not align with the temporary, mobile, and project-based nature of construction. When applied uncritically to SMFs, such assumptions obscure challenges related to demand volatility, site-specific customization, and short-term contractual arrangements.

This disconnect becomes particularly problematic given the high capital intensity and demand uncertainty associated with industrialized construction solutions (Čustović et al., 2023b). Without explicit mechanisms for value capture and risk sharing, these characteristics reinforce financial risk perceptions and slow adoption. Although recent construction management reviews recognize that construction business models are evolving (Li et al., 2025), they offer limited guidance on how digital maturity, such as the integration of BIM, IoT, and DTs (Revolti et al., 2025), can be monetized in SMFs. Consequently, the state of the art lacks an integrated perspective that links digital maturity, mobility, and performance outcomes to sustainable business models for SMFs.

Therefore, in this paper we investigate the research question: "*Which business-model configurations are currently emerging for Smart Mobile Factories for Construction 4.0, and how can practitioners select the most appropriate configuration given their digital maturity?*"

Methodology

We pursued a design science approach, yet the nascent state of the field prevents iterative artifact testing (Hevner & Chatterjee, 2004; Peffers et al., 2007; Kuechler & Vaishnavi, 2008). Thus, we started from the canonical Business-Model Canvas (BMC) by Osterwalder & Pigneur (2010) and enriched it with three SMF-specific dimensions (smartness, mobility, site-specificity). The resulting SMF-specific BMC (Table 1) served as the a-priori coding framework for all subsequent document analysis (Hsieh & Shannon, 2005). Seven sources (partly peer-reviewed and a project report) were selected using a purposive sampling approach and structured reading because they (i) discuss SMFs or related mobile-prefabrication concepts, and (ii) contain at least one explicit reference to business-model elements. The corpus comprises: Dallasega et al., 2024; SMF4INFRA, 2025; Martínez et al. , 2013; Park et al., 2019; Frank et al., 2019; Grubic, 2014; Tripathi et al., 2025. Using the SMF-specific BMC as a coding sheet, each document was read line-by-line, and every passage that corresponded to one of the nine BMC blocks (value proposition, customer segments, channels, revenue streams, key resources, key activities, key partnerships, cost structure, customer relationships) was extracted. Extracted excerpts were entered into a shared Microsoft Excel workbook (one column per BMC block, one row per source). The spreadsheet was then synchronised on a collaborative MIRO board so that all co-authors could visualise the coding and discuss emerging ambiguities in real time. Two pilot projects, the SMF4INFRA hyperloop prototype for linear infrastructure (Figure 1) (SMF4INFRA, 2025) and the Flexible Field Factory for housing construction (Figure 2) (Martínez et al., 2013), are further used as case vignettes.

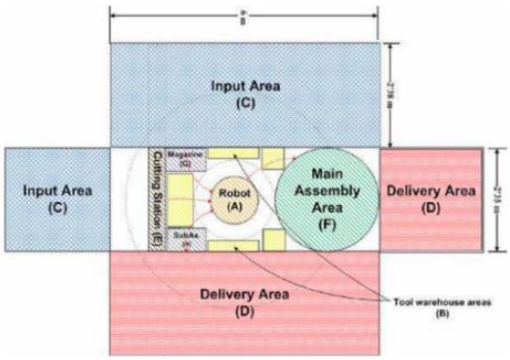

Figure 2: Flexible Field Factory (Martínez et al., 2013)

Result Analysis

Several SMF elements for each of the nine blocks of the BMC are reported in Table 1. The coded BMC allows to reveal the SMF's value-creation logic: the value proposition centres on just-in-time on-site prefabrication that cuts haulage distance and CO_2 emissions; channels and key resources (DT platform, IoT sensor network, mobile plant) describe how the service is delivered, while revenue streams (fixed-term lease, per-component assembly fees, transaction fees, DaaS subscriptions) reveal how value is captured. From these elements, two overarching insights emerge.

First, the plant's mobility reduces on-site inventory and creates a distinct cost item (relocation logistics) that can be monetised with low-to-mid digital-maturity business models (see Table 2). Second, the continuous sensor feed within the DT can enable a high-margin Data-as-a-Service (DaaS) revenue stream, but only when the SMF reaches a very high digital-maturity level. These patterns form the basis for the four business-model archetypes presented in the next section, each grouping a distinct combination of BMC blocks along the servitisation continuum.

Table 1: SMF-specific Business-Model Canvas (BMC)

BMC block	SMF-specific element derived from the literature
Value proposition	Just-in-time on-site prefabrication that eliminates long haulage, cuts CO_2, and compresses the schedule, improved quality and quality control
Customer Segments	Large-scale infrastructure owners (rail, tunnel, hyperloop); modular-housing developers; public-private partnership (PPP) consortia
Channels	Direct turnkey contracts; digital marketplace for on-demand modules (online portal); BIM-integrated procurement API
Revenue streams	Fixed-term lease fee for the mobile plant; per-component assembly charge; KPI-linked performance bonus/penalty (schedule, CO_2); transaction fee on marketplace sales; subscription for real-time production data (DaaS)
Key resources	Mobile modular plant (cranes, CNC, material mixers); BIM/DT platform (cloud server, GIS); IoT sensor network (temperature, vibration, GPS); skilled on-site crew (fabricators, data analysts)
Key activities	Relocation logistics (move plant, set up utilities); production of components; on-site assembly of prefabricated components; continuous data acquisition & analytics (DT updates); life-cycle-assessment feedback loop (track CO_2, adjust processes)
Key partnerships	Equipment OEMs (provide modular plant modules); local utilities (power, water, waste); logistics providers (fuel, auxiliary material transport); municipal authorities (permits, road closures)
Cost structure	Capital purchase/depreciation of the mobile plant; energy consumption (diesel generators, electricity); IT/cloud services (BIM licenses, DT hosting); training & certification of the mobile crew; maintenance & spare-part inventory
Customer Relation-ships	Long-term service contracts (maintenance, upgrades); outcome-based SLAs with bonus/penalty clauses; platform support desk for marketplace users; data-portal access for DaaS subscribers

Emerging Business-Model Archetypes of SMFs

Based on the BMC elements presented in Table 1, we derived four distinct business-model (BM) archetypes. The four business-model archetypes presented in Tables 2-5 are not directly observed in the assessed literature as such but constitute an original typology constructed by the authors through pattern induction across the coded BMC elements. This is understood as being rather projective.

Each archetype was interpreted as a coherent revenue logic and labelled according to the servitisation continuum (product-centric → service-centric → data-centric). In a second step, we linked each cluster to the digital-maturity level required to realise the associated activities (low to very-high). Tables 2-5 summarizes the four archetypes, their defining BMC pattern, the primary adoption drivers, the construction sectors where they are most common, and the digital-maturity prerequisite.

Product-Plus (low digital maturity): In this archetype the SMF is treated as a capital asset that is bought or leased, and revenue comes from a per-module assembly fee. Early pilots (Martínez et al., 2013) report exactly this cost-plus arrangement, and servitisation theory locates it at the product-centric end of the continuum (Grubic, 2014; Frank et al., 2019). Minimal sensor integration means the owner only needs a basic BIM model; risk is shifted to the contractor through the fixed-lease payment. Product-Plus therefore provides a baseline from which higher-maturity models can be differentiated.

Table 2: SMF-specific Business-Model: Product-Plus

Core BMC pattern(s)	Revenue: fixed lease plus per-component assembly fee; Key Activities: on-site assembly; Cost: CAPEX amortisation
Adoption driver(s)	Need for predictable cash-flows and CAPEX spreading; high repeatability of components makes a fixed lease attractive; owners prefer to outsource assembly while retaining design control
Dominant sectors	Low-rise modular and residential housing, industrial plant construction
Required maturity	Low (basic BIM, no continuous data)

Outcome-Based (medium digital maturity): This archetype ties revenue to the achievement of predefined KPIs such as schedule compliance or CO_2 reduction. Performance-based contracts are documented in construction research (Li et al., 2024; Frank et al., 2019), and understood as used in the SMF4INFRA hyperloop case (Cao et al., 2024; Ma et al., 2025). Implementing this model requires a modest digital stack, such as a BIM-linked DT for schedule forecasting and a limited set of IoT sensors that feed KPI data to the client's dashboard. Outcome-Based models adds a performance-monitoring layer to Product-Plus, preparing the SMF for more data-intensive configurations.

Table 3: SMF-specific Business-Model: Outcome-Based

Core BMC pattern(s)	Value: schedule + CO_2 guarantees. Revenue: performance-linked bonus / penalty; Customer Relationships: SLAs
Adoption driver(s)	Contracts tie funding to schedule and carbon-emission KPIs; risk-sharing incentives push both parties toward performance-based remuneration
Dominant sectors	Linear infrastructure (rail, tunnel), infrastructure renewal (bridges, dams)
Required maturity	Medium (real-time KPI dashboard, basic sensors)

Platform-Marketplace (high digital maturity): This archetype turns the SMF into a digital hub that coordinates third-party suppliers through an online marketplace. Platform-based servitisation is well established (Grubic, 2014; Kohtamäki et al., 2019) and BIM-linked API that would enable external vendors to submit designs and receive automated compatibility checks (Cao et al., 2024; Thelen et al., 2022). This configuration demands a full-scale BIM model, open-API interfaces, and a cloud-hosted portal; revenue is generated via transaction fees and optional analytics subscriptions. Network effects increase platform value as more suppliers join. Platform-Marketplace occupies the service-centric pole of the servitisation continuum, extending Outcome-Based by adding active ecosystem orchestration.

Table 4: SMF-specific Business-Model: Platform-Marketplace

Core BMC pattern(s)	Channels: online portal; Revenue: transaction fee; Partnerships: OEMs + utilities; Key Resources: DT platform
Adoption driver(s)	Coordination of many third-party suppliers along a moving front requires a shared digital ecosystem; economies of scale and network effects make a marketplace financially viable
Dominant sectors	Complex infrastructure projects with many suppliers; emerging urban-retrofit projects
Required maturity	High (full BIM-linked twin, open APIs)

Data-as-a-Service (very high digital maturity): this archetype monetises the continuous IoT stream from the SMF, offering analytics-as-a-subscription. IoT-driven construction services can show high margins for subscription-based data models and digital-twin literature confirms that a cloud-hosted twin can act as a data broker (Thelen et al., 2022; Cao et al., 2024). DaaS requires end-to-end IoT streaming, a cloud analytics stack, and secure APIs that expose anonymised sensor feeds to subscribed parties (e.g., OEMs, insurers). Revenue here can stem from subscription fees, pay-per-analysis charges, and licensing of aggregated datasets, making the model largely volume-independent. DaaS sits at the far end of the servitisation ladder, representing the ultimate digital transformation of SMFs and delivering a high-margin, recurring-revenue stream.

Table 5: SMF-specific Business-Model: Data-as-a-Service

Core BMC pattern(s)	Key Resources: IoT sensor network; Revenue: subscription for data/analytics; Value: real-time insights for OEMs
Adoption driver(s)	Monetisation of sensor data reduces rework, warranty costs, and downtime; high-value OEMs seek fleet-wide performance analytics; space constraints make just-in-time logistics dependent on real-time data
Dominant industry sectors	Modular housing, high-rise construction, and critical industrial-plant upgrades that use predictive-maintenance services (power stations)
Required maturity	Very High (continuous IoT streaming, cloud analytics)

As of writing this study in 2026, it is understood that both Platform-Marketplace and DaaS are considered emerging and aspirational configurations based on technical feasibility rather than current mature market standards.

Mapping of Case Vignettes to BM Archetypes

The SMF4INFRA hyperloop pilot is a mobile prefabrication plant that manufactures pre-cast concrete tunnel segments for a Swiss hyperloop tunnel (SMF4INFRA, 2025).

The Flexible Field Factory (Martínez et al., 2013) is a truck-mounted production plant that manufactures prefabricated elements for low-rise residential housing in Spain. The two illustrative projects are examined by populating the SMF-specific Business-Model Canvas with the information extracted from their respective reports and checking the consistency of each case with the block patterns that define the four archetypes (Figure 3). The SMF4INFRA hyperloop pilot aligns mostly with the Platform-Marketplace archetype in terms of ambition. In this project, a DT-enabled marketplace can coordinate a large number of component suppliers through an ecosystem, and a transaction fee can be levied on each component sale. Because the plant also streams continuous IoT data for performance monitoring, a Data-as-a-Service element can be added on top of the primary platform model. In contrast, the Flexible Field Factory (Martínez et al., 2013) exemplifies mostly the Product-Plus archetype. It is assumed the plant is leased on a fixed-term basis and generates revenue through per-module assembly fees. No continuous sensor data are reported for this case, so the model remains at a low-to-medium digital-maturity level, and no secondary archetype is evident. Taken together, these two vignettes provide partial validation of the four-archetype typology.

The hyperloop pilot demonstrates how a high-digital-maturity SMF naturally adopts a platform-centric business model (with an optional DaaS add-on), whereas the Flexible Field Factory shows that even a low-to-medium-maturity SMF can achieve notable productivity gains by employing a Product-Plus configuration. This mapping exercise is only an early suggestion that the digital-maturity level of an SMF is a decisive factor in determining which business-model archetype best fits a given project and organization.

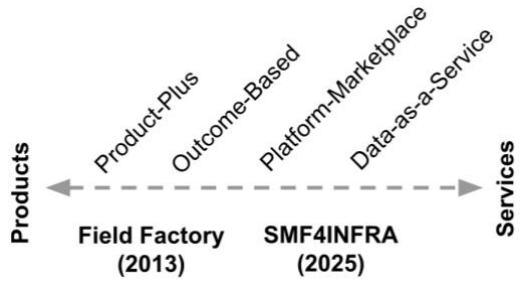

Figure 3: The case vignettes and archetypes mapped on the servitisation continuum

Proposed Business-Model Archetype Map

To help practising stakeholders to identify a suitable business-model archetype for their SMF plans, we propose a simple to use business-model archetype map (Figure 4). This map positions the envisioned SMF along three practical dimensions: the intraorganizational digital maturity, the interorganizational maturity and the servitisation continuum. Taken together, this leads to a three-step screening logic for early-stage feasibility assessment: stakeholders first populate the SMF-specific BMC shown in Table 1 with the project's actual resources, activities, and partners; then assess intra- and interorganizational digital maturity (low, medium, high, very high) based on BIM depth, sensor coverage, and API openness; and finally identify the matching archetype(s) described in Tables 2-5 (Product-Plus, Outcome-Based, Platform-Marketplace, and/or Data-as-a-Service).

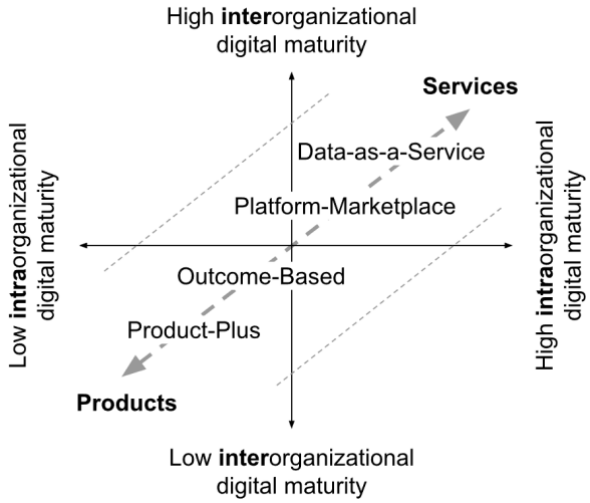

Figure 4: BM archetypes mapped along digital maturity levels

Discussion

This study makes three original contributions to the emerging field of research on SMFs for Construction 4.0. First, we create the first typology of SMF business models. Second, we illustrate and partially test these typologies with two independent case vignettes. Third, we synthesize these findings in a Business-Model Archetype Map (Figure 4), which helps stakeholders, such as contractors, investors, and public agencies, to align their digital capabilities (BIM, IoT, DT) with an appropriate revenue structure, and capitalize on the benefits documented in SMF life-cycle studies. This map aligns digital maturity in SMF contexts with the servitization continuum.

The four archetypes uncovered in the results correspond in principle to the servitisation continuum described by Grubic (2014) and Frank et al. (2019). The case mapping shows that a high-maturity DT (SMF4INFRA) enables a Platform-Marketplace revenue logic, whereas a low-maturity plant (Flexible Field Factory) relies on a Product-Plus structure. This pattern mirrors the servitisation continuum: firms progress from product-plus offerings to data-driven services as their digital capabilities mature. Furthermore, the sectoral distribution in Table 2 shows distinct servitisation drivers. In linear infrastructure, the dominant driver is performance-based risk allocation: governments and financiers attach penalties / bonuses to cost and time schedules, and CO_2 KPIs, which align naturally with the Outcome-Based archetype (Frank et al., 2019). The concurrent use of a Platform-Marketplace arises because a moving front requires real-time coordination of multiple suppliers, a rather classic ecosystem-centric servitisation pattern (Grubic, 2014). In modular housing, the primary driver is cost predictability; developers may prefer a fixed lease

that spreads the capital burden of the mobile plant (most closely related to Product-Plus).

But as data-collection technologies become cheaper, housing firms may add a Data-as-a-Service layer to extract value from sensor streams, reflecting the "data-driven servitisation" stage identified by Frank et al. (2019). Further, industrial plant construction can combine both drivers: high CAPEX pushes firms toward leasing, while simultaneously stringent certification deadlines create a need for outcome-based guarantees. Finally, the nascent adoption of data-centric models in urban retrofit projects is understood as primarily driven by space scarcity and the necessity for just-in-time logistics, which arguably only a real-time data service can reliably support.

Limitations and Future Research

The evidence base for this study is rather small, purposively selected, and heavily Euro-centric. Consequently, (i) emerging or niche SMF revenue models may be missing, (ii) sustainability conclusions rely on a limited set of LCA studies, (iii) no primary data (surveys, interviews, or field observations) were collected, (iv) cost-estimation and unit-economic analyses are absent, and (v) rapid advances in IoT, blockchain, AI and performance-contracting could generate business-model configurations beyond the four archetypes presented. To address these gaps, future research will certainly have to:

(1) expand the literature pool by adding recent scientific papers, industry white papers, technical reports and region-specific case studies (e.g., North-America, Asia-Pacific) to capture additional revenue models and test the universality of the presented typology;

(2) collect mixed-methods stakeholder data (surveys and semi-structured interviews) to validate the archetypes, map preferences (Wu et al., 2024), perceived barriers (Tan et al., 2025), and willingness-to-pay for services such as Data-as-a-Service;

(3) apply appropriate cost-estimation / unit-economic analysis methods (see Marcinkeviciūtė et al., 2025; Walzer et al., 2024a; Walzer et al., 2026) to quantify CAPEX, OPEX and ROI for each archetype;

(4) track firms longitudinally to document the evolution from Product-Plus to Data-as-a-Service and identify the critical capability-building turning points;

(5) conduct comparative, longitudinal case studies (for example high-rise urban vs. linear-infrastructure projects) to evaluate net-present value, CO_2 emissions, schedule adherence and risk exposure; and, lastly,

(6) refine this initial three-step screening logic into a calibrated multi-criteria decision-analysis (MCDA) tool that integrates financial, environmental and risk criteria from a standpoint of epistemological and methodological plurality (Walzer, 2025) that also considers social aspects, such as human-technology interactions (Johansen et al., 2024; Tan et al., 2026).

Conclusions and Implications

This study may be a first to analyse the business model aspects of SMFs across varying degrees of digital maturity. This was achieved by adapting the Business-Model Canvas to the construction context.

The analysis revealed a four-archetype continuum (Product-Plus, Outcome-Based, Platform-Marketplace, Data-as-a-Service) that aligns with the servitisation ladder, and is ordered by increasing digital-maturity requirements. The three-step screening logic operationalises this insight and two real-world pilots (SMF4INFRA hyperloop and the Flexible Field Factory) demonstrate that SMF projects can illustrate the identified archetypes fairly well, yet require further validation.

The typology itself yields concrete implications: For practitioners, the four archetypes make explicit which digital investments (depth of BIM models, IoT sensor layers, openness of APIs) are prerequisites for moving from low-value (Product-Plus) to high-value (Platform-Marketplace, Data-as-a-Service) revenue models, enabling staged technology roll-outs and, respectively, risk-adjusted financing. Policymakers can steer SMF deployments toward the most sustainable structures by embedding CO_2-performance KPIs in outcome-based contracts and utilising, for example, tax-credit incentives. For scholars, the work extends servitisation theory to a mobile, construction-site context and establishes a baseline for longitudinal research on business-model evolution in Construction 4.0 environments. Moreover, this work provides a taxonomy that can be used as a coding scheme in future empirical studies of digital-enabled construction ventures.

In conclusion, SMFs for Construction hold the promise of reconciling the speed and precision of factory production with the flexibility demanded by on-site construction. By clarifying how value can be captured, this paper helps advance SMFs from a purely technical curiosity into a potentially commercially viable, sustainability-enhancing construction paradigm. The archetypes and the screening logic presented herein lay the groundwork for both immediate industry adoption and a future agenda of scholarly inquiry.

Acknowledgments

We are thankful for the constructive and inspiring discussions within the SMF4INFRA Consortium, in which this work has been developed. A special gratitude is directed towards Prof. Guillaume Habert of ETH Zurich, who enabled the collaboration of the co-authors. This study has received funding from the Swiss National Science Foundation under grant agreement No. 204852 and the Autonomous Province of Bolzano/Bozen – South Tyrol. We further thank the Institute of Virtual Design and Construction (VDC) at FHNW for adopting this work within their didactic framework, allowing it to inform the coursework of the students in a recent semester project.

Abstract

Digital twins (DTs) promise improved decision-making under project uncertainty, but real-world implementations are costly and hard to compare. As DT research moves toward tighter feedback loops and greater autonomy, affordable and controllable environments for evaluating such DTs are lacking. This paper presents a modular DT testbed that combines LEGO®-based physical components with Raspberry Pi computers to support controlled variation of DT scenarios, feedback loops and automation levels. Two studies conducted in the testbed illustrate how DTs can be systematically evaluated across computational processes and physical execution. The testbed facilitates cost-effective and repeatable future research on autonomous DTs for construction management.

Introduction

DTs for construction management are receiving significant attention because project execution remains inefficient (Kookalani *et al.*, 2026). The basic promise is straightforward: link on-site conditions with a digital representation that supports situation awareness and more informed control. DT research has moved from isolated twins for a single building in operation to integrated systems intended to support complex project-level decisions (Whyte *et al.*, 2025). This shift matters because project disruptions are not isolated events; they emerge from complex interactions across trades, zones and time.

Current DT research follows two intertwined trajectories: speeding up feedback loops and increasing autonomy. Faster, more frequent data integration is motivated by the need for timely responses to disruptions and the desire for preventive action (Boje *et al.*, 2020). Accordingly, DT applications span timeframes from weekly coordination to more continuous monitoring under unstable conditions (Chacón *et al.*, 2024; Soman *et al.*, 2025). At the same time, DTs are envisioned to evolve from supporting data analysis in routine situations toward autonomous execution of non-routine actions, often realized through mobile on-site robotics (de Soto and Skibniewski, 2020; Agrawal *et al.*, 2023). However, accelerating feedback loops and automation levels do more than improve responsiveness; they reshape how work and decisions are distributed between humans and digital systems (Parasuraman, Sheridan and Wickens, 2000).

The value of DT implementations depends on alignment between automation level, organizational context, and intended use case, rather than on technical sophistication alone (Čustović *et al.*, 2025). Without such alignment and early user involvement, DTs risk underperforming when exposed to real project variability.

This situation creates a methodological bottleneck: transitioning DT concepts into operational prototypes and systematically studying their effects remain difficult. The inherent variability and the complex system-of-systems that characterize construction projects make it difficult to isolate the effects of specific DT features (Zhu *et al.*, 2024). It becomes unclear whether improvements are driven by the DT itself, by users' responses to it, or by coincidental project dynamics. While real-world DT studies provide valuable insights, they largely focus on monitoring and low-autonomy use cases and often depend on large, well-funded consortia (Brell-Çokcan and Schmitt, 2024; Soman *et al.*, 2025). As DT research shifts toward tighter feedback loops and greater autonomy, the field lacks affordable, controllable and repeatable environments that allow DT design choices to be tested and compared under realistic but manageable conditions.

To address this, we introduce a modular DT testbed that links digital intelligence with physical sensing and actuation in a miniaturized construction environment. The testbed builds on a LEGO®-based haptic simulation approach combined with Raspberry Pi single-board computers (SBCs), enabling controlled experimentation with bi-directional DTs and management strategies without access to full-scale construction sites. To support reuse and further development, the source code and digital models are available as supplementary data to this article.

Point of Departure

Digital Twins for Construction Management

DTs are virtual representations of physical objects, processes, or systems that are linked to the physical domain through bi-directional communication and are instantiated to perform specific operational or analytical functions (Čustović *et al.*, 2023; AlBalkhy *et al.*, 2024). The literature characterizes DTs as information systems that integrate heterogeneous data in real time, provide advanced analysis, predictive models for early disruption detection and automated recommendations (Sacks *et al.*, 2020; Saif, Doukari and Kassem, 2026).

Implementations and empirical testing are essential to demonstrate the functionality of a digital artifact beyond conceptual design (Tommelein, 2020). In construction, the dynamic nature of sites and the one-off character of projects make such testing significantly more difficult than in industries with stable and repeatable processes, such as manufacturing. Consequently, most field-based DT studies emphasize data acquisition and status visibility rather than active control. Virtual-to-physical interaction is generally realized by human managers, with DTs providing structured, timely input that informs planning adjustments and operational responses within existing supervisory workflows (olde Scholtenhuis and Soman, 2026). Even when DTs are designed to operate with limited autonomy, practical challenges persist.

Challenges with Digital Twin Implementations

Establishing fast feedback loops and high levels of DT autonomy in construction is difficult due to changing site conditions and organizational constraints (Saif, RazaviAlavi and Kassem, 2024). Chacón *et al.* (2024) show that technical feasibility alone is insufficient: although data collection and system deployment were successful, the insights generated were not adopted in site management procedures. Similarly, Zheng et al. (2025) report that data ownership concerns and commercial policies limit the application of DT systems in complex project settings involving multiple subcontractors. Soman *et al.* (2025) develop a comprehensive DT that integrates multiple production data streams to support weekly project meetings. Yet, despite the significant resources of a consortium setting, the study does not assess how the DT influenced managerial decisions or project performance, nor does it execute any physical work. Even when the DTs are deployed onsite, controlling the many interdependent variables to ensure research validity is very difficult.

In addition to methodological and organizational challenges, financial constraints strongly shape DT research. Deep process integration, real-time monitoring, and autonomous action typically require substantial investments (AlBalkhy *et al.*, 2024). For instance, the *Internet of Construction* project enabled controlled investigation by setting up a dedicated construction site with a simple load-bearing structure, but this was only possible through substantial financial and organizational resources of a large consortium (Brell-Çokcan and Schmitt, 2024). Higher levels of DT autonomy depend on cyber-physical systems capable of executing decisions, i.e., construction robotics. Although these have been widely studied, the significant capital investment required for robotic hardware has led to slow adoption (Walzer, 2025). Together, these examples illustrate the substantial practical constraints that limit testing of operational DT systems intended to support construction management.

Laboratory Environments for Construction Management Digitalization

Experiments are a valid method for evaluating the effectiveness of information system designs because they allow researchers to test defined design choices under controlled conditions (Hevner, March and Park, 2008). Laboratory testbeds provide a practical setting for such experiments. They enable researchers to specify the system design and boundary conditions, allowing selected parameters to be systematically controlled and varied across trials. Construction research has long relied on lab-like setups to address the scale, messiness, and risk of real projects, where controlled trials are hard to stage (Herbsman, 1986). In construction research, serious games have become a popular experimental tool, especially for studying lean construction practices (Bhatnagar *et al.*, 2023; Martinez *et al.*, 2023).

For DTs, however, the experimental requirements differ. DTs depend on a tight coupling between physical assets and virtual representations. This duality means that computer-only simulations or offline board games often cannot test key DT functions such as sensing, feedback, and control across physical and virtual layers. Laboratory testbeds for DT research, therefore, need to include both layers while still allowing researchers to control conditions and observe outcomes.

Only a few studies have built such DT-oriented laboratory setups, and they often address narrow technical goals. Jiang *et al.* (2022) use a 6-axis robot arm to simulate assembly processes of prefabricated modules. However, such robotic testbeds can be expensive, safety-critical, and difficult to reproduce when documentation is limited. Hasan *et al.* (2022) present a DT of a laboratory tower crane with a strong focus on physical realism and crane control. Yet, the setup does not connect DT capabilities to construction management decisions or project scenarios. Li *et al.* (2025) develop a DT testbed for status monitoring using computer vision. However, it focuses on monitoring and does not include actuators or user interfaces for instructing workers or coordinating actions. A further weakness across these efforts is their monolithic, purpose-built nature, which restricts replication and makes reconfiguration to other DT use cases difficult, especially when source code and reusable modules are not provided.
